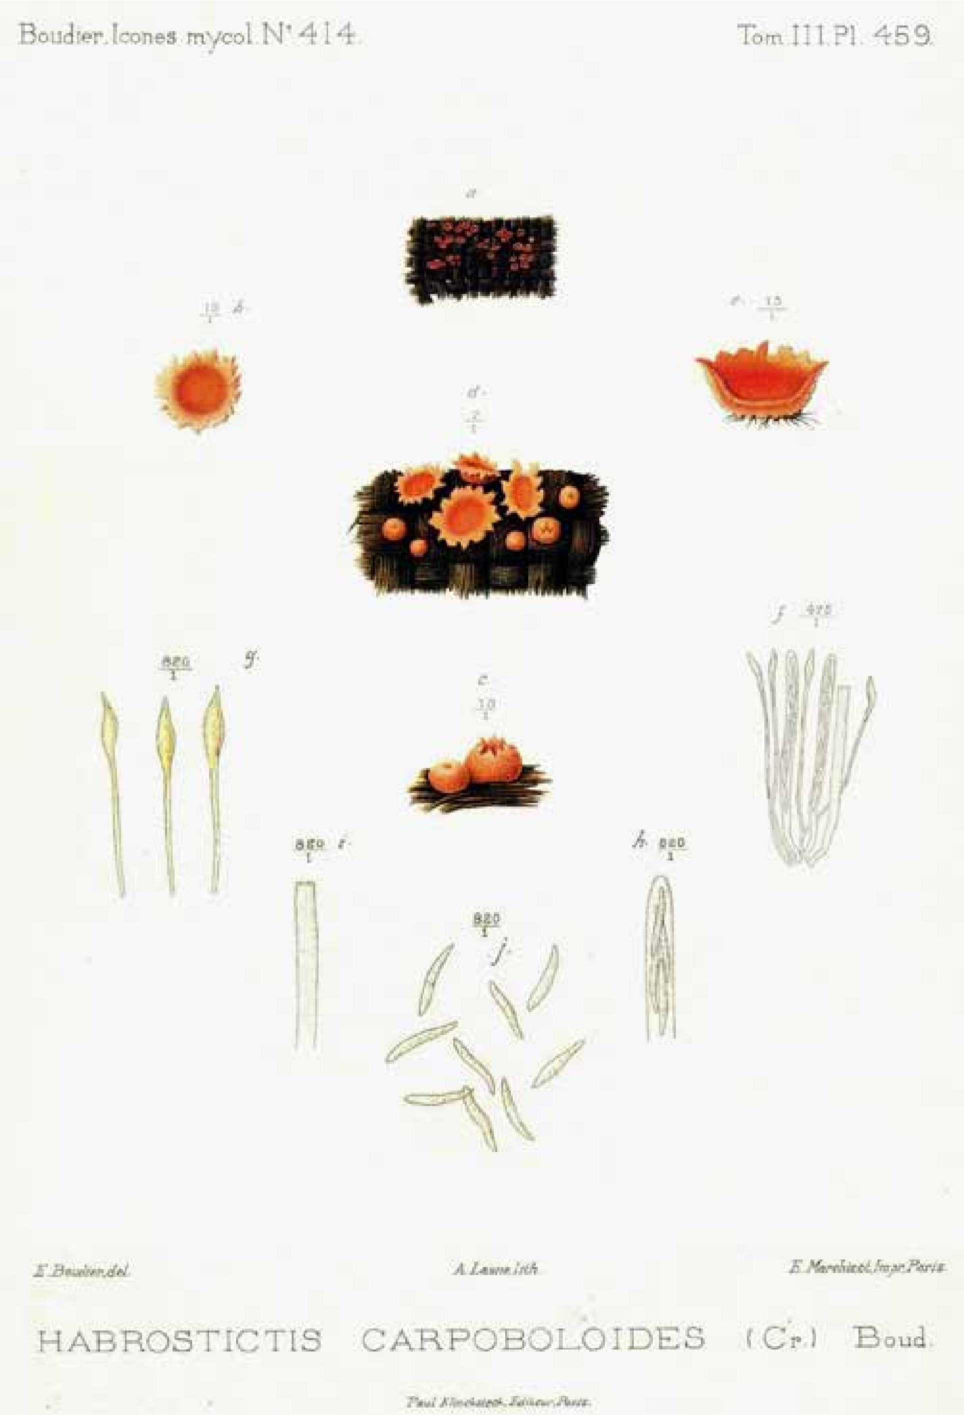
MONOGRAPH OF ORBILIOMYCETES (ASCOMYCOTA) BASED ON VITAL TAXONOMY

Part I

MONOGRAPH OF ORBILIOMYCETES (ASCOMYCOTA) BASED ON VITAL TAXONOMY



Orbilia carpoboloides (= *Habrostictis rubra*), drawn by the famous French mycologist Émile Boudier (Icones fungorum 1904–10, pl. 459). Boudier was among the first to practice vital taxonomy. Nevertheless, his illustrations of orbiliaceous fungi are an exception: all microscopic elements on this plate originate from dead cells, including the ascospores which would contain a prominent spore body in the living state.

‘The sense of science lies in scepticism and not in preservation of achieved knowledge. The present work is thus hopefully soon obsolete.’
(Prof. Klaus Grawe, psychotherapy researcher, Bern, Switzerland).

‘The world would be a better place if more people were working on the inventory of its biota. How could they be encouraged to do so?’
(L.R. Landrum 2001. What has happened to descriptive systematics? What would make a thrive? Systematic Botany 26: 438–442 [440])

Orbilia carpoboloides (holotype of *Orbilia lasia*, on bark of *Ulmus*) drawn by M.J. Berkeley (from Berkeley & Broome 1873: pl. VIII fig. 10). Asci, ascospores and paraphyses are illustrated in the dead state, therefore the spores do not show the characteristic spore body.

National Museum of Natural History Luxembourg (2020)

About the authors

Evi Weber made her thesis on polyploidy of discomycetes under Andreas Bresinsky at the University of Regensburg and later worked at the University of Tübingen on the *Lecythophora-Coniochaeta* complex during a project on storm-damaged forests. In the course of the present monograph she was employed at the National Natural History Museum in Luxembourg for a four years study on anamorphs of *Orbiliomycetes*. Since 2014 she is managing editor of the journal Mycological Progress.

Hans-Otto Baral got interested in fungi through the 'Pilzverein Stuttgart', a mycological association in which also his father was a member. At the University of Tübingen under Franz Oberwinkler he made his diploma on the *Sarcoscypha* species complex. Later he concentrated on inoperculate discomycetes and, after presenting together with German Krieglsteiner a survey of the species known in Germany, published on various genera, including a taxonomic clarification around *Hymenoscyphus fraxineus*, the cause of the ash dieback disease. In 2016 he covered the non-lichenized discomycetes in a survey ('syllabus') of the families of ascomycetes. Various projects were done in collaboration with institutional and amateur colleagues world-wide.

Guy Marson was educated as a metalworker and worked until his retirement as an engine driver for the Luxembourg railroad company CFL. Because of his interest in fungi since 1968 he became 1983 a foundation member of the mycological working group (GRM) of the 'Société des naturalistes luxembourgeois' (SNL). One year later he was accepted as scientific collaborator of the National Museum of Natural History of Luxembourg. His interest for fungi soon concentrated on ascomycetes and particularly those growing on xeric dead plant parts. His technical skill resulted in many self-made equipments around microscopy and photography. At the museum he obtained numerous cultures and since 2011 he concentrated on molecular research.

TABLE OF CONTENTS

Part I

Part II

SUPPLEMENTARY INFORMATION

Supplementary tables

Tab. S1: Primary structure of entire rDNA in *Orbiliomycetes*, exemplified by *Orbilia xanthostigma*, comprising SSU (V1–V9), ITS1-5.8S-ITS2, and LSU (D1–D12), IGS not shown
Tab. S2: Infraspecific variation of ITS rDNA in selected taxa of *Orbiliomycetes*
Tab. S3: Synoptic table of morphological characteristics of all included species of *Orbiliomycetes* (Excel)
Tab. S4: Variation in semi-conserved stem-loop B8 region of 5.8S rDNA
Tab. S5: *Orbiliomycetes* sequences included in this study (Excel)
Tab. S6: Species observed in the laural forest zone (Tenerife & Madeira)
Tab. S7: List of taxa combined in *Arthrobotrys* (Excel)
Tab. S8: List of taxa combined in *Dactylella* (Excel)
Tab. S9: List of taxa combined in *Dactylellina* (Excel)
Tab. S10: List of taxa combined in *Drechslerella* (Excel)
Tab. S11: List of taxa combined in *Gamsylella* (Excel)

Supplementary phylogenetic analyses

Phyl. S1: *Orbiliomycetes* (SSU V1–V5)
Phyl. S2: *Orbiliomycetes* (SSU V8–V9, excluding *Orbilia*)
Phyl. S3–7: Section *Hyalorbilia*
Phyl. S8–11: Section *Lentiformes*
Phyl. S12–13: Section *Hemiorbilia*
Phyl. S14–16: Section *Aurantiorubrae*
Phyl. S17–19: Section *Helicoon*
Phyl. S20–22: Section *Habrostictis*
Phyl. S23–24: Section *Ovoideae*
Phyl. S25–28: Section *Orbilia*
Phyl. S29–37: Section *Arthrobotrys*

Alignments of all phylogenetic analyses (fasta)

List of previously described teleo- and anamorph-typified taxa accepted as orbiliaceous in this study

ACKNOWLEDGEMENTS

This monograph could not have been possible without the assistance of numerous persons and institutions who have collaborated with us or supported our work over the past three decades.

Valuable contributions of personal collections, as specimens and/or photographs or drawings of habitat and macro/micromorphology, have been supplied by Hansueli Aeberhard, Reinhard Agerer, Nick Aplin, Alexander Akulov, Tülin Askun, Antoine Ayel (†), F. Javier Balda, Felix & Valentin Baral, François Bartholomeeusen, Edward Batten (†), Ludwig Beenken, Esperanza Beltrán-Tejera, Martin Bemmann, Hans Bender, Dieter Benkert, Wolfgang Beyer (†), Paul Blank (†), Rafael Blasco, Javier Bometón, Josef Breitenbach (†), Erio Camporesi, Adrian Carter, Brigitte Capoen, Joseba Castillo, Oluna & Adolf Ceska, Jean-Louis Cheype, Jules Cimon, Bernard Clesse, Robert Collot (†), Jerry A. Cooper, Bruno Coué, Pierre Yves Courio, Wolfgang Dämon, Tove H. Dahl, Bernard Declercq, Alain Delannoy, Miguel Ángel Delgado, Jacques Deny (†), Alden C. Dirks, Matthias Eckel (†), Heinz Engel (†), Ove E. Eriksson, Bernd Fellmann, Silvia Feusi, Jacques Fournier, Sheila M. Francis, Gernot Friebes, Ricardo Galán, Annemarie Gallé, Walter Gams (†), XiaoMei Gao, Guy Garcia, Alain Gardiennet, Lucien Gauthier, Jörg Gilgen, Andreas Gminder, Ueli Graf, JianWei Guo, Danny Haelewaters, Michel Hairaud, Viktorie Halasů, Stip Helleman, Karl Helm, Caroline Hobart, Tsuyoshi Hosoya, Wolfgang Huth, Walter Jaklitsch, XianZhi Jiang, Peter Johnston, Peter Karasch, Fredi Kasparek (†), Roland Kirschner, Richard P. Korf (†), Lothar Krieglsteiner, Anna Kujawa, Bellis Kullman, Volker Kummer, Thomas Læssøe, Christian Lechat, ShiFu Li, Jesús Linde, Uwe Lindemann, Bin Liu, Till Reinhard Lohmeyer, Norbert Luschka, Jonathan Mack, Donát Magyar, Matthias Mann, Joaquín Martin, Neven Matočec, MingHe Mo, Rudolf Moosbeckhofer, Gilbert Moyne, Bernd Mühler, Jan Geert Borgergren Nielsen, Ibai Olariaga, Javier Ormad, René Pacaud, Maurice Pélissier, Marja Pennanen, Branislav Perić, Piotr Perz, Donald H. Pfister, Sven Pohlers, Kadri Põldmaa, Adam Polhorský, Eugene S. Popov, Jean-Paul Priou, Peter Püwert, Min Qiao, Luis Quijada, Ain Raitviir (†), Matthias Reul, Alan Reynaud, Miguel Ángel Ribes, Torsten Richter, Inge Rößl, Lucien Rommelaars, Claude Roux, Enrique Rubio, Dragiša Savić, Wolfgang Schößler, Ben Schultheis, René Klaus Schumacher, Beatrice Senn-Irlet, YuanYuan Shao, Klaus Siepe, Brian M. Spooner, Elisabeth Stöckli, Hong-yan Su, Yu-Chih Su, Patrice Tanchaud, Salvador Tello, Raúl Tena, Marie-Thérèse Tholl, Peter Thompson, Dagmar Triebel, Martin Unterseher, François Valade, Gunther Van Ryckegem, Nicolas Van Vooren, Hermann Voglmayr, Ingo Wagner, Jakub Węcławski, Peter Welt, Ilse Wendelin, Chris Yeates, ZeFen Yu, Ying Zhang and many others. Guy Marson's colleagues Romain Reuter, Bontemps Fernand, Carlo Peller, Nico Petit, and Paul Wagner are thanked for bringing promising branches from their overseas holidays. Thanks are due to O. Ceska, N. Matočec (as a part of CNF), and Y.C. Su for their permission to reproduce some of their drawings, and numerous workers for allowing us to include their photographs in our tables.

Jacques Deny (†, Gérardmer, Vosges, 1989, 1990, 1996, 1998), Jean-Pierre Prongué (†, Buchs near Liechtenstein, 1997), and Inge Rößl (Aufham, Bad Reichenhall, 2018) enabled us to collect fungi in their regions by housing us in their homes. We also thank the Mykologische Gesellschaft Luzern for a one week stay in their mountain farmhouse in Hergiswil (2006). Ricardo Galán and the University of Alcalá de Henares (Spain) is thanked for financing us for one month study visit in 1996, and Neven Matočec for organizing and participating in our stay in Korčula Island (Croatia) during two weeks in 2000 and for supplying ecological data about the country. We owe our gratitude to many mycological institutions and associations that provided us with financial support for the participation at numerous ascomycete workshops and forays in Denmark (Universities of Aarhus and Copenhagen, 2005, 2007, and support from funds controlled by the Danish Mycological Society), England (British Mycological Society, 2011, 2017), France (L'association Ascomycete.org, La Société Mycologique du Massif d'Argenson, 2003, 2006, 2008, 2010, 2011), Germany (Deutsche Gesellschaft für Mykologie & Landesamt für Umwelt Bayern, 2005; Arbeitsgemeinschaft sächsischer Mykologen, 2018), Luxembourg (Musée National d'Histoire naturelle, 1989–2001), Netherlands (Nederlandse Mycologische Vereniging, CBS-KNAW, Leiden 2005, Amsterdam 2015), Spain (La Sociedad Micológica de Somiedo, 2013, 2017; Grupo Micológico La Usonera de Jaca, 2016), Sweden (Swedish Taxonomy Initiative, Universities of Aarhus, Copenhagen, Uppsala, Umeå, 2006, 2010), and Switzerland (Union Suisse des Sociétés de mycologie, 2018).

Thanks are also due to the curators of many herbaria who provided us with fungal material: AH, BPI, BR, CO, CUP, FH, G, GZU, H, HBG, HMAS, K, L, LPS, LUX, M, MPU, PAD, PC, PDD, PH, PRM, RO, Rouen, S, TAAM, TNS, TU, UPS, W, YMFT, ZT (for their full name or location see p. 15 or http://sweetgum.nybg.org/science/ih/).

Bin Liu and Luis Quijada allowed us to use their unpublished doctoral theses and to reproduce some of their photographs. Special thanks are due to Martin Bemmann for his repeated help in literature problems and old geographical data. Thanks to Till R. Lohmeyer and Ricardo Galán for using their literature databases. Jan Hengstmengel is thanked for revising Persoon's material of *Peziza aurea* in L. Paul Diederich and Felix Schumm identified associated lichens, and Christoph Allgaier *Cochlodina laminata* used by us for a feeding test. Nigel Fechner helped us in the identification of Australian plants. We thank Antonio Roldán who provided us with a permanent slide of a *Descalsia cruciata* culture, and Manuela Caprioli for kindly providing the rotifer *Macrotrachela quadricornifera* for culture. We greatly thank Martin Bemmann, Thomas Læssøe, and Jens Petersen for donating us photographic and microscopic equipment.

We are much indebted to various workers for retrieving rDNA sequences of *Orbiliomycetes*: Gregor Hagedorn (~1995–2000, Biologische Bundesanstalt für Land- und Forstwirtschaft, BBA, Berlin), Michael Weiß (~2000–2010, Eberhard Karl University, Tübingen), Bin Liu (~2010, Guangxi University, Nanning), Danny Haelewaters and Luis Quijada in Don Pfister's lab (2012–2018, Harvard University, Cambridge, Massachusetts), Sylvie Hermant (~2010–2020, Musée national d'histoire naturelle, Luxembourg), Simone Heitkämper, Eric Kuhnert, and Lucile Wendt in Marc Stadler's lab (2013–2017, Helmholtz-Zentrum für Infektionsforschung, HZI, in Braunschweig), Florian Prell (2017, Institut für Lebensmittelchemie und Lebensmittelbiotechnologie, Gießen), Walter Voglmayr (2002, University of Wien), Adam Polhorský (2018–2019, Comenius University, Bratislava), and others. G. Verkley (CBS) is thanked for sending us some sequences from the CBS database. Research by Adam Polhorský on Slovakian samples was funded by the Operational Program of Research and Development and co-financed with the European fund for Regional Development (EFRD); ITMS 26230120004: Building of research and development infrastructure for investigation of genetic biodiversity of organisms and joining IBOL initiative.

We are very grateful to Adrian Carter, Paul Diederich, Walter Gams (†), Caroline Hobart, Dick Korf (†), Neven Matočec, Don Pfister, Annemarthe Rubner, Markus Scholler, Brian Spooner, Peter Thompson, Gerard Verkley, and Hermann Voglmayr for proof-reading selected parts of the monograph. We thank Shaun Pennycook, Paul Kirk, Dagmar Triebel, and Walter Gams for advice in nomenclatural questions, Walter also for help in Latin diagnoses, which were still required at that time, and in etymological and grammatical questions of Latin names. Martin Bemmann, Paul Diederich and Branislav Perić are thanked for valuable help regarding the layout.

Great thanks are due to the National Museum of Natural History in Luxembourg and particularly the previous director Norbert Stomp, for long-year support of our mycological work and the realization of the present publication as well as to Guy Colling and Alain Faber for their support with the DNA barcoding of Ascomycetes.

Dear friends and family, thank you for the encouragement received over many years and for your patience.

ABSTRACT

The present work is the result of an over 30 years extensive study of discomycetes recognized in the family *Orbiliaceae*, which was previously considered as a comparatively small group within the *Helotiales* but later raised to the level of a class. Our study resulted in the recognition of worldwide ~ 470 species with a known teleomorph, 331 of which being validly described here as new to science. We also propose 38 new combinations and 2 nomina nova, and designate 33 epitypes, 39 lectotypes, 3 neotypes, and 4 reference specimens, including some misplaced species now referred to other classes. The *Orbiliomycetes* are circumscribed here with 1 order *Orbiliales*, 1 family *Orbiliaceae*, 7 accepted teleomorph-typified genera [*Amphosoma* gen. nov. (4 spp.), *Bryorbilia* gen. nov. (1 sp.), *Liladisca* gen. nov. (1 sp.), *Lilapila* gen. nov. (3 spp.), *Pseudorbilia* (1 sp.), *Hyalorbilia* (37 spp.), *Orbilia* (~ 415 spp.)], and 3 anamorph-typified genera [*Lecophagus* (7 spp.), *Mycoceros* (1 sp.), *Retiarius* (4 spp.)], the latter two without known teleomorph. The large genus *Orbilia* is divided into 3 subgenera, 8 sections, and 30 series. Apart from the accepted ~ 470 species, about 90 further teleomorph-based species are treated without a valid name (aff. or nom. prov.). As a consequence of the taxonomic relevance of four main types of plasmatic organelles, the present study was predominantly based on vital taxonomy, a comparative morphological method focused on the living state of fungal cells by using recently collected specimens whenever possible.

Most of the previously known species turned out to be hygrobiotic (desiccation-sensitive), growing in humid regions on damp substrate on the ground. For vital taxonomy studies these species required examination within a few days during which their viability can be maintained in a moist chamber. Their often very small hymenial elements are difficult to study under the light microscope, which explains why these fungi have often insufficiently been investigated in the past. The vast majority of new species are described from subhumid to arid regions with more or less long-lasting dry seasons, representing an overlooked ecological niche for various groups of desiccation-tolerant fungi. The capacity of these xerobiotic taxa to tolerate complete desiccation of the holomorph for one or several years and their often much larger asci and ascospores providing a higher optical resolution considerably facilitated our vital taxonomic and cultural work.

The most remarkable and relevant discovery in this study of *Orbiliomycetes* was an organelle of vacuolar nature inside the living ascospores, the spore body (SB), as it is currently called. Due to their high refractivity, SBs are usually very easily observed when studying viable spores, whereas in dead spores they get more or less completely invisible. This organelle, which was found to be formed by invagination of the plasmalemma, not from mitochondria as earlier believed, could by now not be observed in any other class of *Ascomycota* and thus permits recognition of a taxon as orbiliaceous. A high diversity in size and shape of the spore bodies was recorded when comparing the many species and infrageneric groups, which provided more important criteria for classification than the high variety of ascospore shapes which often derived from convergent evolution. In the large genus *Orbilia*, but also in *Liladisca*, *Lilapila*, and *Lecophagus*, only one spore body is enclosed in each ascospore, rarely none, whereas more than one spore body is typical of *Amphosoma*, ?*Bryorbilia*, *Hyalorbilia*, and *Pseudorbilia*. Characteristic but transient cytoplasmic bodies (SCBs) in the living cells of paraphyses and ectal excipulum turned out to provide further important species markers.

The present study confirms the consistent absence of amyloidity in any part of the *Orbiliomycetes* holomorph. Further remarkable characteristics of the teleomorph include different types of ascus apices (thin- vs. thick-walled, truncate-shouldered vs. hemispherical) and ascogenous hyphae (croziers vs. simple septa), the latter feature often coupled with sessile vs. stalked/bifurcate ascus bases. Within *Orbiliomycetes*, ascus apical thickenings were exclusively observed in xerobiotic taxa, whereas truncate-shouldered asci occurred with a similar frequency in both ecological groups. A surprizing number of xerobiotic *Orbilia* species show different degrees of polyspory (16–128-spored), which appear in various subgroups and provide valuable species markers of otherwise very similar taxa. A further peculiarity of *Orbiliomycetes* was found in the inverse orientation of a varying number of spores within an ascus: usually the lower, more rarely the upper spores point with their spore body downwards.

Capitate paraphyses and waxy apothecia have been considered as typical of *Orbilia* in ancient treatments, but are attributed little taxonomic value in the present study. Likewise, lanceolate paraphyses, glassy processes, and septate hairs, previously used to define *Habrostictis*, *Hyalinia*, and *Orbiliaster*, are found to be unsuitable generic markers. Instead, the earlier overlooked croziers at the ascus base turned out to be useful at the generic level, characterizing *Lecophagus*, *Liladisca*, *Lilapila*, *Hyalorbilia*, and *Pseudorbilia* (with the restriction that in *Lecophagus* also simple-septate bases occur), whereas stalked and bifurcate simple-septate ascus bases characterize *Amphosoma*, *Bryorbilia*, and *Orbilia*. Ascus apices, excipular textures, and anchoring hyphae also support phylogenetic relationships, e.g., thick-walled hemispherical apices characterize *Orbilia* subgenus *Hemiorbilia*, a textura prismatica *Hyalorbilia*, and exceedingly broad anchoring hyphae *Lecophagus*.

For many teleomorph-typified species of *Orbiliomycetes* a connection to an anamorph could be affirmed based on either pure culture and/or sequence data. Possibly all members of the class possess an anamorph, but the connection is uncertain or unknown in a fairly large number of taxa. Orbiliaceous anamorphs are hyphomycetous, rarely synnematal. Conidiophores and conidia are consistently hyaline, and conidiogenesis is holoblastic. The conidia have frequently been found close to the apothecia on the natural substrate, particularly in xerobiotic taxa. They exhibit a high morphological diversity, including multicellular, unbranched or variously branched types. Although branched conidia are known as Ingoldian fungi from water courses and lakes, those of *Orbiliomycetes* are almost exclusively formed on xeric substrate, where they are adapted to transport by stemflow during rainfalls.

Anamorphs of *Orbiliomycetes* have earlier been classified in numerous genera, viz. *Anguillospora*, *Arthrobotrys*, *Brachyphoris*, *Curucispora*, *Dactylella*, *Dactylellina*, *Descalsia*, *Dicranidion*, *Drechslerella*, *Dwayaangam*, *Gamsylella*, *Helicoon*, *Lecophagus*, *Microdochiella*, *Pseudotripoconidium*, *Tridentaria*, *Trinacrium*, and *Vermispora*. Under the new rules of nomenclature that give anamorph names equal priority, most of these generic names fell into synonymy with *Orbilia* s.l. and a few with *Hyalorbilia*, with exception of *Lecophagus*, *Mycoceros*, and *Retiarius*. Teleomorphs of *Lecophagus* are reported here for the first time, and curucispora-, descalsia-, and tridentaria-like anamorphs for the first time as belonging to *Orbiliomycetes*. Many, mainly hygrobiotic species of section *Arthrobotrys* are reported to capture minute invertebrates such as amoebae, nematodes, rotifers, springtails, and tardigrades by means of sophisticated trapping organs, for which reason they can be used as a biocontrol agent against plant parasites, particularly nematodes. Which role the spore body plays in the life cycle of *Orbiliomycetes*, particularly its function in regard to endoparasitism, could not be clarified, but the high diversity in ascospore and spore body shapes hints at some kind of coevolution with unknown parameters, perhaps in animal trapping.

Increasing availability of molecular data questioned current species and higher taxa concepts and revealed cryptic species without evident distinguishing features, or various unexpected synonymies among hyphomycetous, mainly nematode-trapping taxa. Although the here practised classification was largely based on rDNA data (SSU V8–V9, ITS1-5.8S-ITS2, LSU D1–D2), priority was given in critical cases, especially when DNA data were poorly available, to morphological criteria. For instance, the three series within section *Habrostictis* are predominantly morphology-based.

A broad generic concept was applied to the genus *Orbilia*, and paraphyly was accepted as a natural consequence of evolution in genetically heterogeneous groups such as subgenus *Hemiorbilia* and section *Aurantiorubrae*, or when sharp morphological differences do not correlate with DNA data, e.g., in the separation of series *Phanosomates* from series *Lentiformes*.

INTRODUCTION

The first studies of members of the class *Orbiliomycetes* by first author were undertaken between 1974–1977. At that time, this group of inoperculate discomycetes was recognized as a family *Orbiliaceae* of the *Helotiales* and was believed to constitute one of the smallest families within this order (Kimbrough 1970, Spooner 1987). As a result, species numbers in various regional systematic treatments ranged between about five and ten. On the other hand, a large number of more or less dubious taxa have been assigned in the older literature to the genera *Orbilia* Fr. and *Hyalinia* Boud. Therefore, *Orbilia*, which comprised in its earlier circumscription also taxa now recognized in *Hyalorbilia* Baral & G. Marson (2001), was considered by Korf (1973) to be 'a large genus', at least when including also *Hyalinia* in its scope. Critical revisions with detailed illustrations are largely lacking, for which reason Dennis (1978: 187) stated that 'the genus is one of those which most needs monographic study on modern lines'.

The family *Orbiliaceae* received comparatively little attention, probably because asci and ascospores in most of the hitherto known species are very small, being regarded as close to the resolution limit of the light microscope. The reported differences in spore characters are, therefore, often vague and inexact, and resulted in much confusion about the proper application of names. As an example of the small microscopic features, Nannfeldt (1936: 199) stated that the cells of *Orbilia*, particularly the spores, were usually 'extremely difficult to see [..] in herbarium specimens'. Also Dennis (1978: 187) wrote: 'The essential characters, apart from colour, are largely those of the ascospores, which are small and often hard to see'. In his treatise on the Macaronesian *Orbiliaceae*, Korf (1992) similarly argued that 'species identification is exceptionally difficult and requires good oil-immersion optics and staining with Cotton blue in lactophenol for many species' in order 'to see what is not to be seen'.

Such experiences appear surprising when comparing Boudier's (1904–10 [1906, 1908–9]: pl. 459–467) detailed drawings of nine, mostly small-spored taxa of *Orbiliaceae* made with a microscope with a presumably less advanced technical standard than we have today. Contrary to the prevailing custom, Boudier exclusively examined fresh specimens in water as mounting medium, which enables to study living cells (vital taxonomy, Baral 1992). This method resulted in distinctly larger cell sizes due to internal turgor and cell wall elasticity, stronger optical contrast and transparency on account of the high water content of the cytoplasm, and visibility of cytoplasmic organelles that become irreversibly destroyed in dead cells.

For instance, spores inside asci are very clearly visible when the asci are intact, but often hardly discernible in dead material, sometimes despite the application of cytoplasmic stains. As a consequence, polyspory of asci has repeatedly been overlooked in herbarium material. Free spores are often rare, and those inside asci cannot easily be seen in the dead state, which prompted authors to consider mature collections to be immature. This difficulty with herbarium material explains the frequent use of stains in combination with clearing agents to make spores inside asci better visible. The spores of *Orbilia* exhibit an extraordinarily broad diversity in both shape and size, hence without the spores a collection definitely remains unidentified.

The idea to do this monograph was born between 1988–1989, stimulated by the discovery of the peculiar spore body, a taxonomically highly important and biologically interesting cytoplasmic inclusion inside the living ascospores. This spore body shows a strong contrast under the light microscope, but is very sensitive to lethal media or storage in the herbarium for a shorter or longer period of time. Because of the strong preference of previous taxonomic researchers to study herbarium specimens, spore bodies are largely absent from their descriptions.

In 1989 we knew only twelve central European species of *Orbiliaceae* and could not imagine that these twelve species finally turned out to represent just 2.5% of the diversity recognized in the present work within the family. In the following 20–30 years the number of taxa increased enormously whenever collecting trips were undertaken and the numerous collections taxonomically documented and compared. Once their prevalence for xeric habitats was detected, a strongly neglected niche of any kind of air-exposed, more or less decayed substrate that periodically falls dry, and their widespread occurrence in areas with longer periods of drought, our collecting efforts concentrated on xeric vegetation, particularly of the Mediterranean region, later also western North America and Australia. Despite the vast number of species recognized during each expedition, most collections could be studied in the living state, since these fungi remain viable for about 1–3 years in the herbarium. The detection of these often very small fungi is more or less a matter of accident, therefore, we are convinced that numerous further species await discovery worldwide.

Comparatively few collections from tropical humid regions were available during our study, which explains the distinctly lower species diversity compared to desertic and temperate humid regions and suggests that many more species would occur in the tropical belt. In fact, subtropical humid evergreen forests in southeastern Asia turned out to house a rather diverse species composition and provided many novelties, thanks to the activities of various Chinese scientists. Due to their collecting focus on hygric substrate in these mountain forests, most of the species from China known at present are hygrobionts. They were sent in the dry state as they would otherwise have been ruined during shipment. Therefore, many of these records were studied in the dead state, though sometimes living ascospores were still present, whereby vital characters from the fresh apothecia were often available on photos provided by these Chinese workers.

One of our focuses was to explore the morphological variation of each species. Following the suggestions of Huhtinen (1990a, b) we tried to clarify by drawings and/or photographs of ideally each collection how sharply the taxa are delimited from each other. Single gatherings, which were not sufficiently deviant to be recognized as a separate species, were mentioned and illustrated under the closest taxon. During the past 2.5 decades an increasing interest arose among the mycological community to collect and document samples of *Orbiliomycetes*. We have included these records in our work whenever photographs sent by the collectors allowed recognition of the species, as they increased our taxonomical and ecological knowledge of many species. During sampling and scanning collections we came across a lot of other groups of non-lichenized ascomycetes which co-occurred with members of *Orbiliomycetes* and also frequently appeared to represent new or little explored species. As a consequence, we also often documented these fungi in order to show the transient vital characters.

A large number of type specimens have been reexamined in the present study, because the protologues often did not permit recognition at the species level, and illustrated revisions were lacking for most of them. It was our experience that a detailed knowledge of the relevant characters of a group, including those of the living fungus, is required prior to performing type studies. For instance, although spore bodies are usually invisible in herbarium material, they can sometimes be discerned as very faint 'empty' regions in the spore apices in appropriate mounting media, but only when one's attention is focused on them.

The vast diversity of conidial shapes being connected to members of *Orbiliomycetes*, together with the variance of spore body morphology, caused serious problems in identification of herbarium material, particularly of type specimens, since both serve as key characters of many taxa. Based on this experience, we regard monographic work on living specimens, carried out over a reasonable period of years, as the most important prerequisite for achieving sound taxa concepts and functional identification keys. We prefer comprehensive monographic work on closely related species in a single publication over numerous small papers or large ones on diversely related taxa and groups. If we had published our observations every year, a lot of subsequent corrections to previous papers would have resulted, including a final outline of the whole group.

Another challenge arose when molecular data were included in our study. Ribosomal DNA sequences offered a new perspective on species concepts. The obtained results permitted clarification of controversial opinions on species aggregates, such as *O. vinosa*/*O. subvinosa* or *O. leucostigma*/*O. xanthostigma*, and suggested also the existence of morphologically cryptic species, e. g., in the unsettled *O. auricolor* aggregate, or in *O. tremulae*/*Dicranidion inaequale*. Sequence data also resulted in various infrageneric rearrangements within *Orbilia*, but we hesitated when morphological data did not support the new placement. Last not least, the family had to be raised to the rank of a class, *Orbiliomycetes*, based on morphological and molecular data (Eriksson et al. 2003). It forms a unique monophyletic group of ascocarp-forming *Ascomycota* that occupies a rather basal position within the *Pezizomycotina*.

Since sequences were only available for a small minority of collections of a given taxon, identification was mainly based on morphology, which fairly often caused problems in the correct identification of similar taxa, for instance in *O. luteorubella*/*O. rosea*, *O. eucalypti*/*O. tremulae*, or *O. brochopaga*/*O. orientalis*/*O. yunnanensis*. Specimens older than ~10–20 years usually cannot at present be treated by molecular methods regarding their rDNA, therefore, many type specimens remained unidentified at the molecular level, and epitypes or reference specimens had to be proposed for them.

Although molecular data experience an inflationary increase in databases, many of them originate from environmental samples without knowledge of the fertile structures or the natural substrate. These data obviously neglect important ecological niches by focusing on continuously moist environments such as soil, water, damp wood, or living tissue, though including also air isolates. For this reason, the vast diversity of xerobiotic ascomycetes and other fungi is largely absent in these data.

Because of the time-consuming technique of molecular research, we have laid our main focus on the attractive features of light-optical microscopy, which include (1) comparatively low costs, (2) rapid results, (3) ease of use, and (4) clarity of morphological, particularly vital characters. According to Korf (1994: 16), the increasing application of modern techniques like transmission (TEM) and scanning electron microscopy (SEM), molecular analysis of DNA, numerical taxonomy, chemistry, and genetic mating systems has 'decreased rather than increased the production of monographs'. The paucity of monographs in the past decades is seen as a reason for the hypothesis that '95 or 96 % of the fungi we haven't yet catalogued'.

In summary, the outstanding feature of the present study lies in the large number of new species. This has four main sources: (1) collecting on xeric substrate, particularly in regions with long-lasting periods of drought; (2) the consistently applied method of vital taxonomy, resulting in an increased array of microscopic characteristics for the delimitation of taxa; (3) cultural characteristics, mainly regarding conidial morphology; (4) molecular data, which resulted in splitting of taxa without clear morphological differences.

MATERIALS AND METHODS

Fungal material

More than 7200 records of *Orbiliomycetes* teleomorphs are treated in the present study. In the case of mixed collections, this number includes all orbiliaceous species detected within each sample. Circa 4500 of these 7100 records have been studied by the first author. Almost 3400 of these 4500 records were examined in the living state, the apothecia being either viable regarding all their elements or only for some of them, particularly the ascospores. A majority of the remaining nearly 2700 records came to our attention only through microscopic drawings or macro- and/or microphotographs made by various collaborators and earlier authors. All these records are mentioned under 'Specimens examined', and all those from which we have not seen specimens or microscopical images are marked by 'non vid.'.

3125 teleomorphic records included in this study originate from our personal collecting efforts, while the remaining ca. 4100 were made by other contemporary or historical collectors. Many of these samples have been sent to us in the living state, at least in regard to the ascospores. Herbarium specimens without any living elements were mainly studied regarding type material, but included also various non-type collections, particularly from Asia and Middle America. Five public herbaria (LUX, M, MPU, TAAM, TNS) were thoroughly investigated for orbiliaceous specimens, and some others (CUP, FH, PDD, TU) only regarding selected material. For further consulted official herbaria see p. 15. 90 % of all records were made after 1989, hence the present monograph is mainly based on the study of contemporary collections.

Roughly 2700 of the studied samples were preserved in the first author's herbarium or sent to an official herbarium in case of types of new species. Many samples were not kept since they were either in bad shape or too sparse, or they belonged to frequently recorded species. Collections of the third author which lack a H.B. number were frequently not preserved. More or less comprehensive data (microscopic drawings, macro- and microphotographs, rarely only descriptions) exist for most of the collections reported here. Microscopic drawings were made on ca. 2300 samples, and macro- and/or microphotographs on ca. 3400 samples, including those made by other collectors. Nearly

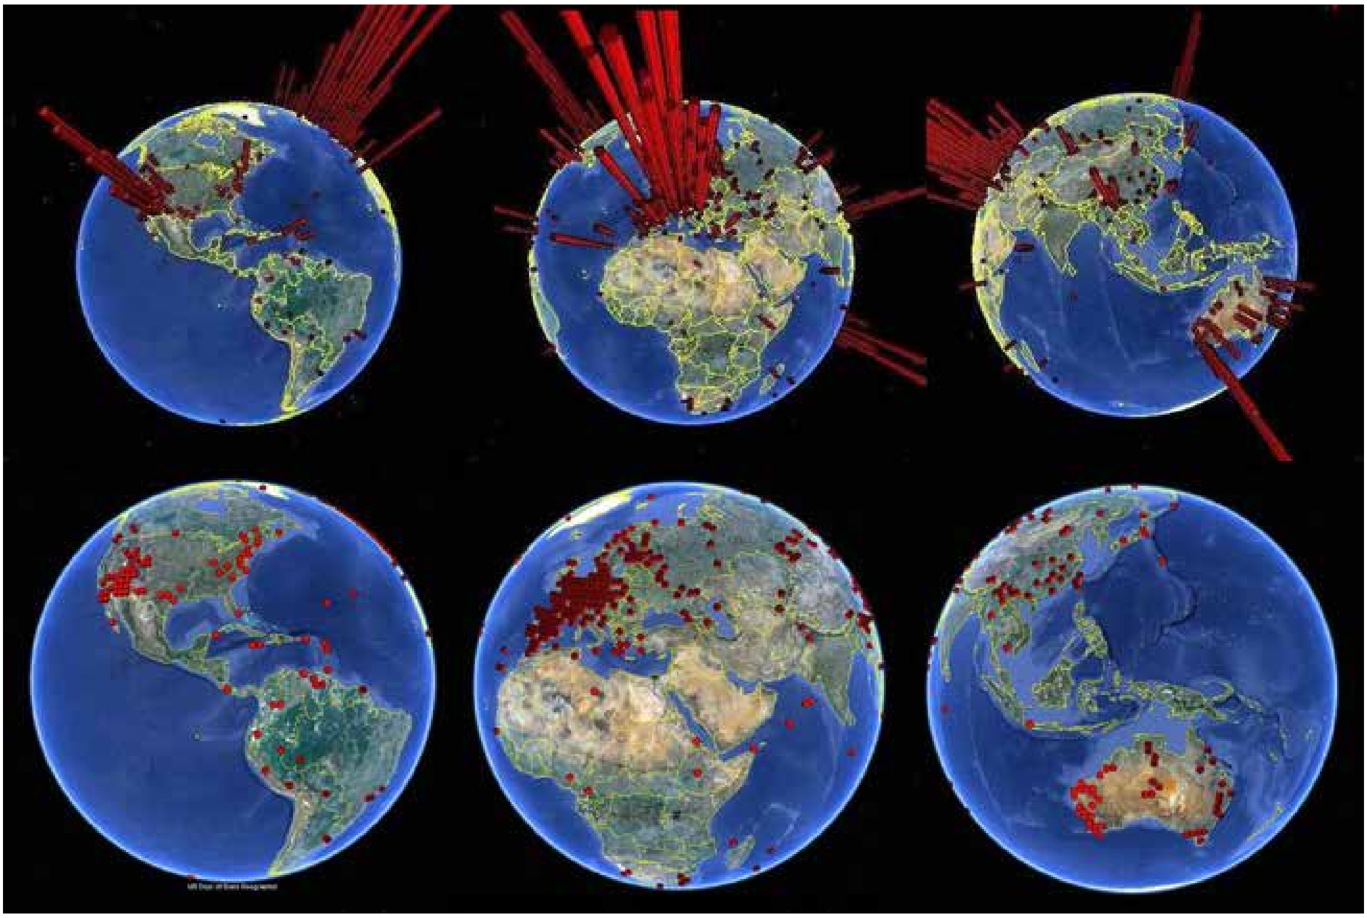

Figure 1: Geographical origin of collections of *Orbiliomycetes* investigated in this monograph (created in 2013 with Google Earth using R2G2: https://recology.info/2012/10/r2g2-package/, later collections not included). In the upper row the height of the polygon indicates the abundance of the collections, whereas the lower row gives a clearer idea of the dispersion of the collection sites. See also Fig. 127.

all drawings by the first author and some by G. Marson and N. Matočec are reproduced in this monograph.

A considerable part of the teleomorph collections treated in this monograph emanates from different, humid to semihumid parts of Europe (~5300 records). An also rather high number of records has a Northern American origin (over 600, particularly from the semiarid southwest) or comes from different, often semiarid parts of Australia (over 450). Records from mainly humid regions of Africa (51), Middle and South America (127), and New Zealand (52) are scanty because we had little opportunity to obtain collections from there. Almost 230 samples came from predominantly semihumid to semiarid sites in Macaronesia (mainly Tenerife), and 80 from mainly humid sites in Middle America (mainly Antilles). Records from Asia (over 370) predominantly derive from China (over 200, many of them from Yunnan Province), but comparatively few from Mongolia, Japan, eastern Russia, Turkey, and the Caucasus region, see also Figs 1 & 127 and Appendix 2.

As to the different ombrotypes, about 8% of all collected populations were from semi- to hyperarid regions, 16% from semi- to subhumid regions (mediterranean and savannah-like climates), and 76% from humid (including winter-dry) climates. The comparatively low proportion of samples from arid regions stands in contrast to the observed high species diversity in this ombrotype (see Tab. 33). Regarding the different thermotypes, 14.5% of the collected populations came from montane-boreal-subarctic (including hemiboreal and orosubmediterranean), 57% from cold- to warm-temperate (including mild-maritime), 7% from submediterranean, 18.5% from subtropical (including mediterranean), and 3% from tropical regions (2% from a tropical humid climate). About 88% of the collections were made on woody substrates, 8% on more or less herbaceous substrates (including leaves of trees), > 4% on fungi (basidiomycetes, pyrenomycetes, discomycetes), 0.2% on animal dung, and 0.07% on bryophytes.

The types of our new taxa were mainly deposited in M, with the exception of those from Australia (MEL, BRI), Japan (TNS), China (YMFT), Russia and Caucasus (TAAM), Puerto Rico (FH), and some from Spain (AH). Because of the frequent intermingled growth and the impossibility to recognize most species macroscopically, a complete separation of the different populations on a given piece of substrate was often difficult or impossible. Therefore, many of our herbarium specimens probably contain different taxa in a single envelope.

Pure cultures gained between 2000–2004 were deposited in BBA (77 strains) and most of them also in CBS (73 strains). They comprise a total of 78 living cultures of 73 species (76 isolates from ascospores and two from conidia). Various further isolates were obtained during the past decades, but most of them were not conserved.

Equipment and documentation techniques

Microscopes. Most drawings were made free-hand by the first author using a Zeiss Standard 14 microscope with 100×/1.25 oil immersion phase contrast achromatic objective and 15× Euromex wide field oculars. Some drawings of conidia were made with a Standard 20 by E. Weber. Drawings by G.

Marson were made with a modified Olympus CH–2 microscope with a Zeiss 100/1.25 oil immersion plan-achromatic objective, Zeiss Kpl W 16×/16 wide field oculars, often with the aid of an Olympus drawing tube (tubus factor 1.25×, equipped with an Euromex 20× ocular used as projective). Most observations were carried out under bright field, i.e. with open or only very slightly closed aperture, whereas photographs were taken at an up to ~⅓ closed aperture. Phase contrast was very rarely applied since it proved quite useless for the observation of taxonomically important intracellular microstructures: in most cases these structures have enough refractivity within the living cytoplasm in order to be easily seen. They often occur in small or narrow cells, or in sections of tissues consisting of several cell layers, conditions being inappropriate for the application of phase contrast. The same applies to differential (Nomarski) interference contrast (DIC) which severely obscures the apical attachment of spore bodies (some photographs taken with this technique at Chinese and Russian laboratories are reproduced in this monograph). Microscopic study was done using oil immersion at 1500× (H.B., E.W.) or 2000× (G.M.) regarding drawings and direct observations. Illumination of the microscopes was either with a high-power LED (Luxeon 3W, H.B., G.M.) or a halogen bulb (H.B., E.W.). For macroscopy, different dissecting microscopes were used: Euromex (10–40×), LOMO MBS–10, Leitz (10–40×).

Drawings. Drawings of asci and paraphyses were generally made at a standard scale of 3000×, ascospores and ascus apices at 4000×, excipular elements at 1500×, 2000×, or 3000×, and conidia at 2000×, exceptionally 3000× or 1000× (see p. 20–21, About illustrations). Drawing free-hand at a uniform scale was done by measuring length and width of the element and transferring the calculated values to the drawing sheet (e.g., an ascospore of 10 × 2 µm is on the drawing sheet 40 × 8 mm). On the printed figures the drawn or photographed ascospores and ascus apices are consistently reproduced at a magnification of 2000×, asci and paraphyses at 1500×, and conidia at 1000×. In order to obtain this standard magnification, the drawings had to be reduced in most cases to 50% of their original size.

Drawings were finished directly onto the original sheet using graphite pencil leads of medium hardness ('HB') and varying thickness (mainly 0.5 mm, sometimes 0.3 or 0.7 mm), in some cases also with a felt-tip pen. When using graphite for the final drawing, a solid base plate was placed below the original drawing which was cleaned step by step with a soft eraser pencil. This method saves much of the original appearance and aesthetic appeal of a drawing, whereas drawing onto a tracing paper over the original sketch, or using a computer program usually results in a more schematic appearance (see Barber & Keane 2007, fig. 1).

The thickness of the drawn line more or less indicates the thickness of the cell wall. Walls thicker than ~0.3 µm are shown as two parallel lines. More than two lines are drawn in the case of a thick, layered wall, e.g., in ascus apical thickenings. The outer boundary of the detached cytoplasm in dead cells is shown as a further line, and the granular cytoplasm is graphically indicated. In the case of cytoplasmic inclusions of living cells (LBs, SBs, SCBs, vacuoles, VBs, nuclei), the thickness of the line indicates the strength of refractivity of the organelle.

Most of the final drawings were scanned at 300 dpi and the elements arranged with Corel Photopaint 10 on plates of 5650 × 4250 pixel (= 48 × 36 cm), resulting in a 600 dpi resolution on the 24 × 18 cm large print space. Older drawings were conventionally photocopied and cut, and the arrangements later scanned and cleaned with Corel Photopaint.

Photographs. Most macro- and microphotographs were made with digital cameras, only a few dating back before ~2003 were made with traditional film cameras. Microphotographs were taken with a Nikon Coolpix 4500 adapted free-hand to a Kpl 10×/20 Zeiss wide field ocular and 10×, 40×, and 100× Zeiss achromatic objectives (H.B.), or with a Canon S70 firmly adapted to a Leitz Periplan 10×/18 mm ocular and plan-achromatic objectives (G.M., older photos were made with a Nikon Coolpix 995). Coolpix 4500 photos were taken at minimum zoom (7.85 mm focal length) in order to avoid ring artifacts (Baral 2004), Canon photos at different zoom positions (mainly 13.15 mm). Contrast was only rarely improved by oblique illumination. Photographs of conidia were rarely taken under dark field illumination.

Most macrophotos were made indoors with Coolpix 4500 on a solid mono- or tripod, usually in combination with several self-adapted macro lenses (Russian Horizon lens 10×, Zeiss wide field oculars 10×, 20×, and 25×) usually at maximum zoom of the camera (32 mm). Apothecia were illuminated by a self-made ring of 4 miniature LEDs, enabling a shutter speed of ~1/15–1/60 sec at an aperture of 7.5–10. The sensitivity was generally retained at 100 ISO in order to avoid optical noise. Some photos of yellowish apothecia were in addition illuminated with a Luxeon-LED (3 W) in order to obtain a characteristic yellow fluorescence which is not seen under halogen or normal LED light.

Photographs were enhanced in contrast and/or adjusted in colour if necessary. Mostly they were made at constant magnification using a fixed zoom position. Microphotos were calibrated using a Zeiss calibration slide; their resolution with Coolpix 4500 at minimum zoom under oil immersion was ~0.1 µm per pixel. Microphotos were enlarged with Corel Photopaint 10 by 230% for ascospores, 173% for asci, and 115% for conidia, so that their magnification on the 2825 × 2125 pixel large plates coincide with that of the drawings.

Methods of collecting

Desiccation-sensitive species were harvested from pieces of substrate close to the forest floor, mainly in shady woods or near water. They were carefully transported in water-tight boxes in order to preserve the vital characters of the apothecia. Fresh apothecia were kept viable and in good condition for a few days or sometimes 1–2 weeks. For this purpose, specimens were stored in these boxes in the refrigerator at ~6–10 °C.

Desiccation-tolerant species were harvested on air-exposed substrate at a height of usually 0.5–2.5 m above the ground. They were for the most part collected in the dry state, and were rehydrated prior to examination using a sprayer. Rarely, desiccation-tolerant species were collected in the hydrated state shortly after rainfalls, or on hydrated substrate recently fallen to the ground. In some cases, substrate at about 3–6 m above the ground was gathered by using a long branch, a rope with a heavy object at one end, or a wire saw attached to a rope. A few collections are from up to 25 m ground level, harvested either during a crane project in the vicinity of the university of Leipzig (Germany), or through the window of buildings, also from trees recently fallen by a storm or when felled by forestry workers.

Whenever possible, the approximate height of the substrate above the ground level was noted for each collection.

Because of the difficulty of detecting apothecia in the field, collecting of desiccation-sensitive species was often done by gathering ample, favourably looking dry substrate in plastic or paper bags. The substrate was usually scanned for apothecia with a handlens (8–15 ×) in the field, but a majority of apothecia and particularly species were generally later detected under the dissecting microscope, often only after rehydration. Branches were cut into ~10–30 cm long pieces in the field in order to be more easily transported and handled. Frequently, a single collection comprised 10–20 or more such pieces from different branches of one or several neighbouring trees from the same species. Bright LED-illumination proved helpful in better detecting dry or hydrated *Orbilia* apothecia due to their more bluish spectrum and a resulting higher contrast between apothecium and substrate. Scattered groups of small apothecia were often tagged using water-insoluble paint markers (Edding Matt Paint Pen) in order to facilitate their redetection, using different colours for *Orbiliomycetes* and other ascomycetes.

The scope of observed branch thickness was noted for each lignicolous species. Thereby, the term 'twig' was usually applied below a thickness of 5–6 mm, the term 'branch' for ~5–100 mm, and the term 'trunk' or 'log' above 100 mm, irrespective of whether it was a young or old branch or a trunk. Besides the rate of decay, we carefully distinguished between bark and wood as support of the apothecia, and also noted the presence of algae and black yeasts causing greying of the substrate. Other fungi (including lichens) and bryophytes growing in more or less close association were noted for each species whenever their identity at some taxonomic level could be assessed. High attention has thereby been paid to discomycetes, whereas pyrenomycetes, mitosporic fungi, lichens, and basidiomycetes were more occasionally identified. Usually we have not distinguished between organisms occurring on the same piece of branch or on other branches, when they were of the same host plant, in a similar state of decay, and collected at the same site and day.

Conidia on the natural substrate. In many collections we have observed conidia on the natural substrate in close association with the apothecia, either lying detached on the substrate surface, or on conidiophores growing out of the apothecia or the surrounding substrate. Conidia occurring on the substrate surface were gathered by placing a drop of water close to the apothecia, and repeatedly transferring the liquid by a glass rod with an inflated globose end or by tweezers to a microscope slide. If the substrate is strongly absorptive for water, several drops were placed on the same spot before transferring liquid to the slide.

In many cases the conidia coincided with those obtained in pure culture, either from the same or another sample of the same species. Often, however, different conidial types belonging to different species were harvested on a given spot. Therefore, records of anamorphs from the natural substrate can often only tentatively be assigned to the associated teleomorph of *Orbilia*. In those species in which we obtained conidia only from the natural substrate, we referred to the anamorph as 'presumed', even if the conidia were repeatedly encountered in different samples of the same species.

Host identification. Host plants were identified whenever living or dead leaves, flowers or fruits were present. Identification was facilitated if the inhabited branches, herbaceous stems, or leaves were still-attached to the plant. Photos were often taken of the inhabited substrate in situ, the host plant, and the vegetation at the collection site, and hosts were sometimes identified from such photos. In the case of substrate being detached from the plant, or attached to entirely dead host plants without characteristic organs, determination of the genus was frequently done on the basis of wood (xylotomy) or herbaceous stem microanatomy. Microscopic cross, radial, and tangential sections of wood were compared with keys (Hassler & Hirschmann 1985; Höster 1969, 1970; Schweingruber 1990, Schweingruber online: http://www.wsl.ch/dendro/xylemdb), and with a personal reference collection of permanent slides and photos. Macrophotographs of transversely broken or cut wood taken with the above-mentioned Horizon macrolens mounted on Coolpix 4500 were made from a large number of substrates, which permitted identification of many genera and revealed various misdetermined hosts.

Plant nomenclature and systematics followed the modern classification, for which mainly Wikipedia and the International Plant Names Index (www.ipni.org) or the Kew plant list (http://www.theplantlist.org) were used. Regarding angiosperms the host list (Appendix 1) is sorted according to Angiosperm Phylogeny Group IV (see https://en.wikipedia.org/wiki/APG_IV_system).

Geographic and climatic data

For georeferencing collection sites, longitude-latitude coordinates (WGS84) were often gained by collectors, either by a GPS device or in Google Earth©, from which also the altitude was taken. Distances between collection sites and towns or villages were taken from the approximate city centre using the distance tool in Google Earth. Distribution maps were generated by exporting the geographical data from the personal database (DBASE IV) to Microsoft© Excel and conversion with the online program http://www.earthpoint.us/ExcelToKml.aspx to a kml file which can be opened in Google Earth. Phenological data are summarized in tables only for those species with more than ca. 25 collections.

Different online maps for bioclimatic zones (thermo- and ombrotypes), biogeographic regions (ecoregions), geology, and vegetation groups were used to analyse the ecological preferences of a species. These were mainly the following:

World: http://portal.onegeology.org/OnegeologyGlobal/.

North America: climate zones, moisture index: http://www.bonap.org/Climate%20Maps/ClimateMaps.html; ecoregions: https://en.wikipedia.org/wiki/United_States_physiographic_region; plant associations: Bennett et al. (2004), Vankat et al. (2013), Forest Cover Types (nationalatlas.gov).

Europe: thermoclimatic belts: http://www.globalbioclimatics.org; geology: http://infoterre.brgm.fr/geoservices-ogc (France), https://map.geo.admin.ch (Switzerland), https://apl.geology.sk (Slovakia) and others, maps of Germany, Luxembourg etc.

Australia: plant associations: http://www.environment.gov.au/resource/major-vegetation-groups-australia; ecoregions: http://www.environment.gov.au/parks/nrs/science/bioregion-framework/ibra/index.html.

Macaronesia: plant associations: http://www.tenerife.es/planes/PTEOActIndustrial/adjuntos/PINF_105.pdf; climatic zones: Del-Arco et al. (2006); geology: https://visor.grafcan.es/visorweb/.

The climate of collection sites (thermo- and ombrotype) was also looked up in Wikipedia in cases when towns were in close vicinity, for which climate charts were available. For thermotypes the terms supratemperate and meso-/thermo-/infratemperate are used in Europe and Azores as equivalents to cold- and warm-temperate in other continents. For ombrotypes the term semihumid instead of 'dry' was used within Europe and Macaronesia for pluviseasonal climates with distinctly less precipitation and humidity during summer, and the term subhumid instead of 'dry' was used for a boreal sagebrush desert scrub in Pinedale in the Wyoming Basin adjacent to the Wind River Range of Middle Rocky Mountains, showing a little more rain in summer than in winter. Because of the low resolution of most online maps, the altitude of collection sites was used to determine their most probable bioclimatic zone. For Europe we mainly used the map of thermoclimatic belts, but a few data of this map were modified: the region of Bretagne in western France was classified by us as mesotemperate, not mesosubmediterranean, following its classification as temperate oceanic on the map of bioclimates, Dalmatian lowlands as thermo- instead of mesomediterranean (N. Matočec pers. comm.), and the northern Caspian lowlands as warm-continental instead of supramediterranean, following the climate charts of Volgograd and Astrakhan. Some small hills and mountains are not included in this map: for instance, Fruška Gora in northern Serbia lies in a suprasubmediterranean lowland of 75 m altitude, but its forests at 250–540 m are classified by us as supratemperate.

Definition of continents (see Fig. 127). The term 'Northern America' is used here to comprise USA, Canada, and Greenland and 'Middle America' to include Mexico to Panama and the Carribean islands (by excluding Trinidad and Tobago though currently referred to the Lesser Antilles). Both regions represent the continent of North America. The South American continent includes all mainland countries south of Panama (including Trinidad and Tobago). Africa includes the islands around Madagascar, whereas Macaronesia shows closer affinities to Europe. Asia includes Turkey to the southwest and the Indonesian islands to the southeast. Australasia is considered to comprise Australia, Tasmania, and New Zealand, and Melanesia to include New Guinea, Solomon Islands and others. Europe is adopted as extending eastwards to the Ural mountain range and Ural river, and southeastwards to the Caucasus and Bosporus, by excluding most of Georgia, Azerbaijan, and Turkey. For practical reasons, the Ural and Caucasus mountains are treated in chorological respect as entities. Central Europe is roughly circumscribed by including Luxembourg and the Pannonio-Carpatian regions, and by excluding subatlantic, hemiboreal (Baltic), continental, and submediterranean regions.

Methods of examination

General. Within each collection, usually a few apothecia were examined, except for very scanty specimens. In rich collections consisting of many pieces of substrate, often up to 10–20 apothecia were examined. Due to the frequent occurrence of mixed populations, different apothecia from each piece of substrate were tested in order to explore the species composition. For instance, about 2–5 more or less remote apothecia were examined from each piece of a xeric branch which has been cut in the field into ca. 10–20 cm long pieces. In the species descriptions, a number in curled parentheses {} indicates the number of collections from which the given data were gained. This number is often lower than the total number of collections studied because of the impossibility to check every collection for the whole set of characters.

Macroscopic examination. In the descriptions, macroscopic data on the hydrated apothecia observed under the dissecting microscope refer either to the fresh (= moist) or the rewetted (= rehydrated) mature apothecia. Shape and colour of dry apothecia are reported separately. Dry apothecia were rewetted either by spraying with tap water, sometimes also by submersing the substrate in tap water for a few seconds, or by placing a water drop on a single apothecium (in order to avoid water stress to the whole population in case that living elements might still be present). Before taking macrophotographs, excess surface water must be allowed to disappear. Depending on the hydrophily or absorptivity of the substrate surface, this usually takes ~1–2 or rarely up to 10 min. In addition to the hydrated state, photos were sometimes also made in the dry state, especially in desiccation-tolerant taxa. Due to the frequent fading of apothecial colour in specimens older than about 5–10 years, the original colour is indicated whenever it was stated by the author, while altered pigmentation is sometimes mentioned separate from the original colour.

Date of examination, **desiccation tolerance**. Fresh collections of desiccation-sensitive species were studied within a few days after they were collected (about one week as a maximum when sent by mail). A few collections from Northern America and China were received by air-mail in the fresh living state without damage. Desiccation-tolerant species were likewise studied within a few days if they were collected close to a working room with available microscopes. Those collected on dry xeric substrate in continents other than Europe were posted in the dry state and studied within a period of some weeks or months, or often ~1–3 years later. After more than 3 years have passed, living elements were only exceptionally found.

Desiccation tolerance was evaluated at random for most of the species seen in the living state. In the descriptions, only the maximum period of time is mentioned after which a given element was found to be still viable when stored at room temperature in the herbarium. This period starts with the moment of collection, but it neglects the fact that the apothecia were dormant the field for an unknown period of time, depending on the weather conditions at that time. The desiccation tolerance given in the descriptions thus refers either to the moment when the fresh specimens were dried in the laboratory, or when the dry specimens were collected.

In rare cases, immature populations were kept under damp conditions in watertight boxes or plastic bags for some weeks (with periodical intervals of dryness in the case of desiccation-tolerant species) in order to obtain mature asci and spores. Fully turgescent asci with tight spore packing, and even active spore discharge could then sometimes be observed, but frequently the maturation process was not initialized.

Sections versus squash mounts. Apothecia were studied in squash mounts or in median sections made free-hand under the dissecting microscope (20 ×) using razor blades. Whenever possible, the study of sections was preferred since they allow to view the marginal region of the ectal excipulum and also the asci and paraphyses in situ, e. g., how much the paraphyses protrude beyond the asci. Sections were executed more or less exactly across the centre of the apothecium (median), in order to permit correct interpretation of tissues in the lower part of the apothecium. Apothecia were usually sectioned in the hydrated state, while in the dry state some species are too brittle, especially *Hyalorbilia*, and others too small. Free-hand sectioning requires firmly attached apothecia and a tough substrate. Sections gained from hydrated apothecia have a thickness of ~20–50 µm, whereas dry apothecia allow to obtain a thickness below ~20 µm. Depending on the diameter of the asci or excipular cells, sections require a minimum thickness in order to study undamaged living tissue. Thanks to the transparency of the living cells, sections of 40–50 µm thickness still allow to see the cells including their contents, even if they are covered by others. For microphotography, however, better results are obtained with thinner sections. In the case of very minute apothecia, the excipular anatomy was sometimes studied by viewing on the cut surface of an apothecium being divided into halves.

To follow a paraphysis or ascus from top to base in situ is often only possible in sections of apothecia in which most of their elements are viable. Studying sections of living apothecia in water mounts thus makes any separation of the elements, or any staining procedure generally superfluous. In dead material, on the contrary, the subhymenial region is usually highly intransparent, and separation of the elements by pressure frequently results in breakage of the asci at the level of their stalks. In order to obtain at least some complete, unbroken asci, enough amounts of water or KOH and a medium strong pressure is required. Alternatively, sections in KOH are treated with iodine in order to stain the ascoplasm (see p. 10).

In addition to sections, entire (dead or living) apothecia, or marginal fragments of apothecia, were examined in top view. This allows to study the marginal cortical cells (Fig. 77: d, f), and also to focus on the hymenial exudate.

Study of living material. All parts of the fungus (anamorph and teleomorph) were examined and illustrated in the living state whenever living cells were available (vital taxonomy, Baral 1992). Living specimens were always studied and measured in tap water mounts. Thereby only gentle pressure on the cover slip was applied in the case of squash mounts, and no pressure in the case of sections, at least during the first minutes of observation. Living fungal cells are highly sensitive to pressure. Any too strong deformation causes irreversible damage to the plasmalemma. When pressing on the slide, thick elements are affected at first, therefore, asci usually die already at a slight pressure and paraphyses and spores when pressing more strongly.

Concerning apothecia of *Hyalorbilia* with generally abundant gel between the hymenial elements, much care and skill is necessary in order to save vitality in a microscopic preparation. Due to this gel, any pressure on the cover slip must be avoided, otherwise asci and paraphyses rapidly die. Very sharp razor blades are necessary to minimize the shearing forces on the hydrated cells in order to avoid destruction of their plasmalemma. When viewing vertically on the surface of the hymenium of an entire apothecium mounted in ample water under the cover slip, the living state of the asci and their spores, and of the paraphyses with their pale chlorinaceous VBs can easily be recognized in optical cross section under oil immersion (Fig. 75: a).

Due to their often rather high refractivity and sharp outline, organelles such as LBs, SBs, SCBs, and VBs are very clearly visible inside living cells, even though being often fairly small. The requirements for their observation are: (1) oil immersion at a magnification of min. 1000×, (2) normal bright field optics, (3) water as mounting medium, and above all (4) living elements. No phase or interference contrast is necessary, even for microphotography (Figs 83–90). On the contrary, such enhancement of contrast obscures, e. g., the exact shape of SBs, particularly their fine attachment. Best contrast and resolution is gained from elements lying close to the cover glass. Due to a slightly higher specific weight of free spores compared to water, spores of seemingly all fungi soon settle on the slide. Therefore, they can usually only be photographed in this situation.

Basic dyes were used for staining the contents of living cells (vital staining), and for staining cell wall layers and extracellular structures. Different dyes were tested [Cresyl blue (CRB), Toluidine blue (TB), Cotton blue = Methyl blue (CB_a), Neutral red (NR)]. For the study of living cells the solution must be aqueous (in tap or distilled water), since current ingredients of these dyes are lethal to the cells. Both CRB and TB have a strong metachromatic property, i. e., they change their colour depending on the pH of the stained microstructure (in Baral 1992: 364 it was erroneously stated that TB does not change its colour in acids towards turquoise, in contrast to CRB, although both dyes turn turquoise when accumulated in VBs).

Staining of living cells was done to determine the type of cell organelle. Basic dyes selectively stain refractive vacuoles (VBs in paraphyses, SBs in ascospores) in a greenish- to violet-blue, and therefore, allow differentiation against LBs and SCBs which remain either unstained in these agents or turn pale rose-red (LBs). Basic dyes were also sometimes used for testing vitality of single cells, and for improving visibility of nuclei and nucleoli, for which also IKI was sometimes applied as a vital stain.

Basic dyes were frequently applied to test the metachromatic staining properties of cell wall layers, external gels, and exudates. Basic dyes were found to stain ascus apical thickenings blue-violet, and external gel lilac. They show a high affinity to exudate, which stains turquoise-blue and thus allows to differentiate glassy processes which remain unstained.

Staining was carried out by adding a drop of the dye to the edge of the cover slip of a water mount. Thereby, the cover slip is slightly liftet so that enough dye comes in contact with all of the cells, then excess liquid is removed. Since staining of cell inclusions usually takes a few minutes until the dye enters both plasmalemma and tonoplast, the process was sometimes accelerated by making the solution very weakly alkaline (by adding a drop of ~0.1 % KOH or NH_4OH to the mount = CRB_A, Baral 1992: 341, Le Gal 1947: 78).

Because CRB and also IKI are slightly toxic, these agents permit vital studies only for some minutes. Clémençon (1972: 52) found aqueous CRB to become useless after some months by flocculation of the pigment, therefore, he added high amounts of concentrated glycerol and alcohol 96 % in order to stabilize the solution. However, although the metachromatic reaction of exudate and gel is not diminished by these high-concentrated ingredients in Clémençon's CRB solution, they destroy the vacuoles and other organelles and shrink the cells. We found aqueous CRB to work well even after many years, despite its flocculation, although it seems advisable to filter the solution once in a while.

Study of dead herbarium material. Quite a large number of figures in this monograph show dead elements. This mainly concerns type specimens of previously described taxa, sometimes also recent records being examined too late. These figures demonstrate the alterations in cell shape and especially the loss of cell contents. Herbarium material was first studied in tap water. If no living elements were found, the dead spores were first examined in water in order to see if the spore bodies are still perceptible as a transparent or (rarely) refractive region. Next, a small drop of KOH (~5%) was added at the edge of the cover slip to the water mount in order to swell the elements and clear the dead cytoplasm. Mostly, a small drop of CR was soon added to the KOH-mount for creating a better contrast of the cell walls, particularly concerning septa of paraphyses and ascogenous hyphae. In such KOH+CR mounts the walls of the spores inside the asci become better visible, and sometimes even the spore body region is faintly perceptible. CR_{SDS} was mainly used to stain ascus apical thickenings. It was either added to a water mount, or (in herbarium material) to a KOH mount. Staining of the swollen endotunica takes some minutes and needs quite a high concentration of the reagent (presence of KOH is not necessary). Best results are obtained when placing the fungus directly in a drop of CR_{SDS}.

If the spores are still not clearly visible within the asci, IKI (rarely MLZ) was added to a KOH+CR (or KOH) mount. By staining the glycogen in the surrounding ascoplasm, the spores of many taxa become more distinctly visible (Figs 10: d–e, 91: a). A method to make the transparent region of the SBs more clearly visible was sometimes applied, especially in order to see spore orientation within the asci: the apothecial fragment was placed in a drop of cytoplasmic stain (CRB, CB_L, or phloxine) for some minutes, then a drop of KOH and a coverslip was added, and the excess liquid removed. Thereby the sporoplasm stains violet or blue whereas the SBs may become perceptible in some taxa as unstained areas. Alternatively, the cytoplasmic stain can be added to the KOH-mount. This method worked quite well in species with comparatively large SBs, but in others, especially those with small globose SBs, it completely failed.

On the drawing plates and in the legends to the photo plates the applied mountants are indicated for each element, except for the frequent case of living cells mounted in water. Since media like KOH, MLZ, or CB_L are immediately toxic to fungal cells (with the exception of brown and thick-walled spores which do not occur in *Orbiliomycetes*), only aqueous mountants (H_2O, IKI, CRB) are headed by the cross (†) in order to indicate the dead state.

Ascus apex. As an exception throughout the monograph, the ascus apex is almost always figured in the dead state because the truncate shouldered apex are only apparent in the dead state, and the apical wall thickening and much more pronounced, due to the loss of ascus turgor. This is in concordance with the practice in other groups of ascomycetes, e. g., the *Helotiales* or *Lecanorales* which often have an amyloid apical apparatus that exhibits its ultrastructure much clearer in the dead (particularly immature) state where the apical thickening is inflated ~2–4-fold in thickness (imbibition effect, Baral 1992: 351). Entire mature asci, however, are figured in the living state whenever such asci were available.

Evaporation. When examining sections of apothecia of *Orbilia* in water mounts, the constant evaporation of water causes a mechanical pressure on the hymenium evoked by the adhesive power between water and glass. This results in a tighter packing of asci and paraphyses, especially when studying living specimens, which strongly diminishes transparency and disables to see branching and anastomoses, or the base of these hymenial elements. Moreover, evaporation may cause flattening of large cells (asci, conidia). Adding water solves this problem instantly. Enough liquid also prevents hymenia in median section from becoming more convex than they are in the natural state, or branched 3-dimensional conidia from getting 2-dimensional. On the other hand, too much water leads to diminished contrast and resolution if the examined structures reside at some distance from the cover slip.

Iodine reagents, **amyloidity and dextrinoidity**. Almost every species of *Orbiliomycetes* was at least once tested with IKI, either directly or, especially in dead material, when KOH-pretreated. KOH (~5%) was applied for ~0.2–1 min, usually at room temperature, rarely by briefly heating the slide. IKI was usually directly applied to the KOH-mount (thereby a part of the IKI gets discoloured): often it gives a dextrinoid reaction to the ascoplasm (rarely to the sporoplasm) due to glycogen, whereas an amyloid reaction (rarely a dextrinoid reaction) to the cell walls was never observed. Sometimes MLZ was used instead of IKI, particularly when testing ascus apical thickenings for dextrinoidity.

Croziers versus simple septa. Croziers and simple-septate ascus bases are best recognized in asci still adhering to the ascogenous hyphae. It is, therefore, recommended to observe the ascus bases preferably in sections in the context of the tissue. In *Hyalorbilia* there is usually no other way to clearly see the ascus base because the asci are firmly conglutinated with the paraphyses and, therefore, impossible to separate. It is further recommended to study specimens in a not too mature stage of development, in order to see the ascogenous hyphae during ascus formation. One of the reasons for the frequent neglect of ascus base characters is that they are difficult to observe in dead herbarium material. Dead specimens require application of CR (Congo red) to a KOH-mount and careful observation of the not too strongly squashed elements, in order to avoid breakage of the ascus stalks. In living material the character is often very easily and immediately seen. Ascus bases are also easily misinterpreted as variable because the visibility of croziers as well as furcate or T-/L-shaped bases depends on the viewing direction (see also Huhtinen 1990a: 66).

Polyspory. Spore numbers in asci were mainly evaluated by counting, predominantly from living material. Dead herbarium specimens were treated by KOH and stained in IKI/MLZ, CR, or CB/CRB. In cases when spore counting was too difficult, a calculation method was used based on the estimated volume of the spore cluster divided by the mean spore volume. This method was only applied to living asci in which the spores are tightly arranged in a cluster at moderate but not full turgescence. In order to determine its volume, the spore cluster was regarded as a cylinder [formula: mean length × mean width^2 × 0.785], its length and width being averaged in order to compensate for the rounded outline of the cluster. The spores were considered as a cuboid [mean length × mean width^2] in order to compensate for the space between the spores. Drawings of asci with spore numbers above 16 usually do not show all spores because the spores lie in several layers one upon the other. Also photographs show only those spores which are in focus.

Microscopic measurements

General considerations. Measurements of asci, ascospores, spore bodies, paraphyses, excipular cells, conidia etc. were taken directly at the microscope, and only sometimes they were evaluated from photos. The latter method may be subjected to some errors, e. g., diminished values are obtained due to eccentric focusing of an element. The length or vertical extension of an element is always given before its width, even if the width is greater than the length (e. g., in short apothecial stipes, marginal teeth, lens-shaped spore bodies, staurosporous conidia, or glassy processes). Excipular cell size is mostly gained in median section, except when 'in surface view' is stated. Their hyphal origin is often not recognizable, therefore, a definition of length and width is problematic here.

A minimum of about 5–15 asci (or ascospores) was usually measured in each collection. Length and width of individual elements were only noted for spores figured on the drawing sheet. Single () and double (()) parenthesis indicate the rarity of extreme values. Values were approximately determined when merging data from all included collections. Statistical methods were not applied, instead, the strict separation between living and dead cells was practised, which usually provides distinctly different ranges.

The stated ascus length consistently refers to the total length of the ascus cell, i. e., from the ascus apex down to the lowermost end of the ascus stalk, including all of its (non-septate) branches. The complete ascus base in *Orbilia* is easily overlooked because (1) the flexuous ascus stalk is often very long and thin, and then difficult to follow among the densely intermingled hyphae when the ascus is still in situ, (2) the asci very easily break at the thinnest part of the stalk above the branching point, when the hymenial elements are squashed by pressure in order to get separated. In order to obtain compatible values, such broken asci must be disregarded for length measurements. Complete separation including their base is generally only successful in some of the asci of a preparation. After gentle pressure on the cover slip, even turgescent asci may sometimes be found detached and floating in the medium. Literature reports sometimes do not encompass the total ascus length as here defined, and those authors being aware of this specified their measurements by a remark (e. g., Velenovský 1934: *sine pedicello* = excluding the stalk).

Whenever available, we recommend to observe and measure asci in the living state in situ, because their stalks are then much easier to follow to the very base due to the transparency of the living cytoplasm and a larger width of the stalk. In the case of dead asci, application of IKI (or MLZ, added to a KOH mount) often yields very clear results by staining the ascoplasm in a bright red-brown. The ascus stalks and their branches thereby strongly contrast with the unstained surrounding paraphyses and ascogenous hyphae, and that without separating the elements (Figs 91b–c, 92a). The effect is due to glycogen which is present in high quantity usually only in ± mature asci.

The measured cell width always refers to the widest point of an element. This is of special impact in biradial symmetrical asci which are in the dead state apically truncate and provided with two shoulders: in our values of ascus width we included these shoulders as seen in front view, but we also included those asci seen in profile view which appear distinctly narrower and rounded at the apex. Another complication is caused by the fact that asci with a truncate apex are not perfectly round in cross section below these shoulders, apparently irrespective of the living and dead state. Because in living asci front and profile view are not clearly recognizable, these deviations in width between the two views can hardly be separately evaluated. Drawings in the dead state of biradial symmetrical ascus apices at 4000 × always refer to the front view (the rare case when we figure apices in profile view is specified on the plates). Similarly, marginal cortical cells in *Hyalorbilia* are in external view often wider than in median sections (in top view on the hymenium the marginal cells often look broadly ellipsoid). In such cases we preferred to note two separate values instead of merging in one.

For a practical reason, curved elements like spores, spore bodies, or flexuous ascus bases were always measured ***in situ***. These in-situ values refer to the straight distance between the two ends of the element, or in very strongly curved spores the distance between the most protruding parts of the spore. In the case of distinctly curved spores and spore bodies, the actual length along the two- or three-dimensional curvature was estimated and indicated separately. The actual length has an undoubtedly higher taxonomic significance, but its evaluation is difficult, and for helicoid or irregularly bent elements it requires inclusion of the third dimension.

In branched (staurosporous) conidia there is some controversy concerning terminology, measurements, and number of septa of the extremities. We preferred to measure the stipe length, but some authors, e. g., Ando & Tubaki (1984c), Matsushima (1987, 2005), and Tzean & Chen (1989), measured the length of the 'axis' or 'main axis' by including the entire central cell, which is obvious from their measurements (see Fig. 104). Likewise, we use the term arm, whereas some authors prefer the equivalent term branch. A few authors considered two adjacent extremities as a single element regarding length and number of septa, e. g., Matsushima (1980) in *Trinacrium* with two horizontally projecting arms, Matsushima (1981) and Ando & Tubaki (1984a) in *Curucispora* with two arms forming a 'V', and Matsushima (1981) in *Curucispora* with the apical arm and the stipe included in his term 'axis'.

The number of septa in branched conidia given in our descriptions includes for the stipe the uppermost transversal septum, and for the arms the basal septum (see Fig. 104 left). Arm septa were also counted this way by Peek & Solheim (1958), Tzean & Chen (1989a) and others, whereas, e. g., Ando & Tubaki (1984b) and generally Matsushima omitted the basal septum of the arms. We consider the latter method to be problematic because the basal septum of some of the arms may tend to be more or less away from the arm base, also because of cases in which arms are devoid of any septa, even at their base.

Our measurements of conidia first give the total size (total length × total width, because of pressure by the cover slip a certain inexactness in measurements of total size is possible), and then the size of stipe and arms. Stipe length refers to the distance from base up to the point where the branches emerge, arm length to the straight distance between insertion and tip (see Fig. 104, top left).

Living versus dead elements. Due to the shrinking effect (see Huhtinen 1985a, Baral 1992, and p. below [shrinking effect]), measurements of living and dead cells were separately established. Measurements from living cells were taken whenever new collections with at least a few such elements were available. In the descriptions data on living elements are headed by an asterisk (*). Data in the dead state are headed by a cross (†), and were often evaluated in addition, in order to provide compatibility with specimens which were only available in the dead state. For elements which did not markedly differ in size between the living and dead state, both states were usually combined and headed by (*/†).

Huhtinen (1990a) considered also the influence of mounting media on the size of dead cells as important. However, killing of the cells has a distinctly higher influence than the employed media. Therefore, we refrained in our measurements from indicating the employed mountant. The media in which dead cells were measured were KOH, KOH+CR, KOH+IKI, sometimes also H_2O, H_2O+IKI or H_2O+CRB, rarely MLZ or CB_L. These mountants are indicated on our drawing figures or in the legends of the photo plates.

Measurements of living asci and ascospores always refer to the mature stage of development (for the definition of maturity of ascospores see p. 30, Recognition of maturity). In the dead state, estimation of maturity is much complicated, so that submature or overmature stages are easily mistaken as mature. Estimation of maturity of conidia is more difficult. Generally, all conidia which appeared to being detached from their conidiophores without external influence were considered to be mature.

Separation of measurement data between the living and dead state is of special importance in asci. This involves not only a strong shrinkage (Fig. 25: 1a, 2a), but also inflation of the apical wall, and often also increase in length of the pars sporifera. A speciality of the genus *Orbilia* concerns the fact that living mature asci strongly raise the internal turgor shortly before spore discharge and, therefore, noticeably increase in size (Fig. 25: 1a, 1b). Whenever fully turgescent asci were observed in species of this genus, ascus measurements were gained from both the moderate and the fully turgescent state, and are given as two separate values (before and after the arrow →). Because the spore cluster strongly retracts in length at full turgescence, the pars sporifera is likewise given separately for moderate and full turgescence. The length of the pars sporifera was taken as the distance between ascus tip (including ascus wall) and lower end of lowermost spore, provided that the upper spores reside close to the ascus apex (see Fig. 16).

Separation of the living and dead state is also recommended for ascospores, paraphyses and excipular cells, though these usually show less pronounced shrinkage in the *Orbiliomycetes*. In some descriptions, the stated measurements of the dead elements are larger than those in the living state. This may have different reasons. Often such data are based on different collections, that is, the variation of the taxon could not be fully explored in the living state. Flattening of dead cells is another source for this paradox effect.

Living spores inside dead asci. Because free spores are often not present in sufficient quantities in the *Orbiliomycetes*, a significant part of the drawings and measurements in this study originate from spores inside living, sometimes also dead asci. Due to the rather inelastic spore walls in the *Orbiliomycetes*, the size of living spores is about the same irrespective of whether they are measured inside asci of moderate turgescence, inside dead asci, or when ejected. The observed differences are below the general intraspecific variability and will hardly cause taxonomic conflicts. More obvious are differences in size between living and dead spores. In order to avoid too much complication, we have usually not specified the origin of the drawn spores and their measurements. In any case, living spores inside dead asci are usually difficult to measure since the spore wall is completely invisible and only the transparent sporoplasm is striking (Fig. 25: c left, d left). Due to a reduced vitality in some of the specimens studied, the only chance we had in order to draw and measure living spores was to use those inside dead asci.

Dead spores inside dead asci. Great problems arise whenever dead spores, which always have a thin delicate wall in the *Orbiliomycetes*, have to be studied inside dead asci (Figs 10: b–c; 25: c right). When adding cytoplasmic stains (IKI, CB_L, CRB) to a KOH mount, the ascoplasm is usually deeply stained whereas cell walls and sporoplasm remain unstained (Fig. 10: d–e). Such staining often enables to see the shape of the spores, also their orientation in the case of heteropolar spores, and sometimes the LBs. In rare cases, the SBs become perceptible as an unstained region. Problematic in regard to recognizing spore shape or spore numbers are species with filiform spores or with long spore tails. A clearer image of the spores is obtained in CR, because CR stains the spore walls, while asco- and sporoplasm are not stained. Also in this reagent the region of the SBs may become faintly perceptible, whereas LBs are shown with high contrast.

These two methods worked well in a lot of species, though in some cases the spores remained more or less invisible (Fig. 10: b–c). A final method in such a case is to cut the asci. A median section of an apothecium is placed on the slide in a very small drop of water. Under the dissecting microscope the asci are cross-cut by pressing the edge of a razor blade across the hymenium. Free, more or less mature spores escape from the broken asci and are then found in abundance.

The unstained spore wall inside dead asci may easily be considered as a spore sheath (Fig. 10: d–e). However, it seems to originate not only from the spore wall itself but also from some detachment of either the sporo- or the ascoplasm and leads to too small spore measurements if only the sporoplasm is measured. A membrane outside the spores is rarely seen in living asci, and it seems to be the investing membrane that here detaches from the surface of the spore wall. In the dead state, however, this could only be clarified in cases when spores emerged from broken asci. The sheath-like transparent layer has a thickness of ~0.3 µm and thus may provoke an error in spore measurements of ~0.6 µm in both length and width, which is quite significant, especially in the case of narrow spores.

But even living spores may cause problems, when they have a thin basal tail. These tails are usually only well seen in free spores. Sometimes they are visible inside living asci, and rarely inside dead asci, even if the spores are still alive.

Culturing techniques

Isolation. Isolates were taken in most cases from ascospores. Fresh or rehydrated apothecia (often with small pieces of substrate) were put inside the lid of a Petri dish on a drop of vaseline and allowed to shoot their spores on the agar. Illumination with a 40 W light bulb from a distance of ~40 cm was only used in a few cultures by one of us (G.M.). Alternatively, stimulation by vibration and slight heating, e. g., by placing on a running warm harddisk, was found to accelerate spore discharge (P. Perz, pers. comm.). Rarely, apothecia were placed on the agar surface to produce a mycelium or, more frequently, mycelia were observed growing out from apothecia attached inside the lid. Germinating spores were directly observed at a 150 × magnification through the unopened Petri dish. We have not tried to obtain single spore isolates, therefore, the isolated mycelia have always a polysporous origin. When enough spores were on the agar, the apothecia were removed from the lid and mostly checked microscopically for their identity because mixed populations of macroscopically indistinguishable species were often encountered on the same piece of substrate, especially in desiccation-tolerant species.

Agar media and incubation. Spore germination was obtained on CMA:2 (E.W., G.M.), CMA:3, CMA:4, CMA:5, CMA (1 : 1, G.M.), or MEA 2 % (without antibiotics). The plates were kept at room temperature (15–25 °C) under natural light-dark-change. Secondary cultures were incubated under artificial light-dark-change (20/12 °C, each lasting 12 hours, E.W.) or at natural light conditions in Petri dishes (90 mm diam., E.W. & G.M.). Later they were often deposited in the dark at 8 °C (E.W.). The strains were mainly plated on CMA:2, MEA 2 %, or water agar (WA), with the following composition: CMA:2 (half-strength cornmeal agar, Rubner 1996): 8.5 g cornmeal agar (Difco), 12.5 g agar (Merck), 1 l aqua dest.; CMA:3, CMA:4 and CMA:5: 5 g/4 g/3.5 g cornmeal agar (Fluka), 12 g agar (Merck), 1 l aqua dest.; CMA cornmeal agar (Fluka) 17 g, 1 l aqua dest.; MEA 2 % (malt extract agar, Gams et al. 2007): 20 g malt extract (Merck), 15 g agar (Merck), 1 l aqua dest.; WA (water agar): 20 g agar (Merck), 1 l aqua dest.

Water agar with sterilized pieces of rotten wood (*Rosa*, *Salix*), and CMA:2 with sterilized pieces of original substrate of collections were used in order to stimulate formation of conidia or apothecia (E.W.). We also frequently used a method which was often employed in aquatic hyphomycetes for inducing sporulation: submersing in water (see, for example, Ingold 1942, Marvanová & Bärlocher 2001). Thereby, 1–2 large agar blocks with fungal mycelium were placed in sterile, empty Petri dishes and flooded with distilled water; no parafilm was used in this case. Within some days the first conidia could be observed. No near-UV was available during our experiments to induce sporulation. Only in rare cases developed apothecia in our cultures.

Tests with nematodes, rotifers, and pollen

Nematodes were used for inducing the formation of trapping devices in pure culture: either *Acrobeloides maximus* or unidentified nematodes which were isolated from manure, from a contaminated fungal culture, or from a dead xeric trunk of *Ulmus minor* from Spain; in each case some individuals were transferred on agar cultures of ca. 30 species of *Orbilia* and *Hyalorbilia polypori*.

We used individuals of bdelloid rotifers, an unidentified species from dead xeric branches of *Cercocarpus ledifolius* from Navajo Loop Trail, USA, and *Macrotrachela quadricornifera*. The latter was cultivated in deionized water and fed with powdered pellets of goldfish food, according to instructions of M. Caprioli (pers. comm.), who provided us with this species. Some drops of a suspension of this rotifer were given to each of the tested cultures in order to induce trapping organs. Individuals of the unidentified bdelloid rotifer were picked off and given directly to *Orbilia* cultures, and for control also to uninoculated agar plates in order to see whether they might be infected already on their natural substrate.

Fresh pollen grains of *Sambucus nigra* and *Corylus avellana* were added to our cultures in order to observe whether the fungal mycelium invades them. Pollen grains were harvested by wrapping their inflorescences in aluminium foil for a few days. They were placed with a sterilized spatula into sterile distilled water. Some drops of this suspension were given with a sterile pipette directly on the mycelium. The mycelia were cultured on water agar, and inoculated 2 or 4 weeks prior to treating with pollen grains.

Molecular methods

Sequences were gained from pure cultures or dried apothecia. In the latter case, contaminations were frequent, and particularly here sequences were cautiously controlled with the chromatograms. Specimens older than about 5–10 years often failed, and only exceptionally a sequence of a desiccation-sensitive species was successful after 16–20 years. Our methods of rDNA isolation and sequencing at the National Natural History Museum in Luxembourg are explained in Baral et al. (2017a). For the methods used by G. Hagedorn see Hagedorn & Scholler (1999). An incomplete survey of the primers used in the different laboratories involved in this study are listed in Tab. 1. Their location in the rDNA is shown in the example of *Orbilia xanthostigma* (Tab. S1).

Searches for similar sequences were done in GenBank (BLAST, https://www.ncbi.nlm.nih.gov/genbank/) (Benson et al. 2017) and in CBS (http://www.westerdijkinstitute.nl/Collections/BioloMICSSequences.aspx, now under https://wi.knaw.nl/page/Pairwise_alignment). Searches for short motifs of ~15–30 nt length were only possible in GenBank because in CBS a minimum of 100 nt was required. BLAST (blastn) searches were done separately for ITS1-5.8S-ITS2 (by removing adjacent parts of SSU and LSU), LSU D1–D2, SSU V8–V9, or the S1506 intron, but also for other regions of SSU and LSU. Queries for shorter regions such as ITS1, ITS2, 5.8S, D1, D2 were done in some cases.

Molecular phylogenetic analyses. All phylogenetic analyses were done with the freeware program MEGA6 or 7 (Molecular Evolutionary Genetics Analysis) available from http://www.megasoftware.net/, see also Kumar et al. 2016, https://www.megasoftware.net/pdfs/KumarStecher16.pdf), with which also the best nucleotide substitution model was determined. Datasets of sequences were curated and annotated in Microsoft Word. Sequences were aligned using Muscle (integrated in MEGA) or in difficult cases with the online version of MAFFT (https://mafft.cbrc.jp/alignment/server/index.html), generally followed by a manual sorting according to the phylogenetic similarity and a manual adjustment in order to minimize distances between closely related species. Ambiguously aligned sites in the ITS1 and ITS2 region were not excluded from the analysis.

Each rDNA marker region (gene locus) was individually subjected to analysis in order to assess gene congruence, but combined analyses of two or three regions were also often done. The following regions were used: partial SSU (V8–V9: 362 nt, rarely V1–V5: 1057 nt), entire ITS (ITS1-5.8S-ITS2: ~500–550 nt), LSU (D1–D2: ~635 nt, rarely D1–D3: ~830 nt or D1–D6: ~1420 nt). The mentioned regions of the small and large ribosomal subunit are in this work briefly referred to as SSU and LSU, although 'partial SSU' or 'partial LSU' would be more correct as they only represent a small part of the entire SSU (V1–V9) and LSU (D1–D12). The frequent S1506 intron at the 3'-end of SSU was phylogenetically analysed whenever it occurred in more than a few species of the given group, but never in combination with other regions. It was obtained with the primers ITS5, ITS1-F, or SF16a, while being missed with the primer ITS1, which was used in sequences generated early in this study.

Table 1. Primers for the rDNA used in this study by Gregor Hagedorn (GH), Eric Kuhnert (EK), Guy Marson (GM), and Michael Weiß (MW), including some other primers. The approximate gene region obtained by the respective primer is indicated (for the location of regions and primers in rDNA see Fig. 112 and Tab. S1). For primers running in reverse direction ('Rev'), the forward version ('Fwd') is given in the subsequent line to permit localization in single sequences or alignments (in case the forward version is inofficial and unnamed it is given in brackets). Primers can be found, e. g., in the following lists: https://nature.berkeley.edu/brunslab/tour/primers.html, https://sites.duke.edu/vilgalyslab/rdna_primers_for_fungi/, http://lutzonilab.org/nuclear-ribosomal-dna/. Some minor deviations among authors can sometimes be found. Nucleotides deviating between *Orbiliomycetes* and other classes are given in small font. * = personally designed primer, † = according to AFTOL (a variant with GGG instead of GGGG does not fit *Orbiliomycetes* and various other fungi), # = primer includes position of S1506 intron, § = primer includes position of L2449 intron (therefore primers # and § do not work when the strain possesses the intron). Corresponding parts of primers are highlighted in blue; r.c. = reverse complement.

For most analyses Maximum Likelihood (ML) was used, with the settings 'use all sites, nearest-neighbour-interchange, weak branch swap filter'. Neighbour joining (NJ) analyses were done on datasets with very few deviating nucleotides or in rare cases if important clades in the resulting tree received strong support under NJ but no support under ML, using the settings 'p-distance, uniform rates, pairwise deletion'. Branch support is given as maximum likelihood bootstrap percentages from 500 replicates, except for the large Phyls 5 and 7 with only 100 replicates, and S15 with 1000 replicates. Bootstrap values below 50 % are not shown in the trees. At or above 90 % the support was called strong, between 70 and 90 % medium, and between 50 and 70 % weak.

Numbering of nucleotide positions. Following Kim et al. (2006), nucleotide positions in the ITS1 were evaluated by starting after ATCATTA (3'-end of SSU), those in the 5.8S by starting with AAAACTTT (5'-end of 5.8S, in alignments of closely related species also after ATCATTA), those in the ITS2 by starting after GAGCGTC (3'-end of 5.8S), and those in the LSU by starting with TGACCT (5'-end of LSU). Positions in the frequently sequenced V8–V9 region of SSU were counted by starting with CCTTAGAT, a consistent motif adjacent to the NS7 primer downstream. Alternatively, counting was done across the entire ITS1-5.8S-ITS2 region in some cases.

For evaluating position numbers in alignments of conservative gene regions, gappy positions caused by rare inserts were excluded. Due to the rarity of inserts in the SSU V8–V9 (362 nt, starting after NS7) and 5.8S region (155 nt, including AAAACTTT and GAGCGTC), consistent position numbers across the entire *Orbiliomycetes* could be used for these regions. Also in the LSU inserts or omissions occur only infrequently, and the complete deletion of predominant gaps in an overall alignment resulted in invariable position numbers in the D1–D4 domain for all groups. Accordingly, the LR1 primer occurs at pos. 54–69, LR2 at 367–384, LR3 at 636–652, and LR4 at 832–848 (Tab. 1). In contrast to this numbering system, the position number, after which introns in SSU and LSU are named, follows an alignment with *Escherichia coli* (J01695, Gutell 1993).

Specific nucleotides and motifs. Nucleotide positions in different rDNA regions, which were found to be specific to species or groups of species, have been visually explored in MEGA 6 or 7 from alignments of entire datasets of a given genus or infrageneric group, which was sorted according to phylogenetic relationships.

Distance analyses were done with MEGA7 using the settings p-distances, transitions + transversions, uniform rates, pairwise deletion. Distances were mainly evaluated for the entire ITS region (ITS1-5.8S-ITS2, with exclusion of ATCATTA and TGACCT, see p. 18), sometimes also for one of its subregions. Distances were also evaluated for the partial LSU (D1–D2) and sometimes the partial SSU (V8–V9). Whenever the S1506 intron was present, distances were evaluated for this region by excluding the conserved motifs TCGTAACAAGGT and TTCCGTAGGTGAA of the adjacent SSU.

Because of high interspecific variation with numerous gaps in alignments of the ITS1/ITS2 and S1506 intron, distance analyses of these regions were done pairwise or in groups of about 3–5 species, whereas analyses of conserved regions (SSU, 5.8S, LSU) produce unequivocal alignments rare in gaps and allow to analyse large data sets in one matrix.

Abbreviations, Terminology

__General__: **ad int**. = *ad interim* (in the meantime), **aff**. = *affinis* (akin to, used for deviating collections which probably belong to distinct, undescribed species), **agg**. = species aggregate, collective species, **a.s.l**. = above sea level (altitude), **ca**. = *circa*, **cf**. = *conferatur* (compare, used for deviating though possibly conspecific collections), **comb**. **nov**. = *combinatio nova* (new combination), **d** = day(s), **depos**. = deposited, **diam**. = *diametro* (in diameter), **e.g**. = *exempli gratia* (for example), **emend**. = *emendavit* (amended, rectified), **erron**. = erroneously, **et al**. = *et alia* (and co-workers), **etc**. = *et cetera* (and so forth), **excl**. = excluding, **f**. = *forma* (form), **f./ff**. = *folio* (including the following page/s), **gen**. **nov**. = *genus novum* (new genus), **herb**. = herbarium, **hwy** = highway, **i.e**. = *id est* (that is, in other words), **id**. = *idem* (the same, the aforesaid), **ICN** = International Code of Nomenclature for algae, fungi, and plants (Shenzhen Code, Turland et al. 2018), **in litt**. = *in litteris* (in correspondence), **in sched**. = *in schedula* (on herbarium label), **inc**. **sed**. = *incertae sedis*, **incl**. = including, **indet**. = *indeterminavit* (unidentified), **ined**. = *ineditus* (unpublished), **isol**. = isolated, **IVV** = www.in-vivo-veritas.de (link to drawings and photographs), **lat**. **diagn**. = Latin diagnosis, **l.c**. = *loco citato* (at the place cited), **max**. = maximal, **min**. = minimal, **min** = minute(s), **Mt**. = Mountain (or in French 'Mont'), **myr** = 1 million years, **no**. or **nr**. = number, **nom**. **cons**. = *nomen conservandum* (a name which was illegitimate or lacked priority when published but was later conserved), **nom**. **dub**. = *nomen dubium* (a name of unresolved identity), **nom**. **illegit**. = *nomen illegitimum* (a validly published name which is, nevertheless, in conflict with the Code, mostly a binomial which already exists as a homonym), **nom**. **inval**. = *nomen invalidum* (a name which did not meet the requirements of the Code when published), **nom**. **nov**. = *nomen novum* (a new name published in order to avoid an illegitimate combination, i.e., a homonym), **nom**. **nud**. = *nomen nudum* (a name published without a diagnosis), **nom**. **prov**. = *nomen provisorium* (a provisional name published without the intention to fulfil the rules of the Code), **nom**. **[utique] rej**. = *nomen [utique] rejiciendum* (a [by all means] rejected name in favour of a conserved name), **nom**. **sanct**. = *nomen sanctionatum* (a name having priority through acceptance in a sanctioning work), **OCI** = oil content index, **p.p**. = *pro parte* (for a part of the cited taxa or specimens), **p.p.maj**. = *pro parte majore* (for the greater part), **p.p.min**. = *pro parte minore* (for a smaller part), **phot**. = photographed, **pos**. = position, **Rd** = Road, **Rte**. = Route, **s**. = *sensu* (in the sense of), **s.auct**. = *sensu auctorum* (in the sense of authors), **s.l**. = *sensu lato* (in a broad sense), **s.n**. = *sine nomine* (without name), **s.str**. = *sensu stricto* (in a narrow sense), **sec** = second(s), **sect**. **nov**. = *sectio nova* (new section), **ser**. **nov**. = *series nova* (new series), **soc**. = associated with, **sp**. **nov**. = *species nova* (new species), **stat**. **nov**. = *status novus* (new rank) **subsp**. = *subspecies*, **var**. = *varietas* (variety), **viz**. = *videlicet* (namely), **vs**. = *versus* (against).

__Collection data__: **anam**. **apoth**. = anamorph grown out from ascocarp (at lid of Petri dish or rarely on agar), **anam**. **cult**. = anamorph obtained from ascospore isolate in pure culture, **anam**. **only** = only anamorph present on natural substrate, **anam**. **substr**. = anamorph from natural substrate in association with teleomorph, **apoth**. **cult**. = apothecia obtained in pure culture, **conid**. **isol**. = conidial isolate (pure culture gained from conidia or from substrate/soil), **doc**. **vid**. = *documentum vidimus* (microphotographs or drawings seen, rarely only descriptions, but no specimen studied), **ibid**. = *ibidem* (in the same place), **mol**. **extr**. = molecular (DNA) extract from soil, wood etc. (uncultured, without anamorph or teleomorph), **myc**. **only** = mycelium only, **non vid**. = *non vidimus* (no specimen and no images seen by us), **vid**. = vidit (seen), **#** = GPS number of G.M.'s collection site.

__Symbols__: ***** = living (viable) state, **†** = dead state, **ø** = no specimen preserved, **{}** = values in curled parenthesis refer to the number of collections that were examined, **~** = circa. After the host plant and the associated taxa the curled parenthesis contains the number of records with certain/uncertain identity. The arrow (→) is used between measurement values and indicates changes in development or direction: concerning the ascus size and the length of the pars sporifera it stands between moderate and full turgescence; concerning the apical thickening it stands between immature and mature asci; concerning spore body size it stands between mature and overmature spores, and concerning the thickness of the receptacle or the ectal excipulum it stands between lower and mid flanks or margin (if no arrow is present, the values refer to the first of the two cases).

Type specimens (in descriptions and phylogenetic analyses): **T** = type, **ET** = epitype, **NT** = neotype, **RefSpec** = reference specimen.

Mountants and Reagents: **CB$_a$** = aqueous Cotton blue (Methyl blue), **CB$_L$** = CB in lactic acid or lactophenol, **CR** = Congo red (aqueous), **CR$_{SDS}$** = CR with SDS, **CRB** = (Brilliant) Cresyl blue (aqueous), **CRB$_A$** = CRB slightly alkalinized by ~0.1% KOH or NH_4OH, **H_2O** = (tap) water, **HCl** = hydrochloric acid (~90%), **H_2SO_4** = sulphuric acid (1–60%), **IKI** = Lugol's solution of strong concentration (~1% I_2, 2% KI, in H_2O), **KOH** = potassium hydroxide ~3–5% (rarely 10–20%), **MLZ** = Melzer's Reagent (IKI + chloral hydrate 1:1), **NH_4OH** = ammonium hydroxide, **NR** = Neutral red (aqueous), **SDS** = sodium dodecyl sulfate, **TB** = Toluidine blue (aqueous), **PVA** = polyvinyl acetate. On the plates the sign for living state is generally omitted, and that for the dead state is omitted in lethal media such as CB$_L$, MLZ and KOH (the latter stands also for KOH+CR and KOH+IKI), **Réactif de Bailenger**: 0.05 g Crystal violet, 0.01 g Basic Fuchsin, 20 ccm 95% ethanol, 4 ccm phenol crystals, 100 ml H_2O.

Cytoplasmic inclusions: **LB** = lipid body (oil drop), **MC** = metachromatic body, **N** = nucleus, **SB** = spore body, **SCB** = KOH- and HCl-soluble (sensitive), refractive cytoplasmic body, **VB** = KOH- and HCl-soluble (sensitive), refractive vacuolar body, **WB** = Woronin body.

Iodine reactions: **RR** = red at both a high and low concentration of iodine (hemiamyloid), **RB** = red at a high, blue at a low iodine concentration (hemiamyloid), **BB** = blue at either concentration (euamyloid).

Microscopes: **LM** = light microscope, **TEM** = transmission electron microscope, **SEM** = scanning electron microscope, **DIC** = differential interference contrast.

Agar media: **CMA** cornmeal agar (CMA:2 = with half the concentration of undiluted CMA), **MEA** malt extract agar, **PDA** = potato-dextrose agar, **WA** water agar.

Molecular terms: **BLAST** = Basic Local Alignment Search Tool (**blastn** compares a sequence against a nucleotide database, freely available in GenBank); **gene regions** [see also Tab. 1 for primer names]: **ITS** = internal transcribed spacer region of rDNA (composed of three subregions: ITS1, 5.8S, ITS2), **LSU** (or **28S**) = large subunit of rDNA (including twelve domains: D1–D12), **nt**/bp = nucleotide(s)/basepair(s), **rDNA** = ribosomal DNA, **sq**. = sequence (usually rDNA), **SSU** (or **18S**) = small subunit of rDNA (composed of nine regions V1–V9), **nuSSU** = nuclear SSU, **mtSSU** = mitochondrial SSU; **S1506** = group I intron at position 1506 of SSU, **L1921** = group I intron at position 1921 of LSU (in reference to *Escherichia coli* J01695); protein-coding genes: ***RPB1/2*** = largest subunits B1/B2 of RNA polymerase II, ***TEF1*** = translation elongation factor EF-1α, ***MAD1*** = mitotic checkpoint family protein, ***MCM7*** = mini-chromosome maintenance proteins (DNA replication licensing factor), ***TUBB*** = β-tubulin; **phylogenetic analysis**: **ML** = maximum likelihood, **NJ** = neighbour joining, **JC** = Jukes-Cantor, **T3** = Tamura 3-parameter model, **TN** = Tamura Nei model, **K2** = Kimura 2-parameter model, **GTR** = General Time Reversible, **G** = gamma distributed, **I** = with invariant sites.

Repositories of taxonomic and molecular data: **CBS** (http://www.westerdijkinstitute.nl/Collections/BioloMICSSequences.aspx), **GenBank** (NCBI, https://www.ncbi.nlm.nih.gov/genbank/), **MycoBank** (**MB**, http://www.mycobank.org/), **Index & Species Fungorum** (http://www.indexfungorum.org, http://www.speciesfungorum.org), **NBRC** (http://www.nbrc.nite.go.jp/NBRC2/NBRCDispSearchServlet?lang=en), **UNITE** (**UDB**) (https://unite.ut.ee/, https://plutof.ut.ee/#/clipboard).

Ecological terms: **xeric/hygric** = substrate periodically dry/ permanently moist, **xero-/hygrobiotic** = ascomata or conidiophores/ conidiomata drought-tolerant/-intolerant; **thermotypes** (in Europe): **eumediterranean** zone comprising oro- (Or), supra- (Sm), meso- (Mm), thermo- (Tm), and inframediterranean (Im); **submediterranean** zone comprising orosub- (Osm), suprasub- (Ssm), meso- (Msm), and thermosubmediterranean (Tsm); **temperate** zone comprising cryoro- (Ct), oro- (Ot), supra- (St), meso- (Mt), and thermotemperate (Tt); **hemiboreal** zone (Hb); **boreal** zone comprising cryoro- (Cr), oro- (Ob), supra- (Sb), meso- (Mb) and thermoboreal (Tb); **ombrotypes**: precipitation > evaporation: humid (winter- to somewhat summer-dry); precipitation < evaporation: subhumid (winter-dry or not), semihumid (summer-dry), semiarid, arid.

Acronyms of institutional herbaria (abbreviated according to Index Herbariorum, http://sweetgum.nybg.org/ih/, * = not included in Index Herbariorum): AH (Alcalá de Henares, Spain), ARAN (San Sebastián, Spain), ARSEF (Robert W. Holley Center for Agriculture & Health, USDA ARS, Ithaca, USA), B (Berlin, Germany), BAFC (Buenos Aires, Argentina), BAK (Baku, Azerbaijan), BP (Budapest, Hungary), BPI (Beltsville, USA), BR (Meise, Belgium), BRA (Bratislava, Slovakia), BRI (Brisbane, Australia), BSIP (Honiara, Solomon Islands), C (Copenhagen, Denmark), CAS (California Academy of Sciences, USA), CBCD* (College of Biology and Chemistry, Dali University, China), CMMF (Montréal, Canada), CNF (Croatian Mycological Society, Zagreb, Croatia), CO (Concarneau, France), CUP (Cornell University, Ithaca, USA), CWU (Kharkiv, Ukraine), DAOM (Ottawa, Canada), DMS* (Danish Mycological Society), FFPRI* (Forestry and Forest Research Products Institute, Japan), FG* (Fruška Gora National Park, Vojvodina, Serbia), FH (Farlow Herbarium, Cambridge, USA), FLAS (Gainesville, Florida, USA), FR (Frankfurt, Germany), G (Genève, Switzerland), GENT (Gent, Belgium), GH (Harvard University, Cambridge, USA), GJO (Joanneum, Graz, Austria), GXU* = (University of Nanning, Guangxi, China), GZU (Karl-Franzens-University, Graz, Austria), H (Helsinki, Finland), HBG (Hamburg, Germany), HKU (Hong Kong, China), HMAS (Chinese Academy of Sciences, Beijing, China), HR (Hradec Králové, Czechia), HT* (Kunming, Yunnan, China), IMI (Egham, England), IMS (Chapel Hill, North Carolina, USA), JA-CUSSTA (Junta de Andalucía, La Trufa, Zagrilla, Priego de Córdoba, Spain), JE (Jena, Germany), JOE (Joensuu, Finland), K(M) (Kew, London, England), KMU* (Karamanoğlu Mehmetbey University, Karaman, Turkey), L (Leiden, Netherlands), LE (St. Petersburg, Russia), LPS (Buenos Aires, Argentina), LUX (Luxembourg [J. Feltgen]), LZ (Leipzig, Germany), M (Botanische Staatssammlung München, Germany), MA (Madrid, Spain), MAMU* (Mykologischer Arbeitskreis München Umland), MEL (Melbourne, Australia), MFC* (Matsushima Fungus Collection, Japan), MFLU (Mae Fah Luang University, Thailand), MPU (Montpellier, France), MSTR (Münster, Germany), NMLU (Luzern, Switzerland), NY (New York, USA), O (Oslo, Norway), PAD (Padova, Italy), PC (Paris, France), PDD (Auckland, New Zealand), PH (Philadelphia, USA), PRM (Praha, Czechia), PUL (Purdue University, Indiana, USA), REG (Regensburg, Germany), RO (Roma, Italy), S (Stockholm, Sweden), SBP* (Herbarium of Laboratory for Microorganisms, Dali, China), STU (Stuttgart, Germany), TAAM (Tartu, Estonia), TFC (La Laguna, Tenerife, Spain), TMUE* (Taipei, Taiwan), TNM (Taichung, Taiwan), TNS (Tsukuba, Japan), TRL* (Tsukuba Research Laboratories, Japan, transferred to TNS), TU (Tartu, Estonia), UBC (British Columbia, Vancouver), UME (Umeå, Sweden), UPS (Uppsala, Sweden), W (Naturhistorisches Museum Wien, Austria), WU (University Wien, Austria), YMFT* (Kunming, Yunnan, China).

Culture collections: APCC = Aquatic Phycomycete Culture Collection (Reading, England), AS = Academia Sinica (later changed to CGMCC), ATCC = American Type Culture Collection (Virginia, USA), BBA = Biologischen Bundesanstalt für Land- und Forstwirtschaft (Braunschweig, Germany), BCRC = Bioresource Collection and Research Center (Taiwan), CBS = Centraalbureau foor Schimmelcultures, now: Westerdijk Fungal Biodiversity Institute (Utrecht, Netherlands), CCRC = Culture Collection and Research Center (Hsinchu, Taiwan), CCT = Coleção de Culturas Tropical (Brazil), CGMCC = China General Microbiological Cultural Collection Center (Beijing, China), GA/TF = University of Georgia (Tifton, USA), IFM = Medical Mycology Research Center, Chiba University (Chiba, Japan), IFO = Institute for Fermentation (part of NBRC), IMI = CABI Bioscience UK Centre (U.K., England, Egham), MUCL = Université Catholique de Louvain (Belgium, Louvain-la-Neuve), NBRC = National Institute of Technology and Evaluation (Osaka, Japan), NHL = National Institute of Hygienic Sciences (Tokyo, Japan), NRRL = Northern Regional Research Center (Peoria, USA), SBUG = Biological department, University of Greifswald (Germany), SQU = Sultan Qaboos University (Oman), UCR = University of California, Culture Collection of Nematode-Destroying Fungi (Riverside, USA), USDA-ARS = United States Department of Agriculture, Agricultural Research Service (USA), VKM = All-Russian Collection of Microorganisms, Russian Academy of Sciences (Russia), WAC = Plant Research Division Culture Collection, Western Australian Department of Agriculture, (Australia), YMF = Key Laboratory of Industrial Microbiology and Fermentation Technology of Yunnan (Kunming, China), YNUCC = Yunnan University Culture Collection etc.

Exsiccatae: FFE = Karsten, Fungi Fenn. Exs. (Fungi Fenniae exsiccati), P.A. Karsten (1861–1870); FSE = Fungi Sel. Exs. (Fungi selecti exsiccati), O. Jaap (1903–1923); MFE = Triebel, Microf. exs. (Microfungi exsiccati), D. Triebel (1991–); NAF = Ellis, N. Amer. Fungi (North American Fungi), J.B. Ellis (1878–1885); Rehm Ascomyc. (Ascomyceten), H. Rehm (1870–1914).

Private herbaria or culture isolates (an 'ex' before the private herbarium means that the entire specimen was transferred to another herbarium): A.G. = Andreas Gminder (Jena, Germany), A.Ga. = Alain Gardiennet (Véronnes, France), A.K. = A. Kujawa (Poland), A.Ka. = Attila Koszka (Hungary), A.Ky. = Abdullah Kaya (Karamanoğlu Mehmetbey Univ., Turkey, in KMU), A.P. = Adam Polhorský (Bratislava Univ., Slovakia), A.R. = Annemarthe Rubner (Karlsruhe, Germany), B.C. = Bernard Clesse (Fagnolle, Belgium), B.C.P. = B.C. Paulus (New Zealand), B.Ca. = Brigitte Capoen (Penvénan, France), B.D. = Bernard Declercq (Stekene, Belgium), B.G. = Bernt Grauwinkel (Bremen, Germany), B.H. = Bernd Hanff (Coburg, Germany), B.L. = Bin Liu (Nanning Univ., China), B.P. = Branislav Perić (Podgorica, Montenegro), B.S.I. = Beatrice Senn-Irlet (Birmensdorf Res. Inst., Switzerland), B.W. = Björn Wergen (Hornberg, Germany), C.C. = C.J. Chen (Taiwan), C.L.D. = C.L. Duddington (†, London, UK), C.L.L. = Christian Lechat (Villiers-en-Bois, France), C.R. = Claude Roux (Mirabeau, France), C.Y. = Chris Yeates (Huddersfield, Great Britain), D.H.P. = D.H. Pfister (Harvard Univ., USA, in FH), D.M. = Donát Magyar (Budapest, Hungary), E.B. = Edward Batten (†, Wenhaston, Great Britain, in K), E.C. = Erio Camporesi (Emilia Romagna, Italy), E.R.D. = Enrique Rubio Domínguez (Avilés, Spain), E.S. = Elisabeth Stöckli (Rüschegg, Switzerland), E.S.P. = Eugene S. Popov (St. Petersburg Univ., Russia), F.B. = François Bartholomeeusen (Turnhout, Belgium), F.G.A. = Fernando García Alonso (Alicante, Spain), F.J.B. = Francisco Javier Balda (Pamplona, Spain), F.O. = Franz Oberwinkler (†, Tübingen Univ., Germany), G.B. = George L. The employed terminology of cell inclusions follows Baral (1992: 356f.), that of ascus structures Verkley (1992: 5), with the exception that the 'ecto-' and 'endotunica' are preferred over outer and inner layer, and 'dome' is used as an equivalent of 'apical thickening'. We have dispensed with an alphabetical order of the species in order to facilitate comparison of similar taxa, and also the genera, subgenera, sections, and series are sorted according to phylogenetic considerations. In addition to Appendix 3, a hidden hash (#) tag search enables location of the main page of a taxon by adding it ahead of the generic, infrageneric, or specific epithet, for instance, '*#Orbilia*', '*#Hemiorbilia*', or '*#vinosa*'.

Taxa concepts, naming of taxa

Species delimitation. In many of the taxa described as new in the present monograph, but also in some of those described by earlier authors, only a single specimen or a few collections were available for study. As a consequence, little is known about morphological variability and delimitation against closely related taxa. Much future work will be necessary to settle the taxonomic status and ecological range of all these poorly known taxa. Especially when dealing with extra-European collections, problems with the dichotomous key will certainly arise, which indicate that the concerned taxa are either missing in the monograph, or their variation not fully explored.

It is a common experience in morphological taxonomy of fungi that a species can only be defined and delimited on the basis of detailed microscopic data gained from a series of collections. Describing new taxa based on single collections is generally problematic, nevertheless, we decided to do so in a number of cases, because describing such collections in detail without attaching a name to them would perhaps be even more unfavourable for the user. Those collections which deviate from the established taxa only in some minor points are usually only mentioned under that taxon which appears to be most closely related, but they are not included in a description, nor are they proposed as a separate new species.

Problems in species delimitation occurred in almost every group of *Orbiliomycetes*. Considerations on how to define a species depended on our results about the consistency and reliability of both persistent and vital characters. Although the huge number of species recognized here suggests a narrow species concept at first glance, we have actually tended to prefer a wide concept whenever no clear limits were found. Quite a large number of cases could not sharply be resolved due to a remarkable variability in micromorphology among the living populations examined. Nevertheless, we decided to distinguish different taxa whenever the differences were strong enough, even if intermediate populations appear to prohibit such a split. Such problems were particularly encountered in section *Habrostictis*, and in *Hyalorbilia*. Groups of species often appeared to be connected by intermediate populations and suggest interbreeding between them. Especially in *Hyalorbilia* such intermediate populations appeared to occur between almost each of the morphologically similar taxa. Many of these variants observed by us might represent different ecotypes which have evolved under distinct geographical and environmental circumstances and, therefore, need not be separated at the species level. On the other hand, cultural and/or molecular results sometimes supported an even stronger split into different taxa, although distinguishing characteristics of the teleomorph or anamorph could hardly be found.

In some cases the observed variation occurred only between geographically separate collections. We then excluded one of the two groups from the description of the taxon. Such deviations might indicate a separate species, but we decided to describe a separate taxon only if either the deviation was strong enough, or the deviation was constant enough among the collections studied.

Until molecular data became available, we were unable to solve the question as to whether differences in spore numbers need distinction at the species level in every case. One out of many examples is series *Microspermae*, comprising four taxa around *Orbilia euonymi* which differ mainly in four different spore numbers (see p. 57). Their molecular data strongly support their distinction at the species level. But virtually all morphological characteristics of *Orbiliomycetes*, including spore numbers, are subjected to a more or less high extent of variation, and this variation may occur within an apothecium, a population, or between different collections that are considered to belong to a single species. Such variable characteristics comprise also ascus size, thickness of apical thickenings, shape and size of ascospores and SBs, shape and width of paraphysis apices, presence of SCBs, presence and length of glassy processes, rate of gelatinization of excipular cells, etc.

Examples of closely related and, as molecular data were not available for every species, in some cases only tentatively separated *Orbilia* species, which differ more or less in ascospore shape and size, are: *O. ocellata* – *O. lentiformis* – *O. foliicola*, *O. obtusispora* – *O. trapeziformis* – *O. subtrapeziformis* – *O. filiformis*, *O. ovoidea* – *O. subovoidea*, *O. macrotrapeziformis* – *O. pyrenaica* – *O. curvatitrapeziformis* – *O. edulis* – *O. flexisoma* – *O. idahoensis*, *O. myriourosperma* – *O. sedonensis*.

The genus *Hyalorbilia* provides a further impressive example. The following series of taxa are accepted as different species in the present study, but are more or less unsharply delimited from each other (see Pl. 58): *H. citrina* – *H. japonica* – *H. inflatula* – *H. juliae* – *H. berberidis* – *H. arcuata*. Further species are connected to this series: e. g., *H. fomentarii* is only tentatively separated from both *H. juliae* and *H. berberidis*, the series *H. andina* – *H. polypori* – *H. texensis* appears not sharply delimited from *H. inflatula* and *H. juliae*, and another series connected to *H. inflatula* is represented by *H. fagi* – *H. tortuosa* – *H. helicospora* – *H. sibirica*, with a problematic connection between *H. tortuosa* and *H. citrina*.

For various of these taxa we could study many collections and were thus able to explore their variability. When taking only those populations into consideration which possessed the typical morphologies, the specific differences are usually very clear and the existence of distinct species appeared unquestionable. But a few specimens were intermediate, and it has often remained uncertain to which taxon they belong.

Closely related taxa that deviated in just one or two features are sometimes found growing intermingled on the same piece of substrate. Their macroscopical similarity and mixed growth give the impression of a single species that possesses some genetic variability, but the features of each phenotype generally showed little variation. The existence of different though very similar species is supported by the fact that also very different, distantly related *Orbilia* species frequently grow intermingled, and the species composition of mixed populations varies from collection to collection. Therefore, we came to the conclusion that an intimate occurrence of apothecia does not provide any evidence for a close genetic relationship between populations, and a separation into different taxa was usually unavoidable.

Some of the species have earlier been thought to be well characterized, but later proved to represent an assemblage of different taxa that are difficult to distinguish. For example, the cicrumscription of the very frequent *Orbilia vinosa* s.l. turned out to be heterogeneous within Europe. Collections from orotemperate to orosubmediterranean regions now separated as *O. subvinosa* differs from typical *O. vinosa* with trinacrium-like conidia in higher-branched, dwayaangam-like ones, and this distinction is genetically supported, although in the teleomorph they differ only gradually in some minor details. In contrast to this, a similar and likewise very frequent European species with a very similar trinacrium-like anamorph, *O. aprilis*, which was synonymised with *O. vinosa* by Svrček (1954), was found to represent an easily recognizable widespread taxon with much shorter ascospores and SBs. The sharp separation between *O. vinosa* and *O. aprilis* was observed in a total of 366 (*O. vinosa*) and 228 (*O. aprilis*) collections reported here. A high molecular distance between *O. aprilis* and *O. vinosa* s.l. confirms the independence of *O. aprilis*.

More or less distinctive anamorphs were obtained in pure culture of certain species, particularly of sections *Helicoon* and *Arthrobotrys*, in cases when the teleomorphs hardly differed. Reverse cases of morphologically distinctive teleomorphs and hardly distinguishable anamorphs frequently occur mainly in sections *Habrostictis*, *Aurantiorubrae*, and *Hemiorbilia* of the genus of *Orbilia*, but also in *Hyalorbilia*. In these groups a culture with the anamorph can hardly be identified at the species level by morphology alone if the teleomorph is not present. Molecular studies usually indicate that in both cases the observed morphological characteristics are correlated with differences in their rDNA.

The *Orbiliomycetes* seem to represent a group in which species extinction during evolution comparatively rarely occurred. Most sections and series of *Orbilia* are rich in species and not easy to separate from each other. In fact, the different character states seem to occur in nearly all imaginable combinations. We have repeatedly discovered missing links that form, for instance, a connection between a 64-spored and an 8-spored taxon, or between a species with long spore tails and another with very short tails. The spectrum of character states and their combination perpetually increased with every newly detected species. However, an earlier hypothesis turned out to be erroneous, which considered slight differences between closely related taxa to be due to comparatively few changes in the genome. On the contrary, rather high differences in parts of the rDNA were often observed between closely related taxa.

Similar problems are known in some helotialean genera, such as *Mollisia* (Fr.) P. Karst. (Greenleaf & Korf 1980, 'an excercise in frustration') or *Tympanis* Tode (Ouellette & Pirozynski 1974 citing Seaver 1953: 'there are about as many interpretations of the genus as there are workers on the group'). Another example is *Unguiculariopsis* Rehm, an apparently large genus of xerobiotic taxa which are much more common than currently believed. In a majority of collections of *Unguiculariopsis* which we have studied, a convincing morphological species concept was very difficult to acquire, and many of our specimens could not be identified with Zhuang's (1988) monograph.

ITS Barcode. Molecular data offer a valuable additional tool to clarify species concepts, but they need to be handled with care. Apart from the frequent problem of contaminant DNA (Gams et al. 2012b), some species are highly constant while others strongly vary in the ITS rDNA, the currently used fungal barcode. For this gene region, no 'stringent upper limit for intraspecific variability, such as the canonical 3% threshold, appears to be applicable with the desired outcome throughout the fungi' (Nilsson et al. 2008). Jeewon et al. (2016) recommended 'for practical purposes' a threshold of 1.5% as tentatively indicative for a new species, but Nilsson et al. (l.c.) showed in their tab. 1 that 20% of the tested 4185 fungal species varied more than 3% in this gene region. Some species of some groups of fungi, e.g. *Dothideomycetes*, *Eurotiomycetes*, or *Sordariomycetes*, are not clearly resolved at the species level using ITS rDNA, in which case protein-coding genes could be used as an alternative barcode (Hongsanan et al. 2018).

Within *Orbiliomycetes* a comparatively high interspecific distance is observed in the ITS rDNA, which generally ranges at ca. 4–16% among members of a subgroup of a series, although their infraspecific variation is often very low (Tab. S2). An unexpectedly high ITS distance of 16–16.5% was noted in three species pairs, in which virtually no or only slight morphological differences could be seen, apart from a different apothecial colour in case a teleomorph is known: (1) between *O. xanthostigma* s.str. and *O. leucostigma* s.str., which were considered to be conspecific by most authors; (2) between *O. tremulae* and *Dicranidion inaequale*, which share a morphologically identical anamorph; and (3) between *O. cejpii* s.str. on *Salix* and *Sorbus* and *O.* cf. *cejpii* on *Fagus*, which show only slight deviations in apothecial colour and ascospore characteristics.

Despite such high distances between closely related taxa, an ITS variation above 1.5–3% could already be taken as a hint that different species are involved, particularly in cases of highly constant subclades. However, we never found distances in this range to be coupled with clear morphological differences, so we preferred to apply a broad species concept in such a case. But even ITS distances below 1.5% may be disputable. For instance, variation of 2–6 nt (0.4–1.1%) and 3 gaps is observed within *O. aurantiorubra* between samples on *Fabaceae* and non-fabaceous hosts (*Salix*, *Ulmus*, and *Rhamnus*) (Tab. 69, Tab. S2, Phyl. 14). A tendency to shorter spores in the *Fabaceae* group appears to support distinction, but sharp separation of the many collections of *O. aurantiorubra* based on spore length proved impossible, and the affiliation of rare hosts (*Acer*, *Euphorbia*, *Frangula*, *Fraxinus*, *Prunus*) remained unclear because of absent DNA data. The single sequence of a *Frangula* sample (H.B. 7278, with long spores) refers it to the *Salix-Ulmus* clade, but another *Frangula* sample (J.P.P. 29241) was short-spored.

The infraspecific variation of numerous species ranged at only 0–0.2(–0.6)%, e.g., *O. xanthostigma* s.str., *O. leucostigma* s.str., *O. aurantiorubra* s.str., and *O. tremulae*. A low ITS variation of 0–0.8% was even observed between samples from different continents (Europe and eastern Asia), as exemplified by *O. tremulae*, *O. xinjiangensis*, and *O. zhongdianensis*, whereas particularly *O. xanthostigma* and *O. leucostigma* (s.l.) developed various strongly deviating genotypes in continents other than Europe. *O. oligospora* showed a worldwide variance of 1.3–3% by forming various more or less homogeneous cryptic lineages, some of which included samples from more than one continent.

In contrast to the typically low infraspecific variation in *Orbiliomycetes*, remarkably high variation was observed among European samples of *O. xanthoguttulata* (0.6–3.5%) and *O. eucalypti* (4–11.5%) (Tab. S2), and the observed subclades did not show a clear geographical correlation or host specificity. Similar examples of cryptic speciation are observed in various nematode-trapping taxa, such as *O. auricolor*, *Arthrobotrys musiformis*, and *Gamsylella cionopaga*.

Infraspecific ranks. The question of recognizing infraspecific levels was variously discussed. For instance, R.P. Korf (pers. comm.) tended 'not to use *varietas* at all, believing that *forma* is the appropriate rank for simple variants that seem to differ in only a few genes, and *subspecies* as appropriate for geographically or ecologically isolated populations that seem not to be interbreeding'. A different opinion was advocated by Huhtinen (1990a) who suggested to apply the varietal rank to ambiguous, unsettled cases, such as collections which mainly differed in the presence vs. absence of croziers. In this concept, varieties are no more than a provisorium in the lack of a better solution and also lack of enough collections. In the meantime, molecular research on, e.g., *Hyaloscyphaceae* showed that taxa differing mainly in the ascus base are sharply separable by rDNA data, and also differences in apothecial colour may correlate with striking deviations in the genome (example: *Orbilia leucostigma* and *O. xanthostigma*).

In the present study we have avoided the application of infraspecific ranks, for the following reason: although the usage of infraspecific taxa emphasizes minor morphological differences and the difficulty to separate between them, the infraspecific rank needs some definition which can hardly be provided. The application of infraspecific ranks forces taxonomists to group two or more taxa as, e.g., subspecies of a species, and this method does not warrant that closely related species are then sharply delimited by their morphology. As an extreme consequence, a large series of taxa would be reduced to a single species. Since we did not perform interbreeding experiments and our molecular research still lacks data on various critical taxa, many of the species accepted in this monograph are to be considered as tentative.

Generic concepts and higher taxa. – **1**. **Taxonomic rank**. Baral et al. (2017b) saw three possibilities to classify the taxa within *Orbiliomycetes*: (1) the generic name *Orbilia* is used in a wide sense to contain a majority of species of the single family *Orbiliaceae*; (2) the generic name *Orbilia* is used in a moderate sense to comprise two subgenera, *Orbilia* and *Ovoideae*, while, e.g., *Arthrobotrys* would include *Neodactylella* and four predacious subgenera; (3) the generic name *Orbilia* is used in a narrow sense with *Ovoideae* as a separate genus, and the genus *Arthrobotrys* would include only taxa with adhesive nets.

In the past a narrow concept has been applied to the anamorph of the class but a broad concept to the teleomorph. As a result, many more generic names exist that are based on anamorphs (Baral et al. 2017b). In the broad concept, most of these genera fall into synonymy with *Orbilia*.

As an advantage of the broad concept, which was chosen in the present monograph, species with critical relationship can be accomodated without doubt in the genus *Orbilia*; a disadvantage would be that the currently used generic names of nematophagous taxa (*Arthrobotrys*, *Dactylellina*, *Drechslerella*, *Gamsylella*) fall into synonymy of *Orbilia*, where they are recognized at the series level. As an advantage of the narrow concept, which would be in concordance with the current trend in fungal classification, the close relationship of a species is recognizable from the generic name; a disadvantage would be that some of the accepted genera are only recognizable by cultural or molecular methods.

Based on a proposal to evaluate the rank of a taxonomic group by the concept of temporal banding according to the geological age estimated from fossils, a suggestion to revise the classification of *Lecanoromycetes* was made by Kraichak et al. (2018). This concept implies that each rank is represented by a period range (temporal band). The authors proposed to assign the ordinal rank to groups diverging in the range of 176–194 myr before present, and families in the range of 111–135 myr. When applied to *Orbiliomycetes*, this concept would raise sections of the present monograph to ordinal level and genera to classes. However, the temporal banding approach neglects the fact that, depending on the group, evolution took place with a very different speed. When considering changes in morphology as the benchmark for taxonomic units, this method may at best be useful within a given group by chosing a scale that is appropriate to it. Therefore, Lücking (2019) proposed that ranking of taxa should follow integrative principles that best reflect their individual evolutionary history.

2. **Paraphyly**. Frequently our phylogenetic analyses resulted in monophyletic groups which reflect very well our morphological criteria. In many other cases, however, they resulted in paraphyletic groups, and in cases of strong morphological evidence we preferred to put more weight on morphology than on molecular data. For instance, *Orbilia vinosa* and *O. aprilis* rarely fell together in a clade in our analyses, which is supported by a strong genetic distance (21–22.5% in ITS, 7.5% in LSU). Nevertheless, their ana- and teleomorphic features are so similar that we have placed them in the same series *Hesperideae*, which formed no less than four different clades with unresolved relationship. Another representative paraphyletic group is the non-predacious series *Neodactylella*, from which the four monophyletic predacious series of section *Arthrobotrys* appear to have evolved. Another example concerns series *Lentiformes* and *Phanosomates* which constitute the two main subgroups of section *Lentiformes*. These two series are sharply distinguished by spore body morphology, but each of them formed a paraphyletic group based on available rDNA sequences. We maintained their distinction because we believe that the different SB types emerged from a common ancestor within each series, contrary to what the tree topology suggests.

Paraphyletic groups are a natural consequence of evolution and require acceptance in the classification of organisms (Zander 2008). Davydov et al. (2010) exemplified this when accepting the monophyletic genus *Lasallia* Mérat and the paraphyletic *Umbilicaria* Hoffm. When trying to apply a strict monophyletic concept, the morphologically well-defined genus *Umbilicaria* would need to be split into numerous genera, for which no morphological support was seen. We agree with Zander (2007) and Schumm & Aptroot (2019), who wrote that the evolutionary process that leads to new species (speciation) must involve paraphyly, by which an ancestral species may remain virtually unchanged and paraphyletic after a budding speciation event; by extension, paraphyly must also be expected among genera and families. The high importance of morphology in classification is expressed in the following quotation from Zander (l.c.): ‘Even if many organismal structures have unknown function, the morphology as clue to phenome/environment interaction should characterize the taxon’.

Etymology. Facing the huge number of species now recognized within *Orbilia*, we nevertheless tried to prefer names that refer to the typical features of the fungus. A convenient solution for giving characteristic names was found in the use of a prefix that indicates the number of spores. This method is exemplified on p. 57–58 (Fig. 41 and Tab. 6) by three new taxa that deviate in spore number from the closely related old taxon *O. euonymi*.

New names introduced in this monograph are also influenced by the history of the species when it was first discovered, which often resulted in more or less inappropriate names. We mostly decided to continue usage of such names that we previously gave them because they appear on many of our notes, and name changes would have caused confusion. For example, the spores of *O. delphinus* in the first collection studied resembled more or less a dolphin, unlike in some later collections, whereas spores of later detected new species resembled more obviously a dolphin. So we refrained from transferring the epithet to a taxon with more obviously dolphin-like spores.

Such historically born, more or less inappropriate names are also a consequence of nomenclatural rules and taxonomic progress, resulting in illogical names that were erected when the species diversity and variation was little explored. We must, therefore, content ourselves with the inevitable consequence that species are named *coccinella* and *rubella*, although dozens of other species have the same colour, or *euonymi* and *eucalypti*, although later collections revealed that these species occur on a very wide range of host plants. In cases when the morphological features of our new taxa did not provide enough peculiarities, we nevertheless continued to create names based on hosts and colour, or used collector's and geographical names.

We early refrained from erecting new names for anamorphs which we obtained in pure culture of described teleomorph-typified species. Herein we followed the recommendation of Art. 59A.3 (McNeill et al. 2006) which recommends that 'authors should avoid the publication and use of binary names for anamorphs when the teleomorphic connection is firmly established and there is no practical need for separate names'. The increasing possibility to clarify the whole life cycle of fungi with molecular methods and the increasing data from molecular environmental extracts supported the practice of using only one scientific name for one species (Rossman 2009).

Regarding priority, the switch to one name for one fungus posed various problems. A proposal by Gams et al. (2012a) to use, e. g., *Orbilia orientalis* as holomorph name when the genus *Orbilia* is adopted in a wide sense, instead of combining the older *Drechslerella brochopaga* in *Orbilia*, was not approved by the new Code (Turland et al. 2018), which gave anamorph names equal priority. Not approved was also a proposal by Hawksworth (2014: prop. 15 Art. 59) to regard the erection of a new species for the teleomorph of an existing anamorph name as a new combination, which was forbidden under the old Code. Art. 59 was replaced in the new Code by Art. F.8 on fungi with a pleomorphic life cycle, which implies (Note 2) that all legitimate names for the different morphs of a fungus have equal priority. Here, Note 3 treats names that were proposed simultaneously for teleo- and anamorph of a single species. They are necessarily heterotypic, which means that they are always typified on different elements, even if they are preserved on the same piece of substrate under a single voucher number. For such not infrequent cases of equal priority, Rossman (2014: 86) suggested to simply adopt that name which stands in the desired genus, but Art. F.8 does not treat this situation in detail.

The main problem in *Orbiliomycetes* is that many species with clearly different teleomorphs possess anamorphs that hardly differ at all. For this reason, we have frequently been unable to unequivocally clarify the identity of existing names of anamorphs, particularly if type strains and molecular data on them are lacking.

Documentation, descriptions, accuracy of observation

How long should descriptions be? Many taxa of *Orbiliomycetes* published over the past centuries have been so inadequately described that their identity can hardly be determine without studying the type specimens, a circumstance being experienced in many groups of fungi (Dayarathne et al. 2016). In our opinion, species descriptions should be comprehensive and detailed. Even though long descriptions may hide the important details, they help in making potentially distinctive characters available for future work, when new taxa will be discovered, new characters detected, and new taxa concepts developed. A large scope of reported characters will help to settle taxonomic problems with difficult groups. Furthermore, comprehensive descriptions aid in the construction of synoptic keys. Reading long descriptions consumes much less time than reexamination of inadequately described type material.

For each species the scope of variability known at present should be presented in a monograph. This only works well when more or less all characters of a fungus that are visible under the light microscope are described, and when data from several collections are illustrated. On the other hand, it is recommended to exclude any unreliable information from descriptions. This mainly concerns redundant characters which are present more or less across a taxonomic unit. Huhtinen's (1990a) monograph on *Hyaloscypha* and allied genera provides an exemplary standard for a sound ascomycete taxonomy in which detailed drawings from different collections were supplied for most of the treated taxa.

Users of a monograph should not simply try to identify their collections with one of the accepted taxa. We recommend to get acquainted with a species by trying to collect it repeatedly and to study it several times before expecting a trustable determination. Furthermore, we recommend to make notes, macro- and microphotographs, or small sketches of a majority of the studied collection in order to explore the individual variation. Brief documentations of the reliable data of the collections under investigation are the minimum demand. By simply applying a name to a fungus, workers often overlook the bad taxonomic exploration of a given taxon.

About illustrations. The crucial focus of this study was to provide detailed drawings of the micromorphology, especially of the teleomorph, and that from several collections of each taxon, following the conviction that 'a good figure is better than a full page of letter-press' (Lange 1935). The frequent absence of meaningful and exact illustrations is the most time-consuming obstacle of any efficient taxonomic work. 'Even the most painstaking and carefully worded description will often fail to give that clear and exact idea of the varying colours and forms of a mushroom which a good portrait will give at a glance' (Lange l.c.). Particularly those older authors who were using a microscope (e. g., Karsten, Fuckel, Rehm, Höhnel, Kirschstein), were used to describe new species without providing visual data. Although Svrček supplied drawings to nearly every taxon he described as new to science, the value of his revision of the 81 taxa being described by Velenovský in *Orbilia* (Svrček 1954) is greatly diminished by the absence of any illustration. The practice of publishing characteristics of fungal records without visual information, a feature typical of the 19th century but sometimes even practised within the past decades, makes constructive taxonomic work extremely difficult.

Drawings require appropriate magnification rates in order to permit proper illustration of the discernible microstructures. It is further recommended to use a constant scale for the same element within a taxonomic group, because this highly facilitates comparison among the drawings. However, it is not advisable to draw all kinds of elements at the same scale. As a general rule we suggest to draw medium-sized ascospores at a scale of 3000 ×. Due to the sometimes very small spores and minute details of the spore bodies in *Orbilia*, a drawing scale of 4000 × for ascospores seemed to be more appropriate within *Orbiliomycetes* and was, therefore, consistently used in the present study. The same applies to the ascus apical structure. For the often large conidia a scale of 2000 × was used instead. Drawings should be reduced to around 30–70 % when printed, which will not result in any loss of information.

Microphotographs are generally closer to reality than drawings but not always as easy to interpret. They sometimes provide limited possibility to arrange the elements, e.g., asci and paraphyses in the context of the hymenium. Asci are usually separated by squashing, therefore, photographs often show them in the dead state. Photographs are inferior to drawings regarding the limited depth of focus, e.g., when elongated spores are obliquely oriented within the asci or when spores lie in several layers inside polysporous asci. This disadvantage can be overcome by taking a series of subsequent digital photographs of a single ascus with different focus. However, such image series can profitably be viewed only on a computer. Photographs are suitable to figure complex excipular textures in median section, also free ascospores and conidia, or isolated hymenial elements, but may also yield good results for asci and paraphyses in situ, either in the living state (in water) or in the dead state, particularly when staining the entire ascoplasm by iodine.

Drawings are never free from a certain degree of imagination and arbitrariness. The role that fantasy may play in descriptions and drawings is exemplified by the fact that, e.g., polyspory, inverse spore orientation, and spore bodies have frequently been ignored in *Orbilia*. These characteristics have often been overlooked when studying dead herbarium material, but workers have also ignored them in studies of fresh collections because they appeared to be abnormities. Unexpected deviations from the general situation with ascomycetes may easily be neglected intuitively.

One example of the inaccuracy of drawings concerns paraphysis septation. Desiccation-sensitive species of *Orbilia* are characterized by paraphyses having the terminal cells much longer than the lower cells. Nevertheless, Velenovský's (1934) drawings hardly account for this fact but, instead, the author put the septa arbitrarily. This became obvious during revision of his type material, but also when comparing his drawings published in 1934 with those of his manuscript. For instance, on his manuscript plate of *O. acuum* the three figured paraphyses show either none or just one basal septum, whereas on pl. 11 fig. 22 Velenovský (1934) put four septa to each of the three.

In our opinion, the characters of every collection we are about to study needs to be annotated in a descriptive way, preferably in combination with either pencil drawings or photographs. Whenever collections show slight micromorphological deviations, microscopic images should be taken, following the suggestions of Huhtinen (1990a: 46) to illustrate such variation of a species from different populations. According to Huhtinen, 'authors of monographs tend to illustrate one, preferably 'ideal' specimen of a species, giving a simplified picture of the situation in nature and excluding undesirable, but inevitable, variation'. We have frequently illustratesd collections from different hosts or geographical areas, even if they did not distinctly deviate. This was also Huhtinen's idea who wrote about his depicted populations: 'In this paper equal attention is paid to stability and variation'.

Apart from rarely encountered taxa, we have documented the micromorphology of a species from a minimum of 2–4 populations. Huhtinen's monograph supplies illustrations from (1–)2–4(–6) collections for each taxon (exceptionally 7–9). Despite the richness of illustrations in Huhtinen's publication, the author published only a selection of the whole set of his annotations and drawings. 'The great majority of the over 1700 collections were depicted in detail' (Huhtinen 1990a: 85). In the present monograph we decided to present nearly all of the drawings, considering the fact that words cannot substitute illustrations. The complete set of drawings, photographs, and annotations are accessible online (IVV).

Resolution limit, **accuracy of measurements**. In the descriptions we have evaluated measurements smaller than 10 µm with an accuracy of ~0.2 µm, since we believe that it is possible to estimate such values and that it is obligatory to measure with an error < 3% for an element above ca. 3 µm diam. Measuring at an exactness of 0.5 µm is inacceptable for elements smaller than about 4–6 µm. This is obvious when doing drawings to a scale above 1000×. At 2000× a measurement error of 0.5 µm causes a deviation of 1 mm on the drawing sheet and severely alters the shape of small spores. In our experience, a microscope magnification of 1500× allows more precise direct measurements of small spores compared to 1000×. Most measurements were gained in the present study under 1500× using a measuring scale with a 1:1 calibration, therefore, the published values behind the point have no mathematical origin.

Filaments or membranes of the living cytoplasm such as the tonoplast or the filum of spore bodies have a thickness of much less than 0.1 µm. They can be seen with the LM under bright field, although the resolution limit of the visible light (~0.2 µm) should forbid observation of such minute structures. However, the limit of resolution indicates at which minimal distance two lines or points remain discernible. For the recognition of small objects the crucial parameter is the recognition limit (for a detailed account on this topic see Françon 1967). According to Clémençon (1974: 249), dots of 0.032 µm diam. or lines of 0.002 µm width are still recognizable under the LM. Also Miettinen et al. (2006: 213) subjectively estimated distances of 0.1 µm with a 1-µm-grid eyepiece, using phase contrast and a viscid mountant (CB in lactic acid) in which the spores stay still.

In the mycological literature, calibration and measurement errors are frequent and show in the worst case a deviation of 10–30 percent or more from the true values. Examples of such errors are found in the works of, e.g., Boudier (differences between text and scale) and especially Velenovský (see p. 190–191).

Vital taxonomy, differences between living and dead cells

The present monograph, including the dichotomous key, is based on a taxonomy that combines persistent and transient (vital) light-microscopic characters. This means that predominantly and preferably recently collected specimens were examined in the living state. During our up to 40 years lasting microscopic work on various groups of non-lichenized ascomycetes, we became more and more aware of the extraordinary taxonomic value of vital characters in many groups of both disco- and pyrenomycetes. Differences in morphology between living and dead cells can virtually be found in every fungal species. Taxonomically important vital characteristics also occur in most groups and concern both anamorphs and teleomorphs. The study of living collections of ascomycetous fungi enormously increased our knowledge in various ways, including desiccation tolerance and spore discharge mechanisms.

One of the aims of this monograph was, therefore, to assess the taxonomic impact of vital characters in the *Orbiliomycetes*, particularly that of the spore body (SB). Baral (1992) gave a detailed account on vital taxonomy, which represents an over a hundred years old knowledge favoured by authors like E.

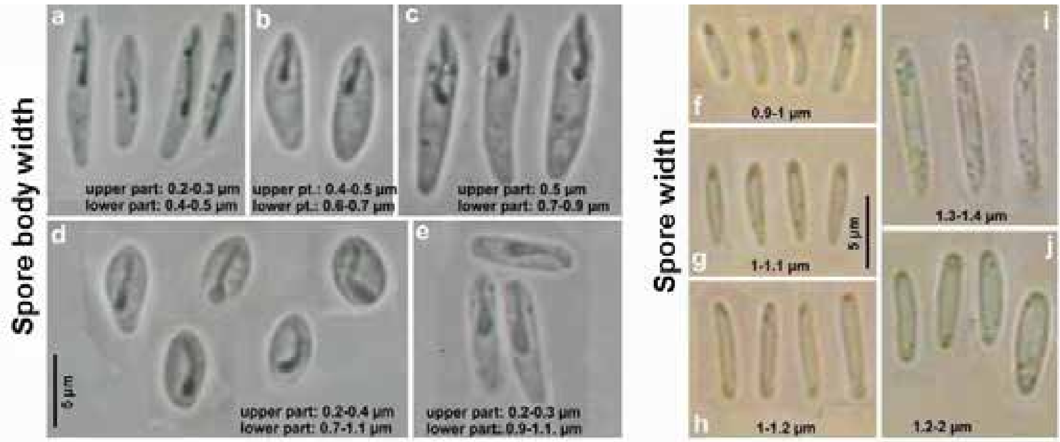

Figure 2: Accuracy of measurements. — **a**. *Orbilia flavidorosella* R.T.L. 10122202; **b**. *O. cylindrosoma* R.T.L. 13083101; **c**. *O. carpoboloides* R.T.L. 13032901; **d**. *O. gambelii* R.T.L. 13083001; **e**. *O. vitalbae* H.B. 9681; **f**. *O. epipora* H.B. 8186; **g**. *O. alba* H.B. 9051a; **h**. *Hyalorbilia inflatula* H.B. 8885a; **i**. *H. juliae* H.B. 8894a; **j**. *H. polypori* H.B. 9211.

Boudier and J. Lagarde (Baral l.c.: 336). In *Orbiliomycetes*, vital taxonomy permits to achieve significantly higher confidence levels in species identification and delimitation based on the teleomorph, to a rate inaccessible by traditional herbarium taxonomy. A monograph of *Orbiliomycetes* based solely on herbarium material would inevitably have resulted in less than half of the species accepted as distinct in the present study.

Vital taxonomy means to base descriptions and illustrations on the living state concerning all kinds of cells of the holomorph. Characters provided by living cells mainly concern plasmatic structures, which are usually completely invisible in the dead state, irrespective of which method is applied. In our simultaneous studies on other groups of ascomycetes, two types of plasmatic organelles were found to be of high taxonomic relevance in both the *Helotiales* and *Pezizales*: lipid bodies (LBs) in ascospores, and refractive vacuolar bodies (VBs) in paraphyses, sometimes also in hairs and cortical excipular cells.

In the taxonomy of *Orbiliomycetes*, LBs in spores and conidia play a subordinate role, and the presence of VBs in the paraphyses of *Orbilia* is more or less restricted to hygrobiotic taxa, except for the xerobiotic genus *Amphosoma* which is characterized by multiguttulate VBs. Yet, two further types of vital characters turned out to have high taxonomic importance, mainly at the species level: the spore bodies (SBs) in the ascospores, and a peculiar type of cytoplasmic bodies (SCBs) in paraphyses and excipular cells. SBs show a high morphological diversity in shape, especially between higher taxonomic units, but little variation within a species. SCBs are mainly important in their crystalloid subtype and are present only in a part of the species, thus serving as a key character in many groups, mainly at the species level. Therefore, SBs and SCBs allow in combination with persistent characters quite a clear and rapid identification of many taxa of *Orbiliomycetes*.

A frequent belief is that vital taxonomy is impracticable because of the unavailability of fresh material. Yet, vital taxonomy does not necessarily mean to study fresh collections (see p. 30–31). On the contrary, living cells can often be found in herbarium material that was dried some months or even years ago. On the other hand, fresh specimens may contain a varying, sometimes rather high amount of dead cells, even if studied at the day when collected. Hence, doing vital taxonomy requires the capability to distinguish between living and dead cells. The use of oil immersion is obligatory in vital taxonomy, and self-evident regarding the often very small structures in this group of fungi.

A widespread usage is to mount a specimen's fragment, irrespective of being fresh or dry, in a lethal mountant such as MLZ, CB$_L$, or KOH. To put fresh apothecia in such a medium is actually equivalent to the study of hundreds of years old herbarium specimens, and it is actually the intention of this usage to achieve a compatibility between fresh and herbarium material. Vital characters are completely overlooked by this method, as they can only be observed when using water with a very low concentration of salts or other ingredients (we recommend tap or rain water as standard mountant).

All who use this monograph must be aware of the demand **to study collections in water mounts and within a period of time during which the cells (asci**, **paraphyses**, **ascospores**, **excipular cells**, **conidia) remain viable**. Otherwise, neither SBs in the mature ascospores nor SCBs in the cells of paraphyses and ectal excipulum can be seen, and the keys will not work. Even the evaluation of spore numbers within asci is hampered when studying dead specimens, especially in taxa with narrow spores, and also ascospore size and shape in the dead state will be difficult to assess, since free spores are often rare and those within the asci usually very difficult to see.

Dead herbarium specimens can often only tentatively be identified. A frequently given advice to provide two dichotomous keys, one based on vital characters, the other on persistent characters, was abandoned in view of the many problems we already had in elaborating an operative key to the numerous taxa and infrageneric groups based on the full scope of morphological characteristics. For the identification of dead specimens we suggest to use our Tab. S3 (Morphological characteristics) by restricting the search to persistent characteristics, which should permit to exclude a vast majority of the taxa.

Huhtinen's (1990b) demand that 'at least one of the depicted populations should represent living specimens mounted in water' is a first approach to a better taxonomy, but does not permit exploration of the variability of vital characters. Huhtinen actually studied only a small percentage of fresh collections as he (1990a: 85) admitted that 'fresh material was available for 50 % of the taxa' only, and 'most of the observations were made on material in CB [CB$_L$] and MLZ'.

Vital characters are bound to the living state and cannot be preserved other than by documentation. Therefore, it was argued in personal communications that such transient characters, particularly of the teleomorph, are less useful for taxonomic work. However, this view neglects the taxonomic importance attached to the shape of chloroplasts and other cytoplasmic structures in living algal cells. Vital characters of fungal anamorphs obtained in pure culture can usually be studied over a very long period of time, if the cultures are still sporulating. Nevertheless, morphological analyses from pure cultures have often been made from dead cells, either due to careless preparation methods or intentional application of lethal mountants. TEM studies on spore bodies and SCBs yield remarkable results, thus offering a possibility to study these organelles from material placed in the living state in fixation solutions. However, the effort is enormous, and artifacts can frequently not be avoided.

Contrary to vital taxonomy, cultural studies became a well-established part in mycological systematics, despite the fact that they require fresh collections. Nevertheless, anamorphs are often unavailable in specimens deposited in herbaria or cannot with certainty be connected to a teleomorph. So, how to determine a taxon for which the anamorph is asked for in a key, if the specimen in question is dead herbarium material? One of the reasons why pure cultures became well-established in mycology was that this routine work served as the only proof for anamorph-teleomorph connections prior to the era of molecular research.

Taxonomic concepts arising from the study of herbarium specimens are based on a reduced set of morphological characters, comparable to the study of fossil organisms. While palaeontologists dream of the possibility of reanimation of extinct species in order to complete the limited knowledge about these organisms, fungal taxonomists are either unaware of the severe changes during cell death, or ignore these effects by arguments such as unavailability of living specimens during their free time.

A possibility would be to speak of a ‘species complex’ for those groups of taxa which are distinguishable by vital characters but hardly so by persistent characters alone. There is, however, no good reason (at best a practical one) to give more taxonomic weight to characters which are stable under the conventional method of air-drying, and molecular data has variously confirmed the value of vital characters in the past decade.

For instance, spore numbers in asci are stable in dead material but sometimes represent the only difference between closely related taxa, whereas spore bodies (SBs) often characterize higher taxonomic units. Shape and insertion of the SBs turned out to belong to the most important characteristics regarding recognition of infrageneric groups. The application of terms like ‘species complex’ for taxa which are difficult to delimit without vital characters would lead to artificial groupings. Quite distant taxa may be confused in the dead state due to a similar spore shape though containing very differently shaped SBs, whereas more closely related taxa with a concordant shape of SBs may differ in persistent characters such as spore size and shape. In the most extreme case, confusion at the level of the class occurred when neglecting vital characters, e. g., in the genus *Pithyella*, which comprised members of both *Orbiliomycetes* and *Leotiomycetes* (see p. 208–209).

As a consequence of this, we doubt the importance that is currently attached to the preparation and maintenance of fungal herbaria. In our experience, morphological work exclusively based upon herbarium material is more an obstacle against a sound and well-founded fungal taxonomy. Fact is that most of the preserved herbarium specimens remain unexamined over a very long period of time, and also usually lack any documentation by the collector, including the fresh apothecial colour. Progress in knowledge about variation and delimitation of taxa is much accelerated when specimens are continuously documented, preferably in the living state, and presented in articles, monographs, or other media such as websites or internet forums. Only when we shift our focus on the documentation of collections instead of merely their preservation, natural taxa concepts can be worked out in a reasonable period of time.

Doing vital taxonomy results in a much higher complexity of character combinations, thus requires a more time-consuming work on each collection. Illustrations need more patience, and descriptions become longer, but the taxonomic conclusions based on these data have a much higher relevance. On the other hand, microscopic work on old specimens is often more difficult and consumes more time than documenting fresh material, an experience also expressed by Svrček (1976: 116). As an example, a very time-consuming task with dead specimens is to discern thin-walled hyaline spores inside the asci, although in living material such spores are seen at a glance.

A frequently heard argument that favours monographs on herbarium specimens concerns the impossibility of microscopic study during an expedition to remote areas of the world. Especially tropical mycology is said to prohibit any such research due to the very high temperatures and atmospheric humidity. Undoubtedly, such climatic conditions involve serious technical problems. Our impression is, however, that it is rather a matter of willingness for making vital studies, to avoid giving up a method practised over decades. In our experience, workers focused on herbarium material are indeed generally unaware of the characters that they lose when treating their fungi with lethal mountants.

Tropical regions undoubtedly require high expense for a thorough study of vital characters of hygrobiotic, desiccation-sensitive taxa, similar as arctic regions do. Boreal, temperate, and subtropical climates hardly cause any problems if taxonomists have the possibility to use working rooms for immediate microscopic study. Mailing specimens from other countries and continents is problematic with such taxa which must be preserved in a way that they retain their hydrated state and are not exposed to mechanical pressure. Mailing between countries of western and northern Europe is hardly problematic since mails are usually only 2–3 days on route. Sending fresh specimens in rather cheap express air mails from other continents turned out to be difficult, but was successful in some cases (e. g., from USA or China to Germany).

In contrast to hygrobiotic fungi, vital studies on xerobiotic, desiccation-tolerant taxa, to which by far the majority of species in this monograph belong, is most convenient because such specimens are collected in the dry state and remain viable over quite a long time. The problems that these taxa frequently impose are those of their minuteness, scarceness, and intermingled growth, which requires collecting of enough amounts of substrate and to search for them under the dissecting microscope. Frequently, the different taxa discovered on a single branch cannot adequately be split into separate herbarium specimens.

As a herbarium taxonomists, one tends to be unaware of how frequent many species are, and how many species exist which have not yet been catalogued and preserved in herbaria. During our monographic study we have never been in want of living material. This was mainly due to the frequent expeditions to semihumid or semiarid areas of southern Europe, Northern America, and Australia by one of us (G.M.), and the enormous desiccation tolerance of most of these species, allowing to study them within a period of 0.5–2 or even 3–4 years. Many further collectors have contributed in sending living collections from Europe, Macaronesia, or China. Mailing hygrobiotic species in the dry state a few weeks after collecting proved to be an acceptable compromise, allowing to study the ascospores of many Chinese collections in the living state.

The ease to collect ascomycetes in the field and the longevity of many desiccation-tolerant taxa fixed the focus of our work on vital research, and relegated herbarium studies with their often only weak or ambiguous results was of subordinate importance, restricted predominantly to type specimens of previously described taxa.

As one of the consequences of vital taxonomy, we advocate the simultaneous research on a broad scope of taxa, including those outside the monographed group, despite the disadvantage that publication is delayed. Especially in the Northern America and Australia we came across a lot of ostropalean, helotialean, and dothidealean discomycetes growing in close vicinity with *Orbiliomycetes*. Many of them we have studied in detail in the living state, and notes and drawings of them can be found on our homepage (IVV). Their immediate documentation turned out to be important because we frequently experienced that several of these species did not show up a second time by now, and a later restudy of the dead material would mean a serious loss of data.

Monographic work based on vital taxonomy requires a strategy completely different from herbarium taxonomy. The availability of recent collections, i.e., the knowledge about how to find apothecia in the field, is of major interest in regard to taxonomic questions such as clarification of species limits, whereas the maintenance of a herbarium, though valuable in various ways, is of subordinate importance.

Arguments pro herbarium taxonomy. Traditional monographs are usually restricted to a few years and, therefore, put their focus on the study of dried personal collections and those deposited in public herbaria all over the world. The advantages are convincing: (1) a collection can be studied at any time and as often as wanted if plenty enough; (2) several specimens of a variable taxon, being collected in different years at different places, may simultaneously be compared; (3) a given species is usually easily located in a herbarium but often difficult to find in the field; (4) a taxonomic study can be planned and finished within a reasonable period of time; (5) due to the restriction on persistent characters, all characters of a specimen can be seen and verified or rejected by later workers at any time. Argument (5) is particularly important concerning type material.

The use of lethal clearing agents such as KOH, MLZ, CB_L and others has several advantages: (6) the preparation becomes clear and transparent; (7) living collections get compatible with herbarium material in their microscopic appearance; (8) viscous media (MLZ, CB_L) suppress annoying trembling and drifting of free spores; (9) MLZ stains iodine-reactive structures, whereas IKI was avoided by most mycologists during a long time because it scarcely improves the aesthetical appearance of a preparation.

Regarding the difficulty of detecting discomycetes in the field (argument 3), reasons to rely on herbarium material may involve arguments such as: (a) the worker has not enough time or experience to undertake field work, especially concerning very remote areas; (b) many fungi form their apothecia only a few months per year; (c) undescribed species are assumed to occur only far away from the worker's laboratory; (d) a high number of fungi are regarded as rare.

Herbarium taxonomy sounds convenient and easy. Fresh collections are put straight on the dryer in order to be studied at any occasion. Apothecial fragments are consistently mounted in lethal agents irrespective of the living versus dead state of the cells. The worker must not rack his brains about differences between living and dead cells, such as the following: why do some cells contain many small droplets whereas others a few large drops or none at all. In herbarium taxonomy water is actually not very often used as a mountant, instead, the above-mentioned agents are preferred to mask disturbing structures of the dead cytoplasm, or various stains are applied to improve visibility of microstructures. As a consequence, microscopic illustrations performed by herbarium taxonomists usually refer to dead elements, irrespective of whether the illustrated specimen concerns old type material or a recent collection.

Arguments pro vital taxonomy. The study of living cells includes not only taxonomic but also developmental, cultural, physiological, and ecological aspects. Taxonomic aspects involve: (1) achievement of more natural concepts at species or higher level due to a higher complexity of character combinations; (2) higher contrast and transparency of living cells, better visibility of septa, spores inside asci, spore sheaths, easier recognition of spore numbers, abortion of spores, inverse spore orientation; (3) awareness of striking effects concerning cell size, shape, and contents during killing: shrinkage and artificial flattening, changes in curvature, imbibition (swelling) of walls and sheaths, loss or coalescence of cytoplasmic guttules, invisibility of nuclei; (4) awareness of severe changes in spore arrangement inside asci; (5) correct interpretation of colours (original colour of apothecia, location of pigments, oxidative colour changes of VBs); (6) recognition of hemiamyloidity which may severely change in material older than ~30 years; (7) easier performance of free-hand sections of apothecia due to cell turgor. Developmental aspects comprise: (8) recognition of development stages of asci and spores, which is important for a precise definition of ascospore maturity, in order to answer questions such as: (a) occur features like septa, wall pigments and ornaments, or cell contents in immature, mature, or overmature spores? (b) are true ascoconidia present (conidia produced on ascospores before spore discharge), or are the conidia only formed on overmature ascospores? Cultural aspects involve (9) morphology of different organs formed in pure culture, including establishing anamorph-teleomorph connections. Physiological aspects include (10) function of asci and their apical apparatus in regard to spore discharge. Ecological aspects involve (11) recognition of desiccation and frost tolerance.

The annoying drift of free spores in water has also an advantageous aspect: it permits to obtain a three-dimensional image of spores and their SBs, for example, if spores or SBs are helicoid, or SBs subapically to laterally attached. Sometimes freely floating living mature asci can be seen rotating slowly along their longitudinal axis, which permits viewing of the arrangement of the contained spores from different sides.

Documentations of recent collections are nowadays presented and discussed in internet forums (like AscoFrance or PilzePilze), and experts can give their suggestions. Herbarium taxonomy produces huge amounts of unexamined specimens which require high efforts of maintenance, but with slow progress in knowledge. Voucher specimens may get lost, apothecia destroyed by arthropods, fragments put back in the wrong envelope, or specimens may contain a mixture of very similar, easily confounded species. Such mixed populations are much easier revealed when enough apothecia of a specimen are studied in the living state, compared to the study of dead material or by molecular methods.

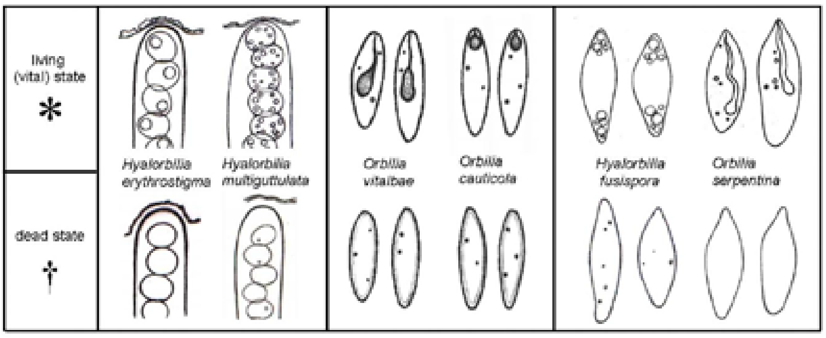

Figure 3: Spore bodies as a species marker, exemplified by three pairs of species with a similar spore size and shape, but very different plasmatic inclusions (upper row). In the dead state these transient structures get completely lost (lower row).

History of vital taxonomy in *Orbiliomycetes*. The first to perform vital studies on teleomorphs of *Orbiliomycetes* were Patouillard (1892), Rolland (1901), and Chenantais (1918), who presented drawings of ascospores with obvious spore bodies (see Fig. 151). The asci and paraphyses in their drawings were dead, however, or uncertain concerning their vitality. Velenovský (1934) favoured vital observations, but only rarely depicted spore bodies in the spores (Figs 154: 4; 156: b), and almost never the spores inside the asci, which indicates that he mainly studied spores and asci in the dead state. Svrček, in his many papers on inoperculate discomycetes, repeatedly studied living specimens, but among the orbiliaceous taxa this mainly applies to his *Orbilia cryptocarpa* (= *Hyalorbilia polypori*, see Pl. 65: 9). Only when *Orbilia septispora* Baral (1989) was described in the living state and the study on vital taxonomy appeared (Baral 1992), the number of papers on *Orbiliomycetes* which included living elements distinctly increased (see p. 201).

The studies by Drechsler (1936–64) on numerous anamorphs of mainly nematode-trapping *Orbiliomycetes* were done on specimens grown in agar cultures, and his detailed microscopic drawings leave no doubt that they were done in the living state. Also other papers on orbiliaceous anamorphs sometimes present living elements, particularly those of Chinese workers from 2005 onwards. Orbiliaceous anamorphs only sometimes provide transient characters of taxonomic importance, for instance SCBs in the conidia of *Hyalorbilia*, but the applied method seriously influences conidial dimensions (see p. 28).

Taxonomic value of spore bodies. The *Orbiliomycetes* are a famous example of the high taxonomic value that morphology and especially vital taxonomy provides. This mainly concerns the spore bodies (SBs), a conspicuous, refractive cell organelle in the mature ascospores, which is unknown in any other class of *Ascomycota* and, therefore, easily permits to recognize a discomycete as belonging to this group of fungi. The high amount of collections with viable spores studied in this monograph allowed us a thorough exploration of both diversity and intraspecific variation of spore bodies. As a result, the SBs turned out to be a feature of high diagnostic value comparable to that of spore shape. Among the ca. 480 taxa examined in the living state, we found a very high diversity in SB morphology on the one hand, and a pronounced intraspecific consistency on the other hand, which both indicate a high biological importance of this organelle.

Spore bodies are mainly diagnostic for higher taxonomic units. This is in contrast to spore shape which is more diagnostic at the species level. In fact, similar spore shapes often occur in very distant groups. Fig. 3 exemplifies this with three pairs of species: the left cell shows two probably closely related species, the middle cell two which belong to different sections of subgenus *Habrostictis*, and the right cell an example of two species that belong to different genera. In the dead state the two species of each pair may easily be confounded by spore morphology alone. Therefore, if only dead herbarium material is available, or if lethal mountants are applied to the living specimen, confusion is predictable.

Many of the here circumscribed sections or series are to a certain degree defined according to shape and attachment of the SBs (for a survey on the various types see Fig. 4). In numerous cases, delimitation between otherwise very similar species turned out to be possible merely on the basis of differences in spore body morphology. There exist many examples of often very distant species which have ascospores of quite a similar size and shape, whereas their SBs are very different. Without information on SB morphology, a collection often remains undetermined. For the same reason, type material can often only tentatively be classified. Some species are so far only known from dead material, without any information on shape and size of the SBs, and are, therefore, difficult to place in a proper infrageneric group.

Quite a complicated group, even for a vital taxonomist, concerns those *Orbiliomycetes* with comparatively small subglobose to ellipsoid-fusoid or ovoid to clavate ascospores and 8-spored asci (Fig. 4). Though in some cases showing a different size and also shape, distinct differences are mainly found in SB morphology, particularly because size and shape of spores of a given species usually show a higher variation than that of SBs. Therefore, these taxa are often difficult or even impossible to distinguish with dead herbarium material, although they belong to three different genera (*Orbilia*, *Hyalorbilia*, *Lecophagus*), and within *Orbilia* to four different subgenera or sections. The contents of the living spores permit rapid recognition in most of these cases, however.

Six of these species have ellipsoid-fusoid to ovoid-clavate spores of *4–8.5 µm length and are shown in the upper row (Fig. 4: a–f). The lower two rows (Fig. 4: g–q) present species with broadly ellipsoid to subglobose spores of *2–5 µm length. Apart from the 16-spored *O. pleioeuonymi*, all species have 8-spored asci. However, not all of them are clear-cut because of more or less strong variation, which also affects the spore bodies to some extent. Two further examples similar to Fig. 4 but with cashew-shaped or tailed (sperm-shaped) spores are shown in Fig. 49.

Another example regards the six known species of *Orbiliomycetes* with black-olivaceous apothecia (Fig. 5). Although these have more or less differently shaped ascospores, spore shape is again rather variable in some of the species and, therefore, of limited value. In contrast, the shape and number of spore bodies show only little intraspecific variation, and almost all species possess their unique SB shape and size. In most of them the SBs are broadly affixed to the spore apex: *Amphosoma atroolivaceum* differs from the remaining in having SBs at both spore ends, *Orbilia purshiae* differs from *O. patellarioides* in SBs with angular to acute internal protrusions, and *O. atrolentiformis* from both mainly in narrower spores. *O. pileosoma* has ovoid spores with very thin and broad, plate-

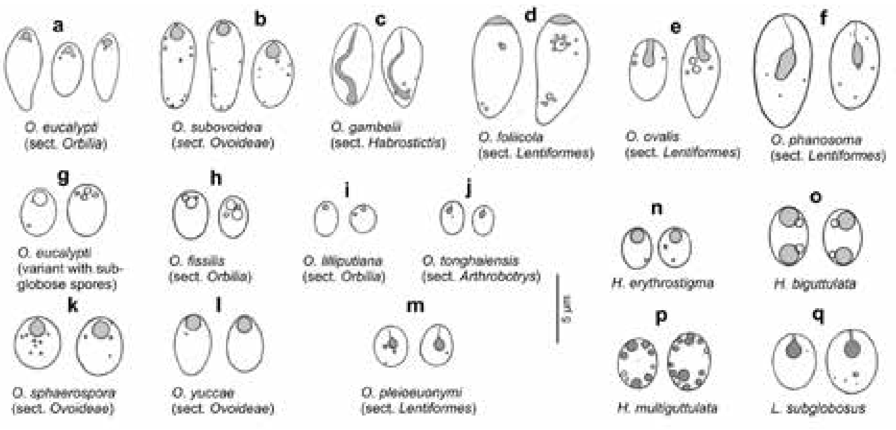

Figure 4: Living ascospores of some selected, mainly 8-spored species of *Orbilia*, *Hyalorbilia*, and *Lecophagus* with partly very different spore bodies (tinted in grey) but a rather similar spore shape. SBs were not seen with certainty in the variant of *O. eucalypti* with subglobose spores and in *O. fissilis*, at least their larger guttules are LBs.

like SBs and deviates in 16-spored asci. *O. olivacea* sharply differs in having ellipsoid to tear-shaped SBs with a narrow attachment to the spore wall. A monographer working with dead material would most probably overlook the autonomy of some of these species, apart from the fact that a relationship of these black apothecia with *Orbiliomycetes* is quite impossible to recognize in the dead state.

Based on the differences in SB morphology, these six species obviously do not form a monophyletic group within the *Orbiliomycetes*. They fit very well three quite distant groups of *Orbiliomycetes*, which otherwise include pale-coloured, whitish to reddish apothecia. *Orbilia patellarioides* matches the light orange *O. lentiformis* (series *Lentiformes*) in having a large lens-shaped spore body at the spore apex, and our molecular data supports this relationship. *O. olivacea* differs from the other five dark-coloured species in the absence of an ascus apical thickening and appears to be related to section *Ovoideae* of subgenus *Orbilia*. The genus *Amphosoma* is characterized by two vital characters: (1) ascospores with a spore body at both ends, (2) paraphyses and marginal excipular cells containing conspicuous guttules (VBs). Mainly because of these two features, *A. atroolivaceum* is undoubtedly closely related to the pale-coloured members of *Amphosoma*.

Another nice example of two species with a very similar spore size and shape concerns the North American *O. cucumispora* and the South European *O. cercidicola* (Fig. 6). The two species sharply differ in SB shape, also in the type of SCBs in the excipular cells. The difference in apothecial colour between the two species (pink vs. orange) becomes obscure in old herbarium material, and only the isodiametrical vs. elongate marginal excipular cells appear to be diagnostic between the two species when dealing with dead material alone, besides ecological differences.

Recognition of the living versus dead state of fungal cells. Both living and dead cells often occur within an apothecium (see p. 30–31), therefore, the recognition of the living vs. dead state of individual cells is essential for the application of vital taxonomy. This requires some exercise, but once accustomed to the involved diagnostic features, the state of the cells will mostly very easily and quickly be recognized, even without applying vital stains. Examples of the characteristics of living and dead cells are given in Figs 7–10, 24–25, 52–53, 67 (see also Baral 1992: 339 ff., figs 1–14, 15f–g, 16f–g, 21–22).

The main characteristics of dead cells are: (1) detachment and increased refractivity of the cytoplasm (Fig. 7: d–f), (2) distortion of regular lipid patterns in cells with high lipid contents, (3) loss of SBs (Figs 7: b, d; 9: c–d), (4) loss of VBs, (5) loss of SCBs (Figs 9: a–b; 87: g–h), (6) shrinkage of cells (Figs 7: a–b, d; 8), (7) inflation of the apical thickening of the ascus wall (Fig. 31). These more or less striking alterations can easily be induced in living cells, either by mechanical pressure, by briefly heating the slide, by drying out and rewetting in the case of desiccation-sensitive cells, or by adding lethal mountants to the preparation.

A differentiation between living and dead cells is also possible using vital stains (basic dyes or other cytoplasmic stains like phloxine) which serve as a proof for vitality (Fig. 7: a–c; see also Baral 1992: 340). The entire cytoplasm of dead cells is stained by these agents due to a loss of semipermeability of the plasmalemma, whereas in living cells

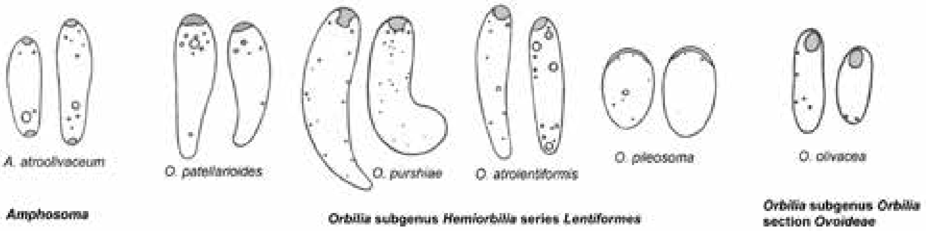

Figure 5: Living ascospores of the six known species of *Orbiliomycetes* with black apothecia. The spore bodies (tinted in grey) differ in size and shape and occur either at both spore ends or only at the apical end, in correlation with the generic affiliation of the species.

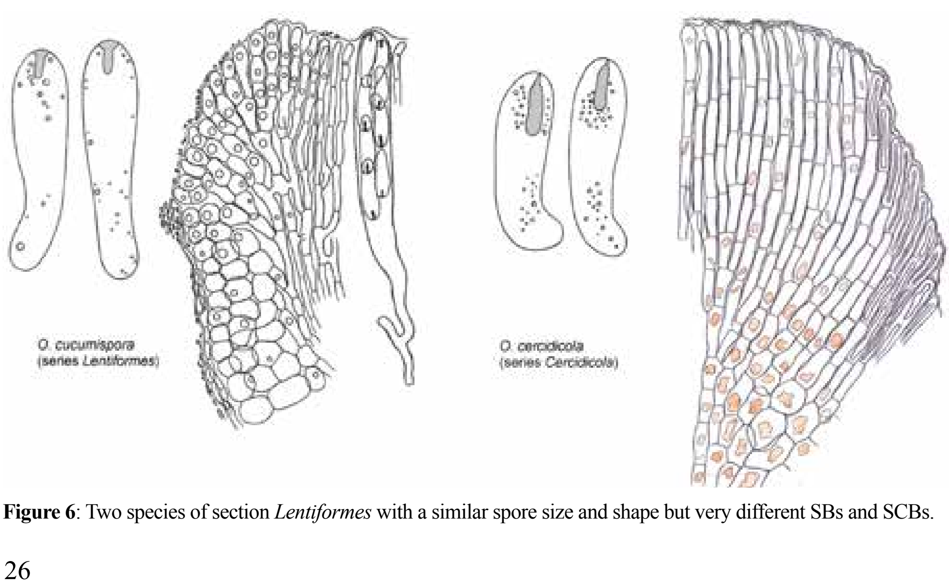

Figure 6: Two species of section *Lentiformes* with a similar spore size and shape but very different SBs and SCBs.

only the vacuoles (including VBs and SBs) are stained through accumulation (in the case of basic dyes such as CRB).

Vitality of individual cells can usually be recognized on microphotographs of unstained fungal cells made under oil immersion. However, images taken with Nomarski interference contrast are sometimes difficult to interpret because the strong contrast lowers the resolution and masks the cell contents, especially those situated close to the cell wall. Some of such images on our plates are, therefore, unclear as to their living state.

The living or dead state can often also be recognized by drawings. For instance, a number of figures in Huhtinen's (1990a) monograph clearly show living elements including turgescent asci, namely figs 36, 62, 150, 175, 180, 212, 231 and 255. Only those parts of these figures show living elements which Huhtinen marked by 'H_2O', and even here some of the depicted cells are clearly dead. For example, his fig. 231b shows three dead spores with large non-globose oil drops. In order to be precise, drawings made from aqueous mounts should be marked by a sign that indicates the living or dead state. As a further example, Scheuer (1988: pl. 12b) figured only one out of 153 ascomycetes in the living state (*Psilachnum acutum*).

Drawings or photographs made from KOH mounts sometimes have the appearance of viable material, particularly if the oil drops, which are well seen in that medium, did not form large aggregations by fusion.

Shrinking effect. When cells die in the hydrated state, they irreversibly lose turgor and thereby often show a more or less strong decrease in size (without collapsing) by losing water mainly from the vacuoles, though they remain surrounded by plenty of liquid. Thereby, the rate of shrinkage depends on the strength of turgor of the intact cell, and on the elasticity of the cell wall. Irreversible shrinkage is induced by lethal mountants, such as 50 % chloral hydrate (in MLZ), 99.5 % lactophenol (in CB_L), or 1–5 % KOH, also by mechanical influence, or by applying heat. All these treatments irreversibly destroy the semipermeable properties of the plasma membranes (see Baral 1992: 340 ff.).

The effect of shrinkage is most pronounced in asci, particularly in those ascomycetes which are capable of forcible discharge, whereas ascospores, paraphyses, excipular cells, or conidia have usually a lower turgor and less elastic walls, and sometimes do not noticeably shrink at all, although exceptions occur. That asci strongly shrink is a consequence of their ability of active discharge: forcible spore ejection requires a highly elastic ascus wall. At full turgescence, ample vacuolar water is present in the lower half of the ascus. Even though authors drew attention to this striking property of fungal cells (e. g., de Bary 1887: fig. 6, Huhtinen 1985a: 18, Baral 1992: 345, Matočec & Focht 2000: 75), the mycological community neglects the effect. Very rarely authors indicate whether their measurements refer to living or dead asci, while it can usually be assumed that they were gained from dead asci, according to the prevailing usage of studying herbarium specimens or placing fresh specimens in lethal mountants.

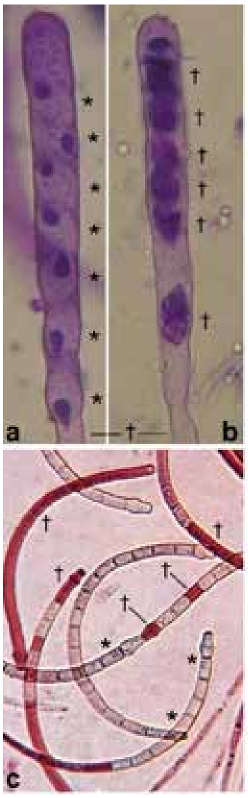

Figure 7: Recognition of the living state of cells: living cells are unstained in cytoplasmic stains (except for vacuoles and spore bodies), whereas dead cells exhibit a deeply stained cytoplasm which is often detached from the cell wall; SBs in dead ascospores strongly lose contrast or get entirely invisible). — **a–b**, **d**. living and dead spores inside dead asci (*Orbilia arizonensis*, **a–b**. H.B. 8002a, in CRB: SBs in living spores deep blue-violet; **d**. H.B. 4566, in H_2O); **c**. living and dead cells occurring mixed in multiseptate ascospores (*Ophiobolus acuminatus*, from Erb & Matheis 1983 fig. 119, in phloxine); **e**. paraphyses with dead terminal cells and living lower cells (*Orbilia commarosa*, H.B. 7302b, in H_2O); **f**. living and dead ascospore (*O. megaocculta*, H.B. 6775, in H_2O).

Particularly within the *Orbiliomycetes*, considerable differences in size between moderate and full turgescence complicates **ascus** measurements (see Figs 24, 43: d). Fully turgescent asci of *Orbilia* spp. have roughly a 1.5 × higher volume compared to asci with moderate turgescence. An evaluation of data from 12 species revealed an ascus volume at moderate turgescence of only 60–75 % of that at full turgescence. Asci of moderate turgescence show again a roughly 1.5 × higher volume compared to dead, non-turgescent asci, showing a shrinkage during killing of likewise 60–75 %. The volume difference between full turgescence and complete loss of turgescence lies at about 40–55 %. Differences in ascus length and width are in the range of 10–15 % when asci shrink for ~25–40 %, and in the range of 20–25 % when asci shrink for ~45–55 %. Depending on the species or genus, the shrinkage factor may differ somewhat between length and width: for instance, a living ascus of 100 × 10 µm may measure in the dead state 80 × 8.5 µm, or 85 × 8 µm. These values of shrinkage more or less concur with those observed in other classes of ascomycetes, such as *Leotiomycetes*, *Lecanoromycetes*, *Pezizomycetes*, and *Dothideomycetes*.

The percentage of shrinkage is best evaluated from a single ascus by applying lethal agents, or during spore discharge. The above values of shrinkage were mainly evaluated by comparing measurements of living and dead asci from several collections. In a few species (e. g., *O. sarraziniana*, *O. luteorubella*, *O. rosea*) hardly any shrinkage (or only 5–10 %) in ascus length could be noted, although data from numerous collections was available.

Not only ascus turgor determines ascus size. Dead asci which contain living spores are often slightly wider than those containing dead spores because the living spores are wider and

Figure 8: Shrinkage of asci and elongation of pars sporifera (in water). Left: living state, right: dead state; both asci contain living mature spores (*Orbilia ocellata*, H.B. 9151a).

may press against the lateral ascus wall. Therefore, dead asci should be measured preferably after adding killing agents like KOH. Also the ascus stipe is distinctly thinner in the dead state. Since asci scarcely shrink in length in the region of the stipe, ascus stipes appear in the dead state seemingly longer in comparison with the upper part of the ascus. Similarly, perforations in croziers increase in the dead state because their arches shrink in thickness.

The stronger shrinkage of asci compared to paraphyses evokes that, in the living state, asci often protrude beyond paraphyses whereas, in the dead state, paraphyses protrude beyond asci. Living asci of *Hyalorbilia* may protrude 1–2 µm beyond paraphyses by lifting the overlying exudate, which dead asci never do. Similarly, in those species of *Orbilia* with spathulate to mammiform paraphyses, their tips may protrude 0–7 µm in the living state but 3–10 µm in the dead state. Fully turgescent asci of *Orbilia xanthostigma* project 7–10 µm beyond the hymenial surface (Fig. 45), while those of moderate turgescence are still slightly shorter than the paraphyses (see also Pl. 875: 15).

Living **ascospores** of *Orbiliomycetes* in water mounts are usually distinctly larger compared to dead spores mounted in any medium. (Figs 9, 52, 53: b; 67). An evaluation of data from 15 species of *Orbilia* revealed that the volume of dead spores is around 75–85 % of that of living spores, but sometimes only 60–70 % (e. g., *O. flavida*) or also 90–95 % (e. g., *O. cercidicola*, *O. sarraziniana*). Both length and width of dead spores lie in the range of about 85–98 % of the living spores. However, the spores often show a stronger shrinkage in width than in length, but sometimes also the reverse was noted.

Within the ascomycetes, shrinkage of ascospores varies considerably among the groups. In four species from four different genera of *Helotiales* examined, shrinkage varied between about 6 and 18 % in length, and between 7.5 and 25 % in width (Baral 1992: 345). These differences are probably mainly due to differences in spore wall elasticity among the genera: highly elastic spore walls provoke high degrees of shrinkage whereas inelastic walls may collapse when placed in high-concentrated media.

Shrinkage and collapsing is not only observed between living and dead spores, but also under dehydration without loss of viability, either by a high osmotic pressure in the surrounding medium, or by dehydration in dry air. Inside living mature asci the spores are often considerably smaller, especially narrower, compared to discharged spores, due to osmotic effects (Baral 1992: 350). Considerable spore shrinkage occurs, e. g., in the genus *Hymenoscyphus*: spore width inside turgescent asci is here around 85–90 % of free spores. Measurements of such compressed spores should, therefore, be avoided or separately stated.

Within the *Orbiliomycetes* we experienced that living mature spores inside asci of moderate turgescence generally did not noticeably deviate in size from recently ejected spores, or from living spores inside dead asci (see Fig. 8), obviously due to the comparatively low elasticity of the spore wall in this group of fungi. However, measuring dead spores inside dead asci was often troublesome and resulted in ambiguous values because of a problem in the exact recognition of the spore wall (see p. 11, also Fig. 10: d–e)

Inside fully turgescent asci the spores often collapse by dehydration and are usually quite obscured within the spore cluster that neither their shape nor their contents can adequately be studied (Fig. 43). In fully turgescent asci of the *Helotiales* collapsed living spores were never seen, apparently because of a more elastic spore wall.

Also **conidia** show a varying rate of shrinkage when treated, e. g., with KOH (Fig. 9: a–b). An evaluation on six species of the genera *Lecophagus*, *Hyalorbilia*, and *Orbilia* revealed a volume decrease of dead conidia to around (55–)70–80(–90) % of the volume of living ones. The linear decrease in size was thereby to around (80–)85–95(–100) % in both length and width, thereby shrinkage in width was sometimes a little higher than shrinkage in length.

If measurements did not markedly differ between living and dead conidia, this was either a result of variation between populations or, in the case of their width, a result of artificial flattening. Particularly cases of very broad conidia cause problems of artificial flattening, even in the living state: such conidia may get compressed by the cover slip as soon as the water beneath evaporates below a critical level. Thereby the width considerably increases, resulting in erroneous values. Adding enough water to living conidia instantly removes the effect.

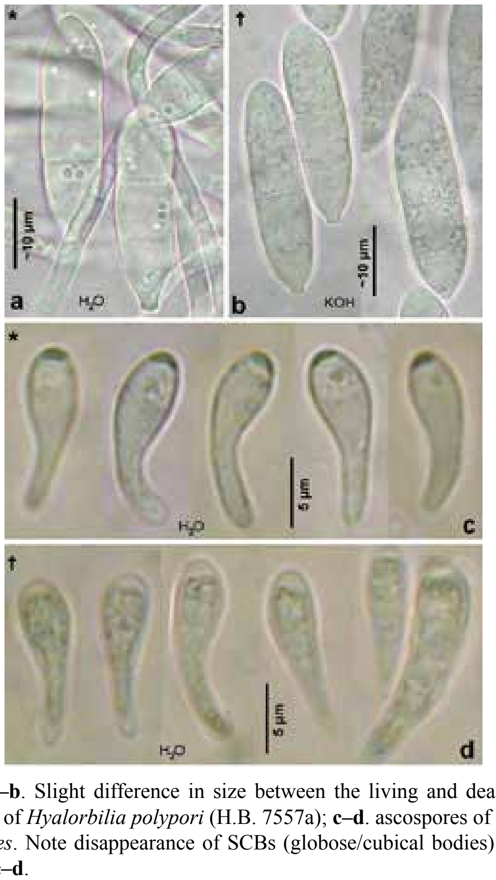

Figure 9: **a–b**. Slight difference in size between the living and dead state. a–b. conidia of *Hyalorbilia polypori* (H.B. 7557a); **c–d**. ascospores of *Orbilia patellarioides*. Note disappearance of SCBs (globose/cubical bodies) in **a–b** and SBs in **c–d**.

Shrinkage may also affect spore shape: curved (falcate or helicoid) ascospores in section *Arthrobotrys* are generally distinctly less curved in the dead state (in water or KOH) and, therefore, slightly shorter in the living state when measured in situ (see Fig. 52: c). The actual length is probably slightly longer in living spores but can only approximately be measured.

Vegetative (somatic) cells of paraphyses, excipulum, and anchoring hyphae also shrink to an often considerable extent when they die, therefore, measurements in the literature are also here generally smaller than from living samples. In an evaluation on 13 species of *Orbilia*, the volume of dead terminal cells of paraphyses was around (50–)60–75(–85)% of that of the living ones. Thereby, the length of the dead cells was around (80–)85–95(–100)% of the living cells, whereas the width showed a slightly stronger shrinkage to (70–)80–90(–95)%. Cells of the ectal and medullary excipulum and of anchoring hyphae usually shrink to a similar rate, for instance, cells at flanks for 20% in both length and width in *Hyalorbilia lunata*, or anchoring hyphae of *Lecophagus vermicola* for 7–16% in width.

Diagnoses of ascomycetes currently describe how the spores are arranged within the asci. Such descriptions are misleading, however, because **spore arrangement** strongly depends on ascus turgor (see also Baral 1992: 348). Despite the strong shrinkage of asci during turgor loss, the pars sporifera often elongates because of a reduced width of the asci, especially if the spore remain alive. During this irreversible rearrangement, biseriate spores often become more or less uniseriate, at least in the lower part of the pars sporifera. As a peculiarity of the *Orbiliomycetes*, the pars sporifera in the living asci distinctly contracts when the spore cluster is formed at full turgescence. At this stage the pars sporifera has a length of only 65–80 or even 50–65% of that at moderate turgescence, while in dead, non-turgescent asci it is about 110–120% of that at moderate turgescence. Yet, anomalous values of the length of the pars sporifera may infrequently occur, for two reasons: (1) if some of the spores abort prior to maturation, the pars sporifera is shorter than usual, (2) if a gap between the spores or especially between the ascus apex and the upper spores exists. Such gaps were consistently subtracted when the pars sporifera was measured.

Frequency of mature asci and ascospores. In the *Helotiales* or *Pezizales*, free ascospores often occur in rather high abundance when mounting a mature fresh apothecium in water. Spores are ejected from many asci within a few seconds or minutes in a lot of genera. But some genera behave similar as members of *Orbiliomycetes*: often only very few free spores are found in a squash mount, although plenty of mature living asci are present. In our experience, this physiological difference is somewhat correlated with desiccation tolerance: many desiccation-sensitive, short-living species (e.g., *Sclerotiniaceae*) readily liberate their spores, whereas predominantly xerobiotic species very rarely do so, sometimes even if IKI, an efficient stimulans for spore discharge, is added to a water mount.

Therefore, fresh mature apothecia of, e.g., *Hymenoscyphus*, *Lachnum*, *Mollisia*, or *Sclerotinia* are usually rather rich in free spores, whereas those of *Orbilia*, *Durella*, or *Calycellina* are often poor herein. However, in some collections of *Orbiliomycetes* free spores were encountered in considerable abundance in both fresh and herbarium material, irrespective of being desiccation-tolerant or not. Desiccation-sensitive discomycetes usually lose a lot of their mature spores via spore discharge during drying of a specimen, because dry air generally induces puffing. Yet, the paucity of spores in herbarium specimens of *Orbiliomycetes* can hardly be explained this way because we never observed simultaneous spore release in this group.

Visibility of spores inside asci. In recently collected apothecia the ascospores are seen with high contrast inside the asci without applying staining agents (Fig. 10: a, see also Fig. 57: c–d), if a number of rules are followed: (1) spores and preferably also asci must be in the living state, (2) tap water must be used as mountant, (3) oil-immersion (magnification 1000×, better 1250–1500×) must be applied, (4) any strong pressure on the cover slip must be avoided. An ordinary light microscope with a comparatively high numerical aperture (1.25) of the 100× objective is completely sufficient, no phase contrast or other equipment is necessary.

A frequent experience with dead herbarium material of *Orbiliomycetes* is that collections are thought to be immature since no spores are seen inside the asci (Fig. 10: b, see also Figs 24; 25: c right), and free spores can hardly be found. Nevertheless, such specimens are usually fully mature. Application of cytoplasmic stains or, alternatively, cell wall stains to a KOH-mount usually makes the spores better visible (Fig. 10: c–e) and demonstrates that mature asci are present in great number (see also p. 11).

Inappropriate preparation methods applied to dead material are apparently the reason, why the original descriptions of rather many species of *Orbilia* are either devoid of spore data, or incorrect concerning spore shape or spore numbers. Even workers who reexamined type material in the last decades were unable to emend such diagnoses. For example, Berkeley (1875) could not find any spores when describing *Peziza saccharifera*. In the present study of the type specimen, spores could be seen inside many asci in KOH+CR mounts, and its identity could be much more precisely resolved. *O. siculispora* is another example with a very characteristic type of narrow ascospore with an acuminate apex and a small, thickened basal part separated from the main part of the spore by a strong constriction (see Fig. 52: a). This characteristic spore shape could be seen in the holotype in a KOH+CR mount in- and outside asci, but was completely overlooked by Cash (1938) who obviously saw only the thickened basal part of the spores.

The reason why ascospores become invisible inside asci in dead material can be explained as follows: the refractive spore wall optically disappears on account of a dehydration of both asco- and sporoplasm (Baral 1992: 354). In the living state the ascoplasm is strongly hydrated and mainly represents a big vacuole that contains the spores (Fig. 25: a–b). The ascoplasm is, therefore, highly transparent and non-refractive, whereas in the dead state it becomes dehydrated at a considerable rate and, therefore, very intransparent and more or less refractive (Fig. 25: c, d left). The spores remain clearly visible inside the dead asci only in species with more rigid spore walls, for instance in the *Pezizales*. This phenomenon of invisible spores inside asci is a general one, and is also common in the *Helotiales*, if the spores have delicate and hyaline walls. Because of this effect, drawings of dead asci in the literature often do not show the included spores (see also p. 11).

Recognition of maturity – Definition of the term 'mature'. A general observation in all groups of sporulating fungi is that the features of the spores as seen under the light microscope

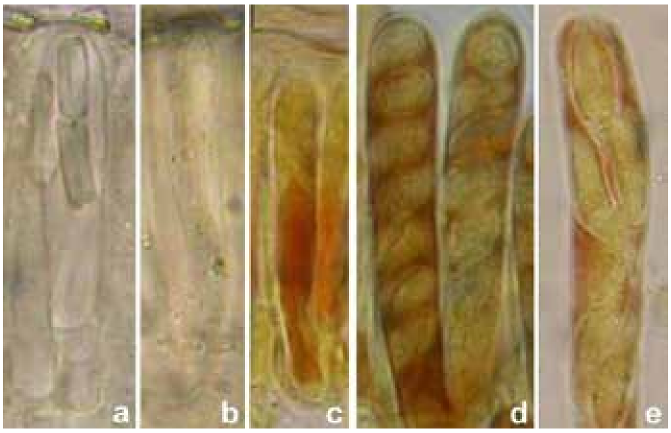

Figure 10: **a–e**: Mature asci of *Hyalorbilia* and *Orbilia* (**a**. living state in water, spores visible with high contrast; **b–e**. dead state (**b**. in KOH, spores hardly visible; **c–e** in KOH+IKI, spores better visible, glycogen stained red-brown, **d–e**: the unstained spore wall is difficult to locate, and a light zone may easily be mistaken for a spore sheath); **a–c**. *H. polypori* (**a**: H.B. 7943b, **b**: H.B. 7971, **c**: H.B. 7965b); **d**. *O. ophiosoma* (H.B. 8095d); **e**. *O. bicknellensis* (H.B. 5669).

change considerably during the different development stages of spore formation and germination. The observed changes concern characters of the cell wall (spore shape, size, septation, pigmentation, ornamentation, and sheaths) as well as those of the living sporoplasm (lipid bodies, spore bodies, nuclei, vacuoles, glycogen). It is, therefore, inevitable for accurate taxonomic work to compare spores at the same development stage. Although there is general agreement that the mature stage of a spore should be used in fungal taxonomy, the definition of the term mature strongly varies among authors. Concerning the ascomycetes, a frequent opinion is that only free ascospores can be considered to be mature. However, this thumb rule does by no means warrant exclusion of immature or overmature stages.

Spores actually do not change their appearance during the process of forcible ejection, apart from some water uptake by the sporoplasm and, therefore, a greater volume after ejection in a water mount. The opinion that spores inside asci are less mature than free spores originates from the study of herbarium specimens. Fact is that the focus on free spores offers only a slight chance to gain more compatible data. Free spores may actually be less developed than those within asci, since (1) free spores may have been squeezed out of broken or cut immature asci, and (2) spores inside dead asci can be overmature and may even germinate inside them. Although the study of herbarium specimens allows to recognize different maturity stages of ascospores, the terms immature, mature, and overmature can credibly be applied only if living asci are present.

Developmental changes in spore wall features such as formation of septa following nuclear divisions, wall pigmentation, and ornamentation are visible in both living and dead spores. Yet, developmental changes in spore contents need to be studied in living spores, due to the frequent confluence or optical disappearance of characteristic structures in the dead state. Changes in the cytoplasm during spore development concern the formation of LBs, glycogen, and vacuoles in many groups of ascomycetes, and, as a peculiarity of the *Orbiliomycetes*, the formation of spore bodies (Fig. 69). In our experience, all these structures in living spores do not allow precise definition of maturity, if only dead asci are present. For example, the occurrence of septa, or a high lipid content, do not necessarily mean that these spores are mature, in comparison with spores without septa or with a low amount of lipid in the same preparation.

Maturity of ascospores was redefined by Baral (1992: 375) who emphasized that the term 'mature' can only properly be applied if restricted to those spores being forcibly ejected from turgescent asci in a water mount. This definition requires living asci capable of active spore discharge. Mature asci are those which are turgescent enough to discharge their spores within some minutes or hours as a maximum. Such asci can be recognized by having a single large vacuole that includes the mature spores and ample water around and below them. Immature living asci contain immature spores and are recognized either by numerous small vacuoles, which are clearly visible particularly below the pars sporifera (Baral 1992: figs 15b, 16b), or by the abundant presence of lipid bodies in the ascoplasm (l.c.: fig. 43a).

This definition of maturity comprises also free spores a few hours after ejection. However, exposition of ejected spores to a humid condition for about 5–10 hours at room temperature may induce metabolic ageing processes such as swelling, consumption of the lipid content, formation of septa, or in the *Orbiliomycetes* retraction in length and increase in width of elongate SBs (Figs 11: e–f, 70) and eventually regression of the organelle. Especially in senescent apothecia such overmature spores are often found inside dead asci if the asci failed to manage spore ejection. If a rehydrated herbarium specimen contains only dead asci, it is generally impossible to determine whether these asci got dead during drying or how long they might have been already dead prior to drying. As a consequence, spore maturity cannot be estimated without the presence of living asci.

This definition of maturity of spores is in discordance with a current opinion which tends to use 'mature' for overmature stages, particularly for spores which are discharged when hyaline but later become brown. It must be noted, however, that such spore ageing may exceptionally occur even within living asci, particularly if apothecia are kept in a moist chamber over several days. Such cases of apothecial senescence are characterized by a high variation among the spores inside the living asci, in contrast to well-developed apothecia showing a high consistency in spore characters.

As a peculiarity of *Orbiliomycetes*, living asci undergo two subsequent development stages (see Fig. 24: E–F) which both may be termed 'mature'. The later stage of the two (F) shows maximum turgescence, with all spores dehydrated and sticking together in a cluster. However, since spores of the earlier stage (E) do not morphologically differ from free spores shortly after ejection, both may be attributed the same stage of maturity because, during turgor increase, the spores seem to undergo merely a reversible dehydration process.

Fresh and dry versus living and dead state. Desiccation-sensitive (hygrobiotic) apothecia are defined here by the inability of their asci to survive more than about one day or even less than one hour after complete drying. Therefore, in fresh apothecia of hygrobiotic species most cells are usually alive, and in dry apothecia most of them are dead. In contrast to this, apothecia of a majority of *Orbiliomycetes* are desiccation-tolerant (xerobiotic), and many other groups of fungi share this peculiarity. Xerobiotic taxa are usually collected in the dry, completely dehydrated state, in which all types of cells are still viable though dormant. Here the term fresh appears inappropriate because mature apothecia have endured a long-lasting period of repeated drying and

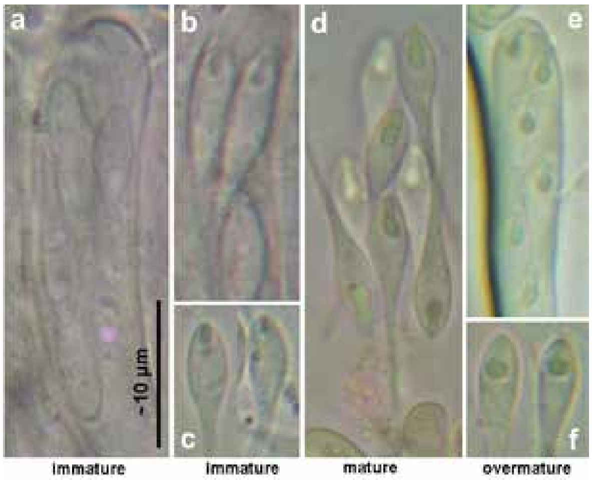

Figure 11: Immature (**a–c**), mature (**d**) and overmature (**e–f**) spores (**a**. inside living ascus, **b**, **e**. inside dead asci, **c**. liberated by pressure, **d**. shortly after active spore discharge, **f**. ejected probably a longer time ago). The development stage of the spores in **b–c** with their rather short and narrow SBs is evaluated from observations in other collections of this species, because such spores were here only seen inside dead asci. Those spores in **e–f** are estimated as overmature because such short and basally inflated SBs have never been seen inside living asci of this species. — *O. aristata* (28.X.2007, phot. P. Perz).

rewetting during their development. Depending on the climatic condition, this period may take several years. Vitality of such rehydrated apothecia is easily demonstrated by active spore discharge and subsequent germination on agar.

However, very recently collected fungi may contain a varying number of dead asci, irrespective of being desiccation-tolerant or not, or collected in the fresh or dry state, even if looking macroscopically sound and being carefully mounted. Of course, a few asci always lose turgor by mechanical influence when taking fragments out of the hymenium. For all these reasons, a water mount frequently contains both living and dead asci at the same time, and recognition of the living state is obligatory in order to restrict measurements and other data on either of the two states (see p. 26–27). An often occurring situation in water mounts is the presence of living spores within a dead ascus (see Fig. 25: c–d: states 2a, 2b), either because asci are more sensitive to mechanical pressure due to their larger width, or because ascospores tolerate desiccation for a longer period of time than asci do.

Particularly in xerobiotic species, some or all asci, paraphyses, or ascospores may be dead, although immediately examined after collecting. The external appearance of rehydrated apothecia of such collections thereby often does not deviate in the least from those in which most of the cells are viable. There is no doubt that the cells of such apothecia have been already dead in the field. Frequently, the excipular cells are still viable while most of the hymenial elements are dead. One could imagine that a longer period of drought or some other stress like frost may be responsible for these mortality effects. It can be assumed that ascomata with a viable excipular tissue are able to produce new asci during more favourable conditions. Sometimes the hymenial elements were dead only in a portion of the population, while the rest showed full vitality. Undoubtedly, the latter represent the younger portion of the population.

When collecting in temperate regions, all cell types of xerobiotic species often showed a certain sensitivity to repeated drying and rewetting. After rewetting for the first time, most cells were usually alive. Yet, after drying at room temperature and rewetting a second time some hours or days later, a major part of the cells were dead. In other cases, particularly in populations from semihumid to arid areas, no such mortality rates were observed after repeated rewetting and drying in the laboratory. A problem with the scanning of branches is that minute apothecia can hardly be detected without rewetting the entire substrate.

Consequently, microscopic study must be done immediately after detecting a population, otherwise valuable vital characters may get lost. The observed mortality is possibly avoided under natural conditions by longer periods of hydration.

Conservation of vital characters. A frequently raised question concerns the conservation of vital characters. Is it possible to preserve SBs or SCBs in herbarium specimens or permanent slides? After testing various methods, we came to the conclusion that conservation for light microscopic study is impossible. Fixatives such as formaldehyde, high-concentrated alcohol, or Carnoy's solution (a mixture of 96 % ethanol, chloroform, and glacial acetic acid) are lethal agents, which irreversibly destroy the refractivity of spore bodies or SCBs. Also when treating SBs with vital stains, such as CRB, they become irreversibly invisible when adding such lethal reagents afterwards.

However, ultrastructural studies have shown that SBs are clearly visible under the TEM when fresh specimens are fixed and stained (see Fig. 71). Likewise, Woronin bodies can very clearly be demonstrated with the TEM in fixed material, although in dead specimens they are impossible to see under the LM. Whether this method works also with dead herbarium material is unknown.

Experiments on the prolongation of vitality during long-term storage were not undertaken. As practised with the storage of dry seeds at -18 °C in the arctic seed bank on Svalbard, storage of dry apothecia of xerobiotic taxa at low temperature might extend the period of time during which they remain viable. Storage in mineral oil as practised for living cultures might offer another method of conserving vital characters, besides further techniques such as liquid nitrogen storage at ultra low temperature (Smith & Onions 1983), or storage in sterile water (Harris undated).

A method that extends the life span of a population of a xerobiotic species to a period of about 5 years imitates the sparse and occasional precipitation under natural condition. Such experiments were only exceptionally undertaken, thereby an extension from about 3.5 to more than 4.5 years was achieved in an Australian collection with ca. ten different species of *Orbilia* (see p. 159).

The loss of visibility of taxonomically important characters, such as spore bodies (SBs) and unstable plasmatic bodies (SCBs) in species of *Orbiliomycetes*, pertains also to the rules of the International Code of Nomenclature (ICN) regarding valid description of new taxa. According to Art. 40.5, 'the type of a name of a new species or infraspecific taxon of microscopic algae or microfungi may be an effectively published illustration (...) if it is impossible to preserve a specimen that would show the features attributed to the taxon by the author of the name'. Since plasmatic structures cannot be preserved by conventional methods of herbarization, the taxonomic value of illustrations is of particular interest in comparison with herbarium material. The application of Art. 40.5 on teleomorphs of *Orbiliomycetes* appears to fail because of the definition of 'microfungi', which implies the absence of multicellular sporocarps, although other definitions emphasize their invisibility with the naked eye. For instance, Barber & Keane (2007) included also minute ascocarps under the term 'microfungi'.

The main intention of Art. 40.5 appears to be that characteristics of certain algae or fungi cannot be preserved because of 'technical difficulties of preservation'. Hence, not their minute size is crucial, but their unstable microstructures cause the trouble. With this understanding, a majority of *Orbiliomycetes* fall in this category, as they become indeterminable in the dead state. Molecular techniques, which enable to distinguish cryptic or otherwise difficult species, might solve the problem in the future even regarding minute and sparse or even disappeared apothecia. In a few cases in which no apothecia remained after study and no piece of substrate was preserved, we rely on Art. 40.5 when describing new species based merely on illustrations serving as holotype.

MORPHOLOGY OF THE TELEOMORPH

General remarks. The apothecia (teleomorph) of the *Orbiliomycetes* provide a fairly large number of characters, particularly when including vital characters. These comprises elements of the sterile (vegetative, somatic) parts of the apothecium (anchoring hyphae, ectal and medullary excipulum, hairs, paraphyses, glassy processes, and exudate) and the fertile (generative) parts (asci, ascospores). Although included in the scope of the teleomorph, the anchoring hyphae at the base of apothecia correspond to the mycelial hyphae on which the anamorph develops. Many of these characters are more or less consistent within a taxonomic group above the species, hence they have no or limited value for species delimitation. The frequently observed morphological variation within a species often diminishes the taxonomic value of characters.

A remarkably high level of morphological diversity of microscopic features has developed in the *Orbiliomycetes*, which makes taxa recognition comparatively easy in many cases. This diversity is largely confined to a few elements of the teleomorph, the most important being the ascospores and their SBs. Tab. 2 gives an overview of the taxonomic relevance that the different characters can be attributed, as experienced in the present study.

Table 2. Selected characters of the teleomorph of *Orbiliomycetes* and their estimated taxonomic relevance for species delimitation in comparison with delimitation of infrageneric and generic groups (* = low, ***** = high). Characters which are more or less exclusively visible in the living state are italicized.

Element	Character	Species level	Infrageneric level	Generic level

Apothecia

Similar to other groups of *Ascomycota*, quite a large number of species of *Orbilia* or *Hyalorbilia* closely resemble each other in external appearance so that only their microscopic features allow identification at the species level. A few species are more or less characteristic in apothecial colour and shape, or their margins being hairy or toothed, which allows to suspect their identity in combination with substrate and geographical origin. As a further complication, macroscopical variation within a species is often comparatively high. Populations with very different colours may belong to the same species. For example, *O. sarraziniana* and *O. eucalypti* may occur with whitish, pale (or bright) rosaceous-lilaceous, or bright yellow-orange apothecia. Also *O. comma* occurs in pale cream or bright orange colours. However, whitish *O. leucostigma* and yellow *O. xanthostigma* were found to belong to two species, differing greatly in the ITS rDNA data, though growing sometimes intermingled. Populations varying between almost smooth and distinctly toothed apothecial margins (e. g., *O. flagellispora*, *O. austrocylindrica*) are considered by us to belong to the same species, whereas *O. aristata* with usually indistinct teeth and *O. subaristata* with very distinct teeth are separable also by their molecular data.

In some species the external appearance of apothecia permits recognition of their generic, infrageneric, or sometimes specific relationship. However, often such characteristics are quite insignificant, for instance in the case of small whitish apothecia, which may belong to either *Lecophagus*, *Pseudorbilia*, *Amphosoma*, *Hyalorbilia*, *Orbilia*, or even to a member of the *Helotiales*. Large apothecia of *Orbilia leucostigma* often closely resemble those of *Hyalorbilia inflatula* and are, therefore, easily confused.

Size. Mature hydrated apothecia of *Orbiliomycetes* show a wide range in size. The smallest taxa measure about 0.05–0.15 mm diam. and are, therefore, invisible with the naked eye. Such a size is not rare in desiccation-tolerant taxa. The prevailing diameters lie between 0.3 and 1 mm, and the largest species attain 2–3 mm, very rarely 4–7.5 mm (*O. alba*). Dry (living or dead) apothecia are distinctly smaller and range at (50–)60–75(–80)% of the fully hydrated state (see Fig. 12). Also when comparing fully hydrated apothecia, dead apothecia are slightly smaller than living apothecia: a test with KOH applied to fresh apothecia of *O. leucostigma* yielded (7–)10–13(–18)% shrinkage, i.e., a diameter of 1 mm was reduced to (0.82–)0.87–0.9(–0.93) mm.

Although apothecial size was found to vary considerably in many species, it can be attributed a certain diagnostic value. A tendency of desiccation-tolerant apothecia to a smaller size can be noted: on average, apothecia of desiccation-sensitive species of *Orbilia* and *Hyalorbilia* are distinctly larger. However, there exist many exceptions, and the reason for this tendency is unclear. For example, the highly desiccation-tolerant species *O. carpoboloides*, *O. siculispora*, *O. euphorbiae*, *O. denticulata*, and *O. anigozanthi* have rather large apothecia (~0.5–2 mm), whereas the desiccation-sensitive species

Pseudorbilia bipolaris, *Hyalorbilia ulmi*, *H. fomentarii*, and *Orbilia flavovacuolata* have rather small ones (~0.1–0.3 mm). Possibly, the depth of substrate decay influences apothecial size. Due to the often very long-lasting dryness and short periods of moisture, xeric substrate is often only superficially rotten, because only the outer layers of the host tissue are soaked with water and available as a nutrient source for the mycelium.

Gregarious versus scattered growth. The water relations in the inhabited substrate and the depth of decay might influence not only apothecial size, but also how dense apothecia grow in a population. Apothecia growing gregariously in more or less large populations are typical of desiccation-sensitive species. One of the most impressive examples is *O. epipora* (series *Neodactylella*) which densely covers large areas with thousands of apothecia. Other desiccation-sensitive species, e. g., *O. polybrocha* and *O. orientalis* (series *Drechslerella*), are usually found in small quantities, perhaps because they are adapted to nematodes as prey. Desiccation-tolerant species mostly grow in scattered to subgregarious populations, or gregariously in small groups. A few exceptions confirm this rule: at least two species, *O. pilifera* and *O. comma* (section *Aurantiorubra*), usually grow densely crowded over large areas of the inner surface of rotten bark detaching from *Ulmus* trunks.

Stipe and receptacle. Although the apothecia of a majority of *Orbiliomycetes* are more or less sessile, a short and broad, often hidden stipe is frequently present. Such short stipes are best seen in median section due to being immersed in the substrate, the covering biofilm, or hidden by the subiculum. The stipes are either obconical to cylindrical and thereby sharply differentiated from the receptacle, or ill-defined by forming an indistinct protrusion of the narrowed base. Sharply differentiated stipes are quite typical of the genus *Hyalorbilia*, but also of some species of *Orbilia*. As a rare exception, the stipes are as long as or even longer than wide (*H. erythrostigma*, *H. anonyma*, *O. aureocrenulata*, *O. pilosa*, *O. orientalis*). The comparatively small apothecia of many desiccation-tolerant species are broadly sessile and without any trace of a stipe, but also very large apothecia may be stipeless and broadly attached to the substrate (*O. anigozanthi*, *O. alba*). The length of the stipes ranges from usually 10–50 up to exceptionally 500–800 µm, the width from 40–70 up to 100–300 or even 700 µm.

The thickness of the receptacle at the junction with the stipe lies between ~35–60 and 150–280 µm, while the total height including the stipe may attain up to 300–800 µm. Receptacle thickness mainly correlates with ascus length and excipulum thickness, less so with apothecial diameter. For instance, *O. alba* has very large apothecia (2–6 mm diam.) but rather small asci, and the unstalked apothecia are comparatively thin (80–200 µm). In contrast, *O. pleistolilacina* has small apothecia (0.15–0.45 mm diam.) but very long asci, and the likewise unstalked apothecia are 180–270 µm thick. The thickness of the receptacle may either be rather equal from base to margin, or often gradually attenuates towards the margin, especially in *Hyalorbilia*.

Superficial vs. erumpent. Apothecia of desiccation-sensitive taxa grow mostly superficial on the surface of the substrate. In contrast, the base of desiccation-tolerant apothecia is often partially or entirely immersed in splits of the decomposed outermost zone of the host tissue. Sometimes the entire apothecia are immersed or hidden within clefts or holes in bark or wood, or are more or less embedded up to their mid flanks in a layer of algae and black yeasts mixed with remains of host tissue. An immersed growth may be simulated if apothecia grow on decayed erumpent pyrenomycetes. For example, apothecia of *O. carpoboloides* grow superficially on old perithecial stromata, which rupture through the periderm of the host long before the apothecia of the *Orbilia* appear.

Outline. Hydrated apothecia of *Orbilia* are usually more or less roundish in outline. Large apothecia often develop an undulating margin. An elliptical shape is observed when growing immersed in fissures of the substrate, due to limited space in lateral direction. When growing densely aggregated, the outline becomes irregularly shaped by mutual 'pressure'. On drying, the apothecia often become more undulating and irregular (Fig. 12: g–j), sometimes hysteriform (Fig. 12: c).

Disc. The hymenial disc is usually flat when hydrated, or may be slightly to strongly concave or convex. In large apothecia it is sometimes centrally depressed (umbilicate) or otherwise uneven. Young immature apothecia have frequently a concave disc, but certain species retain concave discs at full maturity: for instance young *O. carpoboloides* has cup-shaped or almost urceolate apothecia which later become saucer-shaped due to a still raised margin. In other species the apothecia soon develop flat discs which later become more or less convex.

When placing a median section of an *Orbilia* apothecium in water and adding a cover slip, a previously flat hymenium gets more convex due to heaviness of the cover slip. This pressure drifts hymenial elements more apart than excipular texture because of a looser cohesion of hymenial elements. Hymenial elements of *Hyalorbilia* are much more agglutinated in a gel, therefore, the effect is here much less pronounced. Reducing the heaviness of the cover slip, e. g. by adding ample water, reestablishes the natural condition.

Dry apothecia are more or less contracted and usually show a deeper colour than in the hydrated state (Fig. 12: i–j), sometimes even a change in colour (e. g., from yellow to red, Fig. 12: k–l). The hymenium becomes more concave and the margin is much more raised and incurved (Fig. 12: a–b). This is due to shrinkage of the hymenial elements in both length and width and contraction of the medullary excipulum, whereas cells of the compact ectal excipulum are less shrinkable. If the apothecia turn hysterioid in the desiccated state and the margin is hairy, the disc may completely be concealed (Fig. 12: c–d). Erumpent, basally immersed apothecia may deeply retract between the host fibres in the dry state and hereby become almost invisible (Fig. 12: e–f). Complete rehydration of dry, living or dead apothecia may roughly take between ~10 sec and 1 min.

Margin. The apothecial margin of *Orbiliomycetes* is usually more or less smooth and protrudes only slightly or not at all beyond the disc. In a comparatively small number of species the margin is conspicuously raised and often finely crenulate or sometimes strongly dentate or hairy (see p. 85 ff.). Species with such a feature were formerly placed in *Habrostictis*, *Hyalinia*, and *Orbiliaster*. Although most of the species with a hairy or toothed margin are desiccation-tolerant (Fig. 13: f–j), some are not, e. g., *Orbilia pilosa*, *O. polybrocha* (Fig. 13: l), *O. crenatomarginata* (Fig. 13: k), and *Hyalorbilia citrina*. As a rare abnormity, marginal elements were formed in the centre of the disc (e. g., *O. pseudoaristata*, Pl. 524: 2a, 3g, 4c).

Figure 12: Apothecia in dry state and after rehydration (all in living state, image pairs show the same apothecia and have the same scale); **a–b**. median section, showing increase in thickness and diameter during rehydration, change from cupulate to flat; **c–l**. apothecia in situ, changing size, outline, and colour. — **a–b**. *Orbilia aurantiorubra* in median section (H.B. 8130); **c–d**. *O. spermoides* (H.B. 7517), **e–f**. *O. cryptogena* (H.B. 8055a); **g–h**. *O. comma* (H.B. 8505), **i–j**. *O. trapeziformis* (H.B. 9139), **k–l**. *O. xanthoguttulata* (H.B. 7915b).

Pigmentation. Apothecia of *Orbiliomycetes* are usually light-coloured, varying from unpigmented (hyaline, whitish-greyish) to different shades of reddish (orange to rose or sometimes lilaceous) and yellowish (chlorinaceous, golden- to sulphur-yellow, ochraceous). A few species are dark-coloured (purplish-brown, dark purple-lilac, black-olivaceous). Pigments that occur in *Orbiliomycetes* probably belong to different groups of chemical compounds and are located in four different microstructures (see Tab. 10).

Apothecial pigmentation was found to show a high correlation with desiccation tolerance (Tab. 3). More or less colourless apothecia are typical of many desiccation-sensitive taxa, but also occur in desiccation-tolerant taxa of the genera *Lecophagus* and *Hyalorbilia*, and in some species of *Orbilia* and *Amphosoma*. *Hyalorbilia* has typically pale chlorinaceous apothecia. Reddish pigments are frequently observed in desiccation-tolerant species (Fig. 13: a, c–d, g–i), whereas they are rather rare in desiccation-sensitive taxa (*Orbilia rubrovacuolata* Fig. 13: o, *O. martinicensis*, *O. luteorubella, O. sarraziniana*). A few species are characterized by pinkish-lilaceous apothecia, e.g., the desiccation-tolerant *O. lilacina*, *O. plurililacina*, *O. myriolilacina*, and *O. pleistolilacina* (Fig. 13: d); among the desiccation-sensitive taxa, a pale lilaceous colour is typical of *O. rosea* and *O. sarraziniana*, and also occurs in *O. leucostigma.* A few species have bright golden-yellow-orange to ochraceous pigments, e.g., the desiccation-tolerant *O. xanthoguttulata* (Fig. 13: b), *O. pilifera* (Fig. 13: f), *O. suberis*, and *O. eucalypti*, or the desiccation-sensitive *O. xanthostigma* (Fig. 13: n), *O. xanthoflexa*, and *O. flavovacuolata*. Dark pigments are restricted to desiccation-tolerant species: blackish-olivaceous pigments occur in one species of *Amphosoma* (*A. atroolivaceum*), in some members of *Orbilia* series *Lentiformes* (*O. atrolentiformis*, *O. patellarioides* (Fig. 13: e), *O. purshiae*, *O. pileosoma*), and in one species of *Orbilia* section *Ovoideae* (*O. olivacea*); dark purple-lilac pigments occur in *Lilapila* spp. (Fig. 13: j) and *Liladisca*. An intermediate case is *O. polybrocha*, a desiccation-sensitive species with a medium (reddish-)brown colour (Fig. 13: l). The frequent occurrence of reddish pigments in desiccation-tolerant species is apparently a genetic adaptation to a higher UV-illumination in their habitats.

Natural colour variation and method-dependent deviations. The macroscopic apothecial colour exhibits more or less pronounced variation in shade and intensity within a spe-

Figure 13: Examples of apothecial diversity in *Orbiliomycetes*; **a–j**. desiccation-tolerant species, **k–o**. desiccation-sensitive species. — **a**. *Orbilia carpoboloides* (H.B. 9233), **b**. *O. xanthoguttulata* (H.B. 7915b), **c**. *O. delphinus* (H.B. 7892a), **d**. *O. pleistolilacina* (H.B. 8746b), **e**. *O. patellarioides* (H.B. 9173a), **f**. *O. pilifera* (H.B. 8145), **g**. *O. fimbriata* (H.B. 8838a), **h**. *O. flagellispora* (H.B. 8359a), **i**. *O. gemma* (H.B. 9020a), **j**. *Lilapila oculisporella* (H.B. 7063a), **k**. *O. crenatomarginata* (H.B. 9265a), **l**. *O. polybrocha* (H.B. 8317), **m**. *Hyalorbilia inflatula* (H.B. 8150), **n**. *O. xanthostigma* (H.B. 8536), **o**. *O. rubrovacuolata* (H.B. 8492a).

cies. Colour intensity often varies between pale, light, bright, or deep. Typically deeply pigmented species may even occur unpigmented, or vary in rather different colours (e.g., *O. eucalypti* Fig. 14: c, *O. comma*, *O. rubrovacuolata*, and *O. xanthoguttulata*). This variation may occur between different populations but also within a population.

For instance, collections of the *xanthostigma-leucostigma* complex comprise populations with pale to bright golden- or orange-yellow apothecia and those with whitish to pale chlorinaceous or lilaceous apothecia. The microscopic features are the same between these colour variants, hence we believed for a long time that the pale-coloured populations were albinotic forms due to the loss of yellow pigmentation. Likewise, in *O. sarraziniana* apothecial colour may vary between pale rosaceous-lilaceous and sometimes bright yellow-orange, and the typically bright red apothecia of *O. rubrovacuolata* may occur in a whitish-yellowish form. Molecular data have shown that *O. leucostigma* and *O. xanthostigma* represent two different species within Europe, while the colour variants observed in *O. sarraziniana* and *O. rubrovacuolata* are merely due to loss of pigments. In the collection of *O. sarraziniana* in Fig. 14: d–e we have the complex situation that morphologically the pinkish apothecia belong to *O. rosea*, while molecular data assign them to the associated rather rare orange form of *O. sarraziniana*.

Whether or not different species are involved in such colour variants is frequently not clear. Our present data provides evidence that intermingled growth of differently pigmented apothecia with a high microscopical similarity may result from independent populations of genetically different species. Within Europe, apothecial colour turned out to be diagnostic for distinguishing *O. leucostigma* (whitish) from *O. xanthostigma* (pale to bright yellow), and apparently also *O. rosea* (rosaceous) from *O. luteorubella* (yellowish-orange). However, populations with pale or otherwise intermediate colours are difficult to place if no molecular data is available or clear microscopic differences exist. In contrast, red European and whitish Macaronesian populations of *O. rubrovacuolata* turned out to be genetically conspecific. In the case of Fig. 14: d–e) we observed two populations which grew intermingled and differed sharply in apothecial colour and ascospore orientation: the orange form with upper spores inverted, the pinkish form with lower spores (mostly) inverted. Yet, molecular analysis revealed identical ITS sequences that refer both

Table 3. Frequency of apothecial pigmentation (predominant colour in fresh state) in different groups of *Orbiliomycetes* in relation to desiccation tolerance and sensitivity. The numbers of desiccation-tolerant (before slash) vs. desiccation-sensitive species (after slash) are given for each genus or section and include unnamed taxa (aff. or nom. prov.; see also Tab. S3). Apothecia are classified as desiccation-tolerant when surviving min. ca. 1–2 weeks, including their asci. Note frequent occurrence of reddish apothecia in desiccation-tolerant (xerobiotic) taxa and of whitish apothecia in desiccation-sensitive (hygrobiotic) taxa.

Perz); **d–e**. *O. sarraziniana* (orange, H.B. 9691a) and *O. rosea* (pinkish, marked by arrows, H.B. 9691b).

variants to *O. sarraziniana*, although we consider the pinkish ones to belong to *O. rosea*.

Among desiccation-tolerant species, *O. eucalypti* s.l. is a famous example of variable colours. The species mainly occurs with light to bright yellowish-orange to rose-orange colours, but sometimes also in a pale cream or rose-lilaceous form, without showing a clear correlation with its somewhat variable microscopic characters. However, apothecial colour seems here to correlate somewhat with the habitat. Collections close to the ground had always whitish to light yellow apothecia. They tend to have smaller spores and are tentatively separated here under the name *O. tremulae*. Loss of pigmentation was rarely observed in three species with black apothecia (*Amphosoma atroolivaceum*, *O. patellarioides*, *O. purshiae*), in which whitish or orange colour variants occurred closely adjacent to the dark ones.

The reason for a partial or complete absence of pigmentation in usually brightly pigmented species could be sought in a reduced exposure to light. In fact, apothecia of the *xanthostigma-leucostigma* complex are always colourless when growing on the dark underside of a trunk, but usually bright yellow when more on the sides or on the top. In some populations, however, bright yellow and colourless apothecia grew like a mosaic intermingled on the upper side under the very same conditions (Fig. 14: b), which gave a hint that genetically different populations should be involved.

Dry apothecia usually exhibit a more intense colour due to a concentration of pigment during shrinkage. Thereby, light orange apothecia become bright or deep orange-red, pale chlorinaceous ones turn intensely honey-yellow, and yellow colours change to orange-ochre or orange-red, and rehydration reestablishes the paler colour (Fig. 12: g–l). However, this only works with recently collected samples. Apothecial colour fades in the herbarium with the years, therefore, yellow-orange or rosaceous-lilaceous colours eventually turn uniformly cream-ochraceous or whitish (Fig. 15: a–h, see also p. 101, Pigments).

Different types of light sources and different adjustments of white balance of the camera strongly influence apothecial colour on macrophotos. A higher fraction of ultraviolet enhances a greenish-yellow component (perhaps by autofluorescence) which is not seen under a lower fraction of UV (Fig. 15: i–l). Also white balance strongly influences the result. Automatic white balance may suppress an orange component which is seen when using a manual white balance (Fig. 15: m–n). However, the manual calibration of the white balance is problematic as it depends on the computer screen and its adjustment, while the automatic white balance may cause false colours if black and white regions are missing on the image.

Translucency. Fully hydrated, light-coloured apothecia are often more or less translucent, particularly in the central region of the disc, which allows to see the usually darker colour of the subjacent substrate. This translucency depends, however, on the presence of extracellular water in the medullary excipulum. Apothecia exposed to dry air will, therefore, get more and more non-translucent when gradually losing water, whereas rehydration rather instantly reestablishes maximum translucency. During dehydration, the intercellular spaces become air-filled at first in the centre of the apothecium, thereby the border against the surrounding water-saturated area is usually very sharp. A comparable effect is known as hygrophaneity in some *Agaricales*. A certain decrease in translucency appears to be provoked by rough hymenial exudates or protruding paraphyses.

Consistency. In the hydrated state, apothecia of *Orbiliomycetes* generally have a soft consistency which is often called waxy or waxy-gelatinous in the literature, and was currently used as a key character of the group. Yet, in our experience there is scarcely any difference in consistency to be observed between *Orbiliomycetes* and soft-fleshed *Helotiales*. Even high-experienced workers may sometimes confuse orbiliaceous and non-orbiliaceous apothecia by macroscopy. In fact, most members of *Orbilia* are characterized by the absence of a compact gelatinous tissue. A waxy-gelatinous consistency is typical of the genus *Hyalorbilia*, in which the hymenium is usually embedded in gel, and often also the ectal and medullary excipulum is medium to strongly gelatinized. Also in *Liladisca* and *Lilapila* the medullary excipulum is strongly gelatinized. In the dry state, both gelatinized and non-gelatinized apothecia become similarly tough, horny, and brittle.

There is some controversy about whether authors applied the term waxy (or ceraceous) to the consistency or the external appearance of sporocarps. Bresinsky & Besl (2003) pointed out that ‘ceraceous’ has been used by Fries probably more in the sense of external appearance of lamellae in *Hygrophoraceae*. In orbiliaceous fungi, however, Fries, Rehm, Höhnel, Nannfeldt, and Dennis clearly used waxy more in the sense of consistency: in combinations like waxy-gelatinous, but also by referring to

the exudate over the paraphyses as 'waxy' and responsible for the coherence of the hymenial elements. Both senses of 'waxy' may apply to apothecia of some species of *Hyalorbilia* as well as *Orbilia*, but this characterization is quite vague and also applicable to certain *Helotiales*.

Apothecial ontogeny is frequently ignored in monographic studies, although apothecia at different stages of development usually occur in a population. Immature apothecia have frequently been left aside also in the present study, because they seemed to contribute little to taxonomy. It turned out, however, that some members of *Orbiliomycetes* greatly differ from the majority in ascoma development: the hymenium usually develops exposed at a very early stage, but in some desiccation-tolerant species it remains more or less completely enclosed by the overlying marginal excipulum and hairs during different stages of hymenial development, even when fully hydrated.

Van Brummelen (1967: 22–28, pl. 17) presented a scheme of the developmental types in *Ascobolaceae* (*Pezizales*). This involves (a) gymnohymenial ascomata that are permanently open from the beginning (including the archihymenial phase in which young paraphyses are not yet developed), with a semispherical peridium of excipular tissue present below but not above the ascogonium, and (b) cleistohymenial ascomata that produce a spherical peridium which covers the ascogonium also above. This covering tissue of the cleistohymenial type, which is formed in the archihymenial phase, remains closed during a shorter or longer period of time. Therefore, Van Brummelen distinguished three subtypes within the cleistohymenial type, according to the development stage at which the ascomata open: (1) opening in the prohymenial phase (young paraphyses present but no ascogenous hyphae), (2) opening in the mesohymenial phase (ascogenous hyphae present but no mature asci), and (3) opening in the telohymenial phase (at least a few mature asci present). Apothecia that open in the mesohymenial phase are again divided into early (no asci), mid (young asci, the first with beginning spore formation), and late (immature asci at different stages of maturation). Those ascomata that open in the telohymenial phase were perithecioid, and in some cases the ascomata even remain closed until they disintegrate. The term cleistohymenial seems to be somewhat inappropriate when applied to the prohymenial subtype, because the hymenium is formed here just when the peridium opens at the top, and is thus never enclosed by a covering tissue. Since the first appearance of ascogenous hyphae is difficult to see, the prohymenial phase is not easily delimited from the early mesohymenial phase.

In an ontogenetic study of apothecia from various groups of inoperculate discomycetes based on microtome sections, Bellemère (1968: 542–550) treated in detail only a single species of *Orbilia* (unidentified, possibly *O. aurantiorubra*). Since the terminology of the French school is quite different from the Anglo-American terminology of apothecial elements, we here provide a list of relevant terms of both schools (Tab. 4). Virtually all taxa studied by Bellemère can be classified in the cleistohymenial type, because the archihymenial phase includes

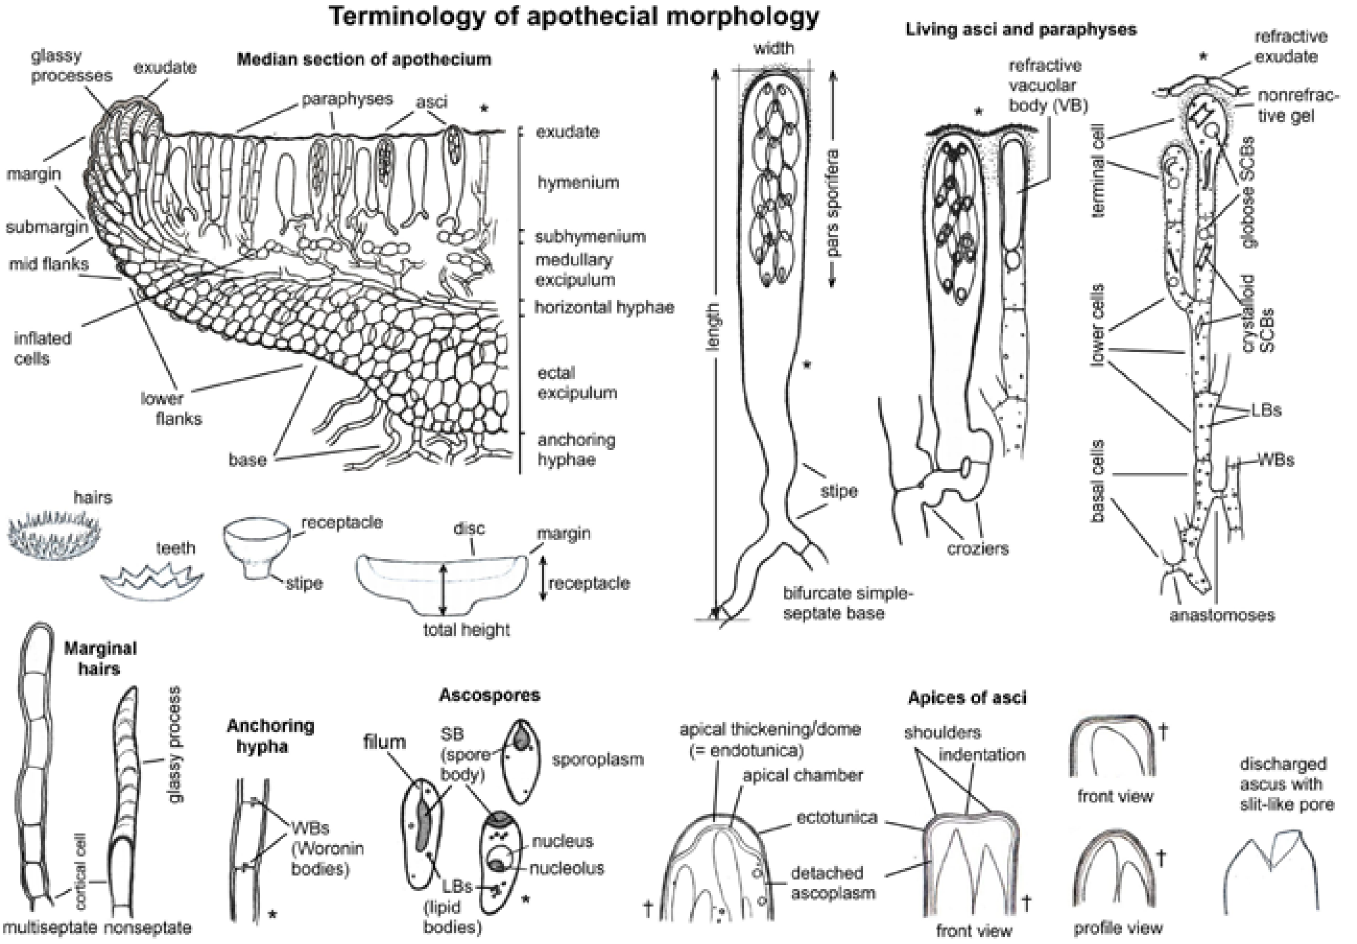

Figure 16: Schematic overview and terminology of elements of the teleomorph in *Orbiliomycetes.*

a stage at which the 'carpocentre' (young medullary excipulum with ascogonial elements) is completely covered by a peridium of ectal excipular tissue. This applies also to the orbiliaceous species investigated by him (Fig. 18), which can be classified as subtype (1), i. e., opening in the prohymenial phase.

Our studies in *Orbiliomycetes* indicate that the prohymenial subtype might actually represent the general case in *Orbilia* and perhaps also *Hyalorbilia*, however, we were so far unable to detect apothecial initials of the archihymenial phase on the natural substrate. Subtypes which open in the meso- and telohymenial phase occur in at least three species, all of which having septate marginal hairs. In *O. siculispora* (Fig. 17: a–b) the hymenium is completely covered by a tissue of cortical elements and opens in the early mesohymenial phase when the spores are not yet recognizable in the asci. *O. pilifera* also appears to belong to this subtype. *O. carpoboloides* (Fig. 17: c) opens in the late meso- and the telohymenial phase when many asci already attained maturity. Here, the hymenium of the as yet closed apothecium lines also the covering tissue which later represents flanks and margin, with the asci and paraphyses oriented upside down (Fig. 17: c).

Also Nannfeldt (1932: 97) observed in *O. carpoboloides* (as *Habrostictis rubra*) that the hymenium is entirely covered for a long time by an overlying tissue which finally lacerates to form triangular marginal lobes. This situation of a hymenium that almost entirely lines the internal cavity of the closed apothecium also occurs in *Cenangium ferruginosum* as reported by Bellemère (1968: fig. 66D), though in *Cenangium* the apothecium seems to open already in the early mesohymenial phase.

Apothecial initials of the archihymenial phase as observed by Bellemère (1968) in *Orbilia ?aurantiorubra* (and Descals et al. 1999 in *O. rosea*) are subglobose and measure about 50–90 µm diam. (Fig. 18: a: A–B). They develop either superficially or sometimes beneath a layer of host tissue (Fig. 18: b). The initials are composed of an ectal excipulum of small isodiametric cells. Like a hollow sphere, this tissue forms a compact layer around a less dense central tissue ('carpocentre') of slightly smaller cells (Fig. 18: b).

The central tissue of apothecial initials, which represents the early medullary excipulum, consists of vegetative paraphysogenous plectenchyma and, more in the centre, of slightly wider ascogonial cells, from which the generative ascogenous hyphae emerge. These two types of tissue systems stain differently, according to Bellemère: the walls of the paraphysogenous cells stain in Vert lumière (Methyl green), whereas the ascogonial cells, ascogenous hyphae, and young asci are more strongly eosinophilous.

In the prohymenial phase, in which the initials usually attain a size of ca. 100 µm, the carpocentre differentiates into a lower layer of paraphysogenous plectenchyma and an upper layer composed of a palisade of young paraphyses. About at this stage the ectal excipulum ruptures at the top of the apothecium. However, this rupture is difficult to observe: the pore-like opening remains rather small at the beginning, and free-hand sections are almost impossible. During further growth (Fig. 18: a: C–E) the cells of the ectal excipulum more and more increase in size, especially in the basal part. The ascogenous hyphae grow upwards and reach the hymenial base where they form ascus

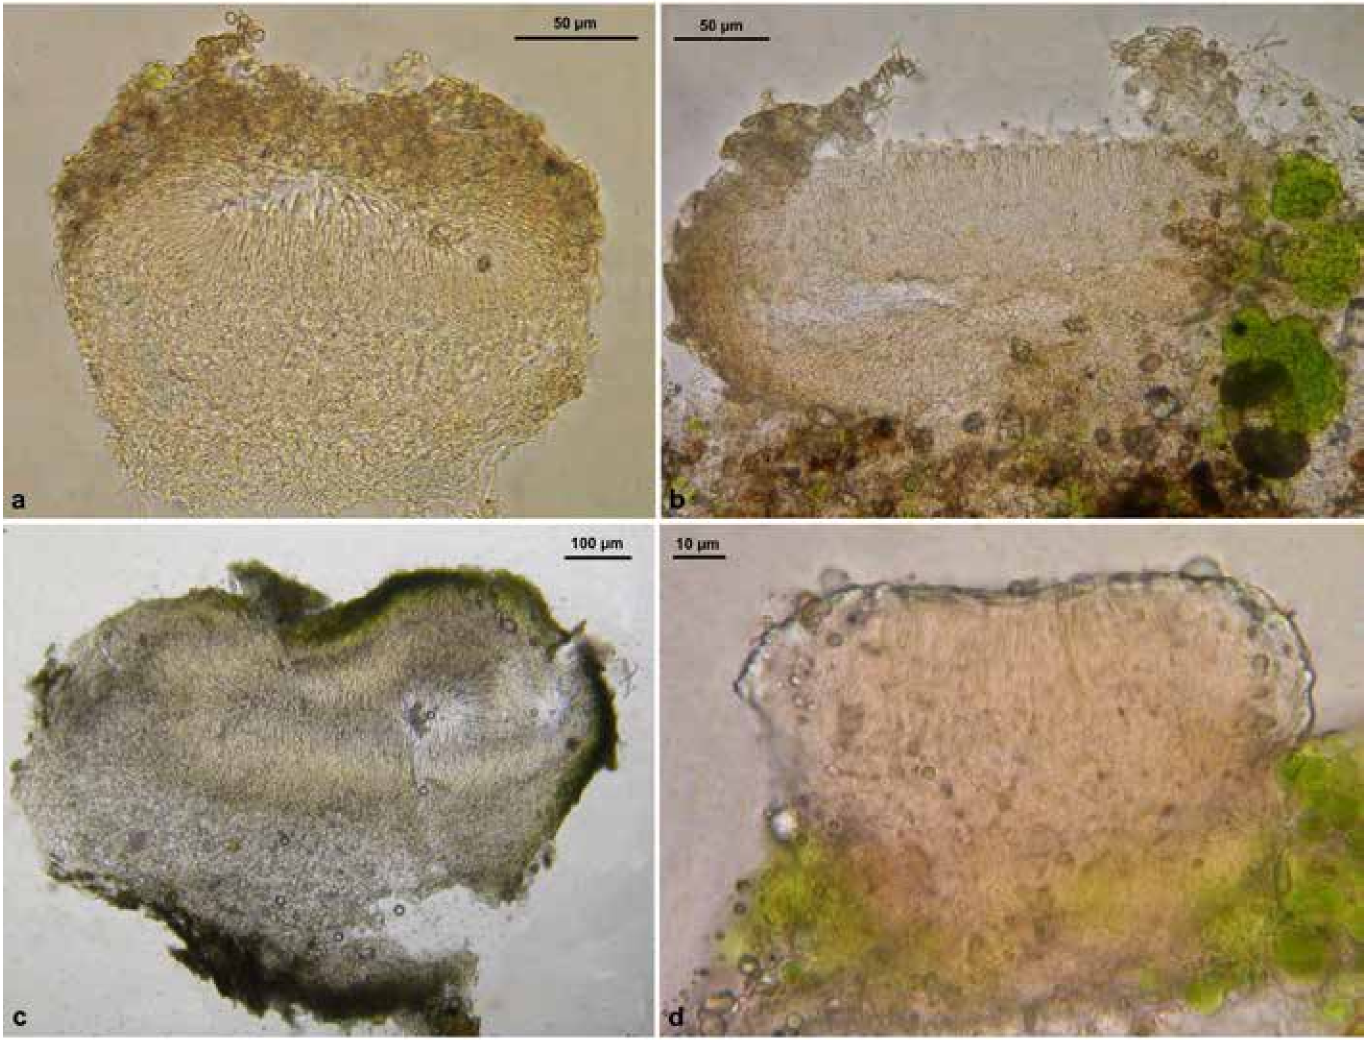

Figure 17: Apothecia in median section, belonging to three species of *Orbilia* and three different subtypes of cleistohymenial development. — **a**. young apothecium of *O. siculispora* (H.B. 8121, prohymenial phase), with marginal excipular tissue and hyphae covering the young hymenium; **b**. more developed apothecium of *O. siculispora* (mesohymenial phase), with exposed hymenium; **c**. mature apothecium of *O. carpoboloides* (H.B. 9233, late meso- to telohymenial phase), the covering layer bears inside a mature hymenium with the asci and paraphyses oriented upside down; **d**. young apothecium of *O. aristata* (H.B. 9226a, pro- or early mesohymenial phase); the paraphyses are already covered by thick exudate.

initials. In the medullary excipulum below the paraphysogenous system, some voluminous cells are found (~10 µm diam., referred to as 'inflated cells' in the present study). They are highly vacuolated. and their wall is stained by Methyl green while being surrounded by a clew ('peloton') of eosinophilous ascogenous hyphae (Bellemère 1968: 547).

In the late mesohymenial phase (stage F in Bellemère's study), a basal layer ('podium hypocentral') between medullary and ectal excipulum differentiates, which is without ascogenous hyphae. This layer represents the lower part of the medullary excipulum, but is sometimes difficult to delimit from the ectal excipulum. Particularly in desiccation-tolerant species

of *Orbilia*, a thin layer of hyphae forming a textura porrecta ('parathecium' in Bellemère's terminology) may occur which sharply separates ectal and medullary excipulum, but this was not observed in Bellemère's specimen. Bellemère pointed out that the exudate over the paraphyses attains its final thickness at stage F (Fig. 18: a), but we have seen fully developed exudate in *Hyalorbilia* and sections *Hemiorbilia* and *Aurantiorubrae* also in the prohymenial phase (Fig. 17: d).

Sexual reproduction. Details about gametangiogamy in *Orbiliomycetes* have very rarely been investigated. Bellemère (l.c.) described the ascogonial cells as having the shape of a small dense clew (Fig. 18: b). Descals et al. (1999: fig. 9) observed hyphal coiling around 3-septate spermatia during formation of apothecial initials in *Orbilia rosea* (as *Orbilia* sp.). An accidental observation in *Hyalorbilia orbiliicola* (Fig. 19) shows helicoid gametangial branches which probably conjugate similarly as in *Ascodesmis* (*Pezizales*) as reported by Claussen (1905, in Gäumann 1964: fig. 191) or in *Talaromyces* (*Eurotiales*) as reported by Emmons (1935, in Gäumann 1964: fig. 132).

We have not conducted studies with single spore isolates, therefore, we have no results on mating types in *Orbiliomycetes*. Yet, a few literature reports give hints that heterothallism occurs. Descals et al. (1999: fig. 9) obtained apothecial initials in a monoconidial isolate of *Orbilia rosea* which showed fusion between microconidia and receptive hyphae of the same colony, but these initials did not reach maturity. Another, apparently multiconidial isolate of that species developed mature apothecia (l.c.: fig. 8). Guo et al. (2009b) found in their studies about sexual reproduction capacity of orbiliaceous anamorphs that none of the 65 single conidial isolates of apparently over 60 different species produced apothecia, and also some multiascospore isolates did (8 out of 20 isolates, about 5 out of 10 species). The ascospore cultures originated from apothecia collected in the field, whereas the conidia were taken from cultures isolated from soil, dung and plant substrate.

Guo et al. (l.c.) speculated that those strains obtained from conidia belonged to a genotype that might have lost the ability of producing a sexual phase, and that such loss of sexual reproduction is frequent in nature. In our opinion, apothecial reproduction was perhaps only suppressed because of a missing mating type in the single conidium isolates. The authors obviously did not test cultures gained from single ascospores, nor cultures gained from single conidia grown in multiascospore isolates: possibly such cultures would likewise have failed to produce apothecia. In the case these tests will show the predicted results, we may conclude that heterothallism was the reason for the failure of apothecium production. Webster & Descals (1979: 420) emphasized the usefullness of preparing multispore cultures along with cultures derived from single spores: 'If ascomata or basidiomata develop in [multispore] cultures, but fail to develop in cultures derived from single spores, this may indicate that the fungus is heterothallic.'

Growth rate, **age of apothecia**. The growth rate of apothecia was roughly evaluated in some species by placing them in a water-tight box at ~18–22 °C. Young apothecia of *Hyalorbilia* *inflatula* (IVV: H.B. 9041a) and *Orbilia leucostigma* (IVV: H.B. 10003) increased in diameter by 25–38 µm per day, evaluated during an observation period of 4 days. When starting from hypothetical initials of ~100 µm diam., this corresponds to an age of 7–12 days for adult apothecia with a final diameter of 0.3 mm, or 30–40 days with a final diameter of 1.5 mm in diam. However, the growth rate decreases with apothecial size. In *Orbilia* cf. *cotoneastri* (IVV: H.B. 9051b) apothecia showed a growth rate of (32–)60–65 µm diam. per day, evaluated during an observation period of 7 days, during which apothecia increased, e.g., from 0.33 to 0.76 mm in diam. Desiccation-tolerant apothecia showed a lower growth rate when kept under continuous moisture at room temperature: apothecia of *O. aristata* (H.B. 9406a) and *O. subtrapeziformis* (H.B. 9406b) grew only by about 5–10 µm in diam. per day. Apothecia would then attain a diameter of 0.3 mm after ~20–40 days.

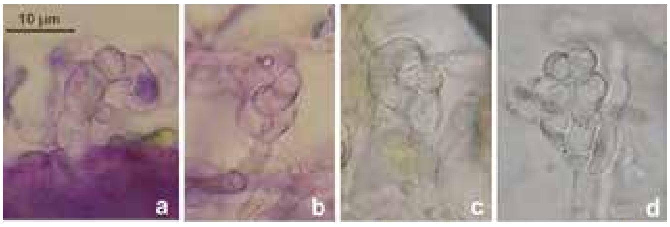

Figure 19: Presumed gametangial branches in *Hyalorbilia orbiliicola* (H.B. 9077b), formed at the apothecial margin of immature *Orbilia eucalypti*, on which *H. orbiliicola* grows as a parasite.

However, continuous conditions of warm temperature and high moisture are exceptional on xeric substrate, even in a cold-temperate humid climate, therefore, desiccation-tolerant apothecia in the natural environment attain a much higher age.

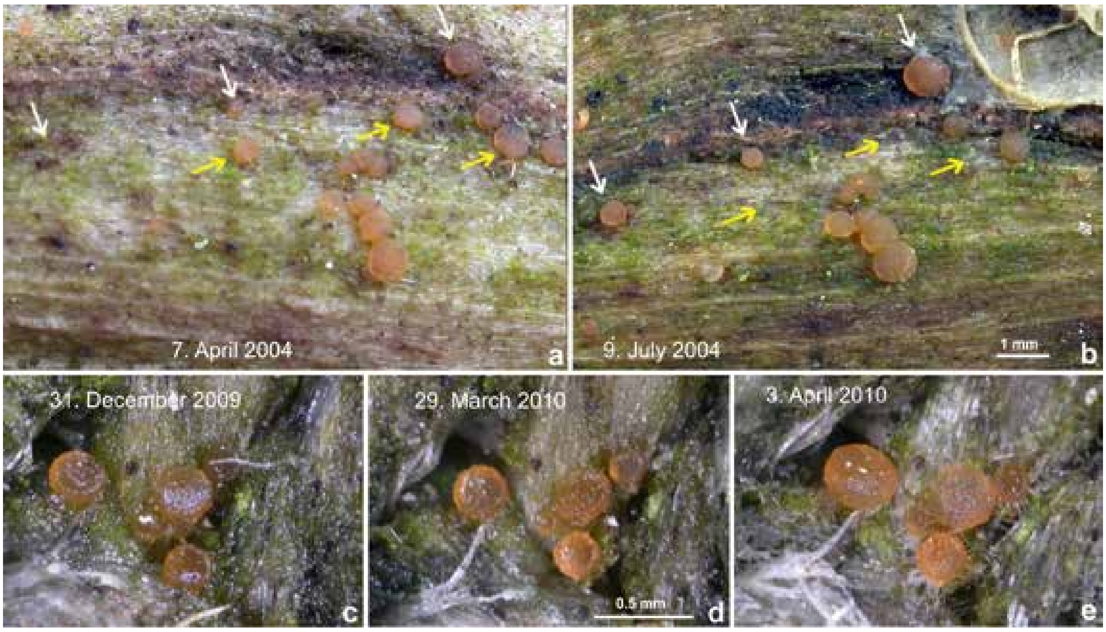

Figure 20: Apothecia of *Orbilia* on xeric substrate in our garden in Pfrondorf (Tübingen) monitored during several months (living state). — **a–b**. *O. trapeziformis* on a decorticated branch of *Juglans* (H.B. 7508c); some apothecia were consumed by animals (yellow arrows), while small apothecia strongly increased in size (white arrows); **c–e**. *O. aristata* on a rotten rope (H.B. 9226a); apothecia survived the winter without showing noteworthy growth, **e**. 3 days after transfer into a Minigrip closure bag kept at room temperature.

Apothecial growth of *O. trapeziformis* under field conditions, with alternate moist and dry periods during 3 months in early summer, can be seen in Fig. 20: a–b. A growth rate of 150–270 µm in diam. in smaller and 50–140 µm in more adult apothecia was observed, which results for the smaller ones in an average rate of ~1.5–3 µm diam. per day. However, in the winter season apothecial growth stagnates: *O. aristata* did not increase in size in a field experiment during a period of 3 months, though frequently moistened by rain and snow (Fig. 20: c–d). However, when transferred to a moist chamber at room temperature, apothecia increased by 55–85 µm in diam. during less than 3 days, which is ~20–30 µm per day (Fig. 20: e).

From this and other field observations we conclude that apothecia in temperate humid areas on xeric substrate attain an age of about 1/2–1 year. In a semihumid subtropical (mediterranean) climate they may grow up during the moist winter months, survive the following dry summer in a dormant state, and resume growth next winter. In semiarid to arid regions there can be no doubt that apothecia attain an age of around 5–10 years, during which period they experience only very rare and short intervals of hydration. There is always the possibility, however, that invertebrates consume some apothecia of a population. This was the case in the experiment with *O. trapeziformis* (Fig. 20: a–b): during June three of the observed apothecia disappeared (yellow arrows), while at the end of July only a few apothecia remained (not shown).

Asci

Ascogenous hyphae and development of asci. The situation of ascus bases in *Orbiliomycetes* is rather complicated, therefore, it seems justified to give a short survey on croziers in ascomycetes in general.

Very similar as with the presence or absence of clamp connections at the secondary mycelium of basidiomycetes, two very different main types of septation can be observed in the generative ascogenous hyphae of ascomycetes: (1) the individual cells are connected by croziers which separate adjacent cells by two septa; (2) the ascogenous hyphae are simple-septate, with a single septum between each cell. Therefore, asci arising from croziers have usually two basal septa (Fig. 21: 1), whereas asci arising from simple septa have usually one basal septum (Fig. 21: 4). However, simple-septate ascus bases may possess two or sometimes three basal septa, but then the ascus base is bi- or trifurcate (Fig. 21: 5), whereby a younger ascus emerges from the base of the older ascus, not from the crozier of the ascogenous hypha.

In contrast to basidiomycetes, the presence vs. absence of croziers has received comparatively little attention in taxonomic treatments in most groups of ascomycetes, including lichenized groups, with a few exceptions. For inoperculate discomycetes it was mainly White (1942, 1943, 1944), Berthet (1964b), Arendholz (1979), Huhtinen (1990a: 66), Hengstmengel (1996: 192), Baral (e.g., 1992: 354, 1997, 1999, 2015 etc.), Baral & Marson (2001), and Baral et al. (2009), who have emphasized and discussed the taxonomic value of the ascus base. Huhtinen (l.c.) and Hengstmengel (l.c.) gave a detailed history on the relevant literature on croziers and clamps (see also below).

Croziers are formed during conjugate or sometimes sequential nuclear division (mitosis) of the dikaryon in the terminal cell of an ascogenous hypha. A lateral outgrowth is formed at the apex or some distance below, which curves downwards. After the two nuclei of the dikaryon performed mitosis, each of the two resulting nucleus pairs are separated by a septum (Fig. 21: 1c, 2a). Thereafter, the downwards curved outgrowth fuses with the stalk cell. As a result, two septa occur between the young ascus and the supporting ascogenous hypha. In simple-septate ascus bases only one septum occurs that separates adjacent cells of the ascogenous hyphae (Fig. 21: 4, 5).

A special type of simple-septate hyphae is termed pseudoclamps in basidiomycetes (Clémençon 2009: 155, fig. 1E). A fully agreeing equivalent of pseudoclamps as seen with the LM is often observed in ascomycetes (Fig. 21: 6): a short lateral downward protuberance or hook emerges at the base of the young ascus, which neither fuses with the stalk cell nor does it give rise to a further ascus. Such ‘pseudoclamps’ are typical of some taxa of *Pezizales* (Berthet 1964b: pl. XII fig. 5, pl. XIII figs 4–5, *Humaria* and *Helvella*) and *Helotiales* (e.g., Berthet 1964b: pl. XI fig. 7, *Lachnellula*; Baral 1984, Baral & Matheis 2000, mainly *L. abietis* and *L. splendens*; Huhtinen 1987b, Baral

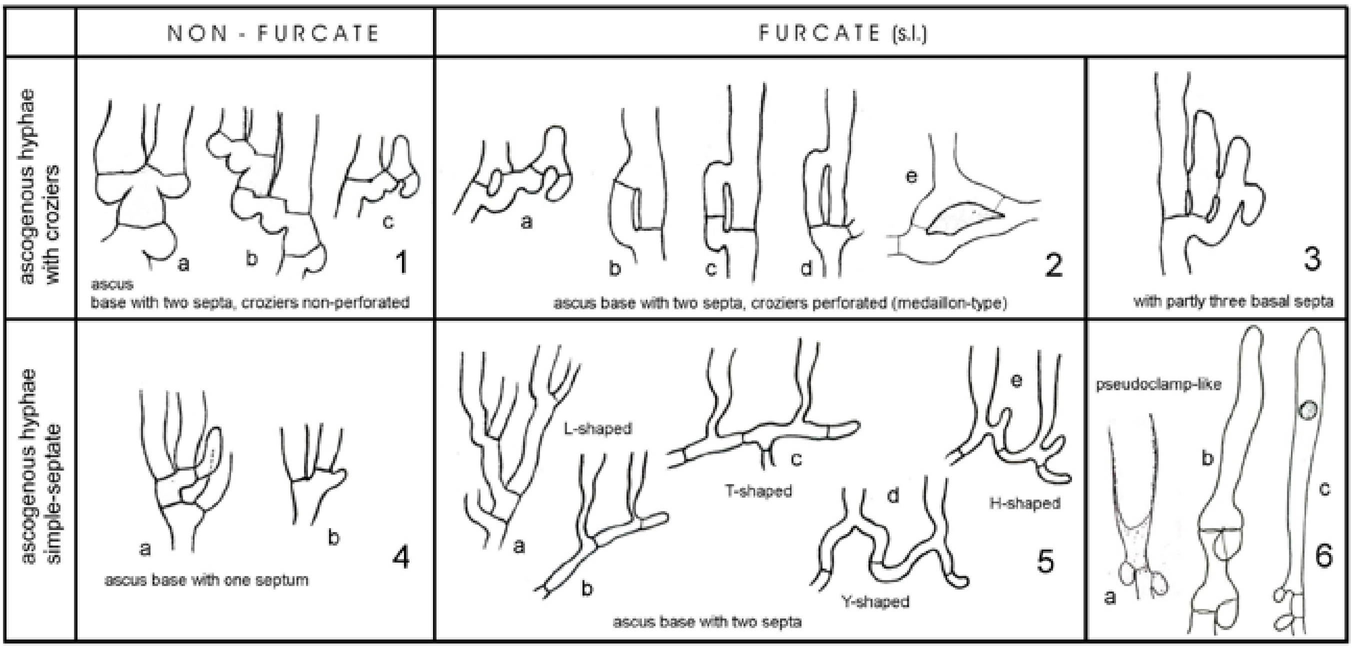

Figure 21: Survey on the different types of ascus bases occurring in ascomycetes. — **1–3**. croziers, **4–5**. simple septa, **6**. pseudoclamp-like. Within *Orbiliomycetes* types **1–5** occur. Drawings schematic, except for **2e** (*H. fusispora*, H.B. 8408), **3** (*H. erythrostigma*, H.B. 6605), **6a** (after Baral & Matheis 2000, *Lachnellula abietis*, as 'crozier-like, not rejoining'), **6b–c** (after Berthet 1964b: pls XI–XII, as 'pleurorhynque à crochet libre', **6b**. *Helvella elastica*, **6c**. *Trichoscyphella calycina* s.auct. = *Lachnellula* ?*subtilissima*).

1993a: 9, *Protounguicularia transiens* [= *P. barbata*]). In the *Orbiliomycetes* pseudoclamp-like ascus bases have so far never been observed, but upward protuberances that similarly do not further develop occur in the H-shaped type of furcate ascus bases (Fig. 21: 5e).

Like pseudoclamps, pseudoclamp-like ascogenous hyphae occur with or without a septum between protuberance and mature ascus. They are often misinterpreted as croziers, especially when the asci are detached, but can then be distinguished from true croziers by the protuberance having a rounded end (Huhtinen 1990a: 67). However, they may rarely occur mixed with croziers in some species of some genera (e. g., Baral & Matheis 2000, *Lachnellula*).

Ascogenous hyphae with croziers are probably generally dikaryotic in all groups of ascomycetes. Simple-septate ascogenous hyphae, in contrast, were shown by Weber (1992: 68) to be either purely monokaryotic, or mixed with dikaryotic cells, depending on the species of *Helotiales* investigated. In the former case all cells of the ascogenous hyphae contained only one nucleus, and these nuclei had always the double relative DNA content (= diplontic), in comparison with closely related taxa that possessed croziers. In the latter case, a mixture of diplontic monokaryons and haplontic dikaryons occurred, and this represented the majority of studied species. But even in species with croziers some diplontic monokaryotic cells were rarely noted (Weber l.c.).

Up to now, the alternative terms 'pleurorhynque' (pleurorhynchous) and 'aporhynque' (aporhynchous) are used instead of 'croziers' and 'simple septa', mainly by French mycologists. This usage traces back to Chadefaud (1943) and Berthet (1964b), who applied them to both operculate and inoperculate discomycetes. Although authors have asserted that these alternative terms are largely equivalent (Huhtinen l.c.), Chadefaud's original concept referred to dikaryotic hyphae in both cases: in the aporhynchous case the cells are wide enough to permit conjugate division of the dikaryon without forming a crozier. Therefore, simple-septate, purely monokaryotic ascogenous hyphae are not aporhynchous, and appear to have been unknown to Chadefaud.

Chadefaud (1943) separated a further type ('acrorhynque'), which he described for *Tarzetta* ('*Pustularia*') *catinus*. It is characterized by a terminal uninucleate cell which does not further develop nor fuse with the uninucleate basal cell, and one or several dikaryotic cells between basal and terminal cell. The dikaryotic cells give rise to asci, while the terminal and basal cell remain uninucleate.

In taxonomic treatments dealing with the ascus base, nuclear numbers in ascogenous hyphae are usually unknown, therefore, a classification in Chadefaud's sense is not easily practicable. From the above it is evident that not all simple-septate hyphae are aporhynchous. Chadefaud's illustration of *T. catinus* is reminiscent of the situation of simple-septate ascogenous hyphae in the *Helotiales* as well as *Orbiliomycetes*. Yet, it also resembles the pseudoclamp-like case, because the terminal cell in the acrorhynchous type strongly resembles the protuberance of pseudoclamps.

Although not fully understood from their genetical background, the two character states croziers and simple septa provide a valuable tool for the delimitation of taxonomic entities in the ascomycetes. In the *Pezizales*, for instance, all studied members of *Sarcoscyphinae* appear to be simple-septate (e. g., Berthet 1964b), whereas *Morchellaceae* and *Helvellaceae* comprise taxa with and without croziers (Berthet 1964b, Häffner 1987). Similarly, many genera in the *Helotiales* include species with and without croziers (e. g., White l.c., Huhtinen l.c., Hengstmengel l.c.). A comparable variation between presence and absence of clamps is known within different genera of *Agaricales* (Tehler 1988: 244).

For instance, in *Hyaloscypha*, *Hymenoscyphus*, or *Lachnum* (*Helotiales*) the ascogenous hyphae frequently differ between very closely related taxa in this respect. In such cases, dividing a genus according to ascus base features would result in highly artificial, polyphyletic groups. Huhtinen (l.c.) found that roughly half of the accepted taxa of *Hyaloscypha* lack croziers. He merely applied the varietal rank to taxon pairs which sharply differed in the ascus base but only gradually in other features, whereas Baral (1999) used the species rank for similar cases in *Helicogonium* W.L. White. However, populations with and without croziers were accepted by Baral (l.c.) in *Helicogonium orbiliarum*. The two character states may exceptionally even occur within a single apothecium (rarely seen in *Proliferodiscus pulveraceus*, Baral ined., or *Pyrenopeziza mercurialis*, Huhtinen 1990a: 66).

From the above it is clear that the crucial difference between croziers and simple septa is linked to the presence vs. absence of a junction between terminal (ultimate) and basal cell. On the basis of detached asci alone it is, therefore, quite impossible to distinguish between croziers with or without a large perforation (medaillon-type), a simple-septate bifurcate ascus base, or the pseudoclamp-like type. In detached non-furcate asci the presence of croziers is more or less recognizable, especially in the turgorless state, by a swollen base with two usually closely adjacent truncate zones which are often oriented to each other at an obtuse angle, whereas a simple-septate, non-furcate ascus base without downward protuberance possesses one truncate basal end which represents the single septum of the ascus.

In the basidiomycete *Schizophyllum commune*, which has heterokaryotic hyphae with clamps, it was shown that monokaryotic hyphae, being artificially prepared from isolated protoplasts, were simple-septate. Homokaryotic hyphae (with two identical nuclei) were also simple-septate but sometimes formed pseudoclamps (Wessels et al. 1976). Later research revealed that mutations in certain genes may result in pseudoclamp formation of usually clampless hyphae (*Coprinus*, Murata et al. 1998).

Situation in the *Orbiliomycetes*. In contrast to *Helotiales*, in which many genera are heterogeneous in regard to crozier formation, the two large genera of *Orbiliomycetes* behave consistent in the ascus base. In all 34 species of *Hyalorbilia* with a known teleomorph recognized here, the asci arise from croziers with or without perforation (Fig. 21: 1–3). Also the genera *Liladisca*, *Lilapila*, and *Pseudorbilia* possess croziers without perforation. Asci of *Amphosoma* (4 spp.), *Bryorbilia* (1 sp.), and *Orbilia* (about 450 spp.) arise from simple septa (Fig. 21: 5), with very rare exceptions of perforated croziers in single asci (like Fig. 21: 2). All these genera are separated by a number of characteristics, therefore, the presence versus absence of croziers in *Orbiliomycetes* has a high significance at the generic level, a view which is supported by molecular data. The small and very uniform genus *Lecophagus* is exceptional within the class in showing either simple-septate ascus bases (as in Fig. 21: 4) or non-perforated croziers (as in Fig. 21: 1), depending on the species.

The nuclear conditions in the ascogenous hyphae have so far apparently never been explored in the *Orbiliomycetes*. We have observed nuclei in ascogenous hyphae only in *Lilapila oculispora*, in which a dikaryon was once seen in unstained living cells (Pl. 29: 2).

Ascogenous hyphae with croziers. Asci arising from croziers always possess two septa at the base, and frequently their stalks are comparatively short and thick. Normally, the two septa are closely adjacent, without a perceptible central perforation of the crozier (as in Fig. 21: 1). This corresponds to the current situation in the *Helotiales* and *Pezizales*. In some taxa of *Hyalorbilia* the croziers are sometimes of the ‘medaillon-type’, i. e., they form an arch over a smaller or larger, round to slit-like perforation, and the ascus base then looks more or less bifurcate, with the two basal septa somewhat distant from each other (Fig. 21: 2). Such perforated croziers are also known from a few genera of *Helotiales* such as *Lachnellula*, *Trichopeziza*, or *Perrotia* (Baral 1984, Baral & Matheis 2000). In rare cases, the perforation may be so large that the asci look prominently bifurcate (*H. fusispora*, Fig. 21: 2e), and only the arch-like connection between the two branches distinguish such a crozier from simple-septate ascus bases of *Orbilia*.

An aberrant type of croziers is characterized by a vertical septum above the perforation (Fig. 21: 3). This septum separates two adjacent asci and resembles an anastomosis though it has a different origin: a hook-like protuberance grows out of the upper part of the arch. Contrary to the normal crozier type, this protuberance later forms two septa, a vertical one between the new and old ascus, and a horizontal one at the place of fusion with the basal cell. Finally all asci except for the first have three septa at their base. This type of croziers was only observed in *Hyalorbilia anonyma* (Pl. 132) and in one collection of *H. erythrostigma* (Pl. 126: 6).

Ascogenous hyphae without croziers. Simple-septate ascus bases possess either one septum as observed in *Lecophagus* (Fig. 21: 4), or two or more septa which is the typical case in *Amphosoma*, *Bryorbilia*, and *Orbilia* (Fig. 21: 5). In the frequent latter case the stalk divides into two or more legs or branches of rather variable length. Each of these branches terminates in a single septum (or sometimes in a blind rounded end), thereby each branching point lacks septa, at least for one of the two branches. The ends of the branches may point in different directions.

Contrary to perforated croziers, the legs do not form a closed ring, instead, one of the two legs gives rise to a further ascus. Thus, the asci are connected to each other with their basal legs like a chain (Fig. 21: 5), and with some dichotomous branches they form a complex tree-like structure. As stated above, such chains formed by connected ascus bases are in contrast to ascogenous systems with croziers, in which several asci emerge from a single basal cell. Yet, in simple-septate ascogenous systems medaillon-shaped true croziers with an elongate perforation have occasionally been observed in a few asci of a few species (*Amphosoma resinicola*, Pl. 34: 1b, *O. cardui*, Pl. 906: 2b, *Orbilia epipora*, Pl. 901: 4b, *O. geijerae*, Pl. 784: 1b, *O. polybrocha*, Pl. 1003: 1b).

Often, one of the two legs of an ascus is very short or even absent so that the ascus base appears unbranched. In this case the missing leg is usually reduced to a septum at the lateral wall of the ascus stalk a good distance above the base of the other leg (Fig. 22: a, d). The presence of two septa is only obvious here if the connecting hypha is not broken, or not hidden behind the ascus stalk.

If two legs point downwards, the ascus base is currently termed bifurcate, in the present work also h- to (inversely) Y-shaped (Fig. 21: 5d, 22: f–j). Irrespective of whether the two legs form a narrow or wide fork, they do not fuse at their base to form a ring. One or both legs are sometimes divided in turn, resulting in trifurcate or higher-branched types (without septa at their branching points). A special case in which only one leg is branched results in a characteristic H-shaped base (typical of section *Orbilia*, Fig. 22: k–m). Here only those two legs

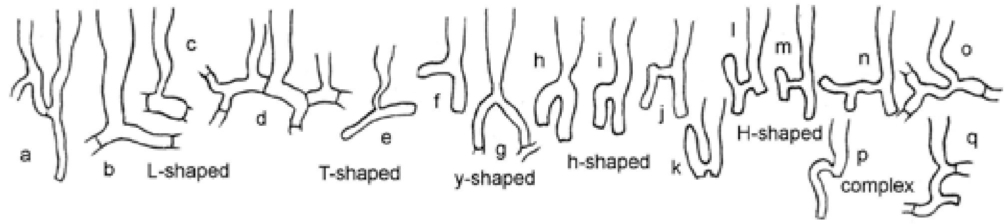

Figure 22: Different types of simple-septate ascus bases as they occur in *Amphosoma*, *Bryorbilia*, and *Orbilia* (schematic illustration).

oriented downwards are connected to adjacent cells (Fig. 21: 5e), whereas the third, upward oriented leg has a blind rounded end and does not give rise to further asci, even when the ascus achieves full maturity.

If the two legs are ± horizontally oriented, the ascus base looks L- (Fig. 22: b–d) or (inversely) T-shaped (Fig. 22: e). Such bases are quite frequent in *Orbilia* but can hardly be termed furcate. They are typical of, e. g., section *Helicoon*, and here the basal part is often distinctly thicker than the flexuous stalk (Fig. 22: c).

Simple-septate ascus bases strongly vary and usually represent several of the above-mentioned branching types within an apothecium. Actually, most species of *Orbilia* vary between furcate (Y and h) and non-furcate (L and T), with various intergradations, and each series and section shows this variation. Furthermore, the ascus stalk above the branching point varies in thickness and length (from entirely absent to very long), also in being often more or less irregularly flexuous, which results in rather variable ascus length values. Due to this striking variability, we did not make too much effort of presenting these various types in the drawings of a single species. Anyway, there are some tendencies recognizable: e. g., desiccation-tolerant species generally possess only L-, T-, Y- and h-shaped ascus bases, whereas the H-shaped type in combination with other types is characteristic of desiccation-sensitive taxa of series *Orbilia* and section *Arthrobotrys*, while rarly seen in desiccation-sensitive taxa of sections *Helicoon* and *Aurantiorubrae*.

No fundamental differences seem to exist between the furcate or otherwise branched ascus bases in *Amphosoma*, *Bryorbilia*, and *Orbilia*, compared to the simple-septate, usually unforked ascus bases seen in *Lecophagus* and in many species of *Helotiales*. Species of *Helotiales* and *Pezizales* without croziers usually have only one basal septum per ascus. However, in some groups the asci often have an L- or T-shaped base: they emerge from a straight, horizontal, oblique or vertical hyphal basal part ending up in two septa, the terminal septum giving rise to a further ascus (similar as in Fig. 21: 5a–b). Such cases were reported for the *Pezizales* by Berthet (1964b: pl. XI fig. 21, XII figs 6, 7, 13, 27, XIII figs 3, 9, 16, 17). Furcate bases as in *Orbilia* almost never occur in the *Helotiales*, but do occur, e. g., in some *Phacidiales* (*Helicogonium*, Baral 1999: 5), *Pezizales* (*Morchellaceae* and *Sarcoscyphinae*, Greis 1940, Berthet 1964b: pl. XI figs 22, 25, XIII figs 13–15; Greis 1940) and the *Saccharomycetales* (*Dipodascaceae*, *Lipomycetaceae*).

Phylogenetical considerations. – **Ascus base within *Pezizomycotina***. Our molecular phylogenetic analyses show a scattered distribution of croziers and simple-septate ascogenous hyphae within the *Orbiliomycetes*. Simple-septate ascogenous hyphae are typical of the genera *Amphosoma*, *Bryorbilia*, and *Orbilia* (Phyl. 1). Croziers are consistently present in the genera *Hyalorbilia*, *Liladisca*, *Lilapila*, and *Pseudorbilia*, and in some *Lecophagus* spp. A similar mixed occurrence of croziers and simple septa is known in other groups of *Pezizomycotina*, particularly in *Pezizales* and *Helotiales*. Here the croziers represent the predominant situation, whereas in *Orbiliomycetes* the simple septate ascus base is much more frequent.

This scattered occurrence of croziers and simple septa in various rather unrelated groups of *Pezizomycotina* indicates that one of these two morphologies represents an apomorphy with a polyphyletical origin, given that restoration of a lost character did not happen. Especially due to the more complicated shape of croziers and their genetic background of conjugate nuclear division of the dikaryon, it seems more probable that those species with simple septa have developed from ancestors with croziers, i. e., simple-septate ascogenous hyphae would then represent the apomorphic character state in all those taxonomic entities which comprise both morphologies (Fig. 23). This hypothesis is also shared by Cain (1948: 165) for ascomycetes in general, and is supported by a phylogenetic analysis of pezizalean genera by O'Donnell et al. (1997) (see also Baral 1999: 22).

A special type of simple-septate ascogenous hyphae, in which the ascus base shows a characteristic bifurcate shape, occurs, besides *Amphosoma*, *Bryorbilia*, and *Orbilia*, in a few very unrelated groups of *Ascomycota* (see above), which supports the polyphyletical origin of this character. As an example, some species of *Helicogonium* possess asci with a bifurcate, simple-septate base. These asci closely resemble those of *Orbilia*, especially section *Hemiorbilia*, where even the ascus apical wall thickenings look very similar. Yet, an evolutionary link can be excluded because ascospores of *Helicogonium* never contain spore bodies and their anamorph is phialidic and often develops directly from ascospores by budding. *Helicogonium* was tentatively placed in the tribe *Calloriopsideae* of *Leotiaceae* s.l. (Baral 1999: 20), for which later the new family *Helicogoniaceae* Baral was proposed (see Jaklitsch et al. 2016).

The two large genera *Hyalorbilia* (with croziers) and *Orbilia* (without croziers), which are both in a process of rich speciation, serve as an example which contradicts a theory advocated by Huhtinen (1990a: 67). The author observed that in *Hyaloscypha* (*Helotiales*) several 'taxon pairs' mainly differ in the ascus base which he thought to offer 'one of the first morphological signs of divergence'. He, therefore, separated these taxa only at the varietal level, and considered the frequent presence of such variation among closely related taxa of a genus as an indication for a rather 'active evolutionary stage' of the group. Genera lacking almost in total taxa with simple septate ascus bases (*Hamatocanthoscypha* and *Phialina* in his monograph) he thought to possibly represent older groups with a 'longer evolutionary history' in which 'the capacity for divergence has decreased'. This theory implies that those species with simple-septate bases are the more primary ones which in some groups disappeared during evolution, a view which is in conflict with the here presented hypothesis. The situation in the *Orbiliomycetes* hardly allows to apply Huhtinen's theory, as the largest genus *Orbilia* is consistently without croziers and, nevertheless, shows a high number of taxa in the process of divergence.

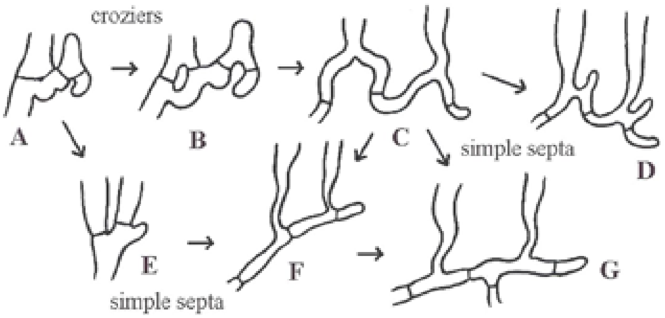

Figure 23: Hypothetical phylogeny from croziers to simple septa in *Orbiliomycetes*. — **A–B**: croziers (*Liladisca*, *Lilapila*, *Lecophagus* p.p., *Pseudorbilia*, *Hyalorbilia*), **C–G**: simple septa. Simple-septate ascus bases either unbranched, with one basal septum (**E**, *Lecophagus* p.p.), or branched, with two or more basal septa, Y-, L-, T-, H-shaped (**C–D**, **F–G**, *Amphosoma*, *Bryorbilia*, *Orbilia*).

Ascus base in other subdivisions of *Ascomycota*. When taking the whole *Ascomycota* into consideration, the first true croziers appeared, to the present knowledge, in the *Orbiliomycetes*, which branched off at first in the six loci ML analysis of Prieto & Wedin (2013). Only two subdivisions of more primitive ascomycetes, *Taphrinomycotina* and *Saccharomycotina*, separated earlier. True croziers in these two subdivisions appear to have never been reported. The asci of *Taphrina* are consistently without any kind of basal protuberances, and the asserted presence of a dikaryotic vegetative mycelium similar as in *Basidiomycota* (Martin 1940, see also Gäumann 1964: figs 182 ff.) was later rejected (see Landvik et al. 2003: 1028). Likewise, the ascogenous hyphae of *Neolecta* are always simple-septate and never showed any basal protuberances (Redhead 1977, Landvik et al. 2003, see also Baral IVV: H.B. 7428). Both genera have multinucleate hyphae in which nuclei form pairs and give rise to asci. The paired nuclei are apparently daughter nuclei, which might explain the absence of croziers (Landvik et al. l.c.).

In those genera of *Saccharomycotina* with a mycelial phase, the situation is less clear because an ascogenous system is in total absent, instead, the gametangium directly transforms into an ascus. In self-fertile taxa the subbasal conjugation branch of the ascus forms an arch with a smaller or larger perforation, similar to a crozier (*Endomyces*, Guillermond 1909, in Gäumann 1964: fig. 104; Helfer 1991: fig. 7). Redhead & Malloch (1977) observed in *Endomyces* crozier-like appendages which strongly resemble pseudoclamps, and the authors believed this to be degenerated croziers. However, Gäumann unmistakably spoke of male and female branches in this genus. Because of this similarity of the conjugation branches of anisogametangiogam (heterogam) taxa, it seems possible that all the ‘croziers’ reported in *Endomyces* concern the stage of conjugation or a reduction hereof.

Gäumann (1964: 113) emphasized that, in the phylogeny of ascomycetes, the genus *Myriogonium* Cain (= *Helicogonium*), which he accepted as belonging to the *Dipodascaceae* of *Endomycetales*, represents the first case of ascogenous hyphae with repeated crozier formation, i. e., the formation of croziers in a chain during mitotic divisions of a dikaryon. Yet, the genus is certainly not related to the *Saccharomycotina* but belongs in the *Pezizomycotina* (see p. 44).

Clamps of basidiomycetes. A long historical discussion about pro and contra of using different terms in asco- and basidiomycetes lasts up to now (see, e. g., Tehler 1988: 244). One of the asserted differences lies in the place where the hook-like outgrowth starts (apically in croziers, laterally in clamps), following the situation reported by Claussen (1912) in *Pyronema*. Yet, laterally outgrowing hooks were, e. g., figured by Björling (1942, in Gäumann 1964: fig. 249) in *Sclerotinia* and can actually often be seen in members of *Helotiales* (e. g., in *Hymenoscyphus*, Hengstmengel 1996: figs 4a, 5b). On the other hand, more or less terminal hooks were described in some basidiomycetes, e. g. in *Sebacina* (Rogers 1936). Another opinion stresses the restriction of dikaryons and croziers to the ascogenous hyphae in contrast to clamps which occur in the entire vegetative hyphal system of basidiomycetes (extended dikaryophase; see, e. g. Esser 1982: 545, Tehler l.c.). An ultrastructural difference lies in the presence of a dolipore in basidiomycetes in contrast to a simple pore with Woronin bodies in ascomycetes.

Authors doubting homology of croziers and clamps as established by Kniep (1915) were, e. g., Savile (1955: 76), who was fully convinced of a convergent evolution of croziers and clamps, by suggesting that basidiomycetes evolved from a taphrina-like ancestor lacking clamps, and Tehler (1988: 244) who supported Savile’s opinion. Authors postulating homology were many, including Rogers (1936), and also Hengstmengel (1996: 192), who concluded that there is general agreement about this topic, as both structures perfectly coincide in any respect of their cell wall morphology. Therefore, he suggested avoiding different terms in the two fungal divisions and to use the term clamps also in ascomycetes.

Homology of clamps and croziers would imply that a common ancestor of asco- and basidiomycetes existed which possessed this morphology. Clamps in *Basidiomycota* occurred apparently for the first time in some groups of *Ustilaginomycotina* (Begerow et al. 2014) and *Pucciniomycotina* (Aime et al. 2014). It was asserted that some groups of *Ustilaginomycotina* have croziers rather than clamps because the septa lack dolipores (Moore 1972), whereas the only group of the subphylum having dolipores (*Tilletiales*) lacks clamps (Begerow et al. 2014). A common ancestor for all *Basidiomycota* having clamps without a dolipore is thus imaginable.

In *Ascomycota* as well as *Basidiomycota*, taxa with simple septa and/or ‘pseudoclamps’ frequently occur as close relatives to taxa with croziers or clamps. This coincidence seems a further proof that the two divisions did not independently develop this morphology but inherited it from a common ancestor. The problem is that there is so far no case of crozier formation known in *Taphrinomycotina*, and in *Saccharomycotina* no ascogenous hyphae exist. The theory of a homology between croziers and clamps implies that the two latter subdivisions have lost croziers and/or ascogenous hyphae. The detection of a taxon with true croziers in this basal group could help clarifying the question.

The oldest fossil with clamps dates in the Visean of the Mississippian period of Carboniferous (~330 myr ago, Krings et al. 2011). This might correspond to the earliest diversification of *Pezizomycotina* which took place about 550–350 myr ago (see p. 133, Molecular clock).

Ascus maturation. During an early phase of maturation, the ascus elongates until it reaches almost the level of the paraphyses. In this phase the ascus is uninucleate. The large fusion nucleus is usually clearly visible in living material by its thin, slightly refractive nuclear membrane and a distinct homogeneously refractive nucleolus (Fig. 24: A–B, see also p. 96–97).

During meiosis the fusion nucleus divides into 4 nuclei. Additional mitotic divisions result in 8 or up to 128 nuclei, depending on the species. These nuclei and their nucleoli are much smaller and usually very difficult to see without applying nuclear stains. Asci up to this development stage are named 'young' in Verkley's (1995) terminology, whereas asci in which the ascospore wall is formed are referred to as 'immature'.

Four different states of mature asci in regard to the mixed occurrence of living and dead asci and spores. Herbarium specimens are either dead in all parts, or they are still viable in regard to all of their cells or often only a part of them. A possible vitality of dried material can be recognized under the light microscope after rehydration (see p. 26 ff.). Vitality depends on the desiccation tolerance of the species, i. e., the period of time the individual cells withstand dryness, also on the condition of the apothecia when collected.

The different cells of an apothecium may differ in their strength of drought tolerance, therefore, it is a normal case that living and dead elements are found side by side when a rehydrated apothecium is examined. But also apothecia collected in the fresh state may show dead cells. This phenomenon is of special interest concerning mature asci, which generally show a less pronounced tolerance than the spores within, or sometimes no tolerance at all. As a consequence, we need to distinguish four main states of mature asci, three of which being regularly found in preparations (Fig. 25). These four states correspond to the four possible combinations of living and dead asci and spores. However, intergradations may occur in which only some of the spores within an ascus are viable (see Figs 7: d, 25: c). In addition to this, the increase in ascus turgor from moderate to full turgescence provokes distinct changes in ascus size and spore arrangement.

State 1 (Fig. 25: a–b): A **living ascus** contains **living spores**. At normally occurring **moderate turgescence** of asci (state 1a) the cytoplasm (including vacuoles) of both ascus and spores is non-refractive and thus transparent. The spore wall and also the refractive SBs are distinctly visible. At this stage of development, the spores well correspond to ejected spores in regard to their shape and size, due to a more inelastic spore wall. State 1a is, therefore, the taxonomically most suitable one, and our illustrations of asci predominantly refer to it. For recognition of maturity of spores, this state is even superior to free spores since the latter, and also living spores inside dead asci, may either be immature, or may have undergone an ageing process, during which the SBs become considerably shorter and thicker by losing much of their taxonomic reliability.

Some minutes prior to discharge, the asci attain **full turgescence** (state 1b). At this stage of development the spores form a more or less compact spore cluster. The spores are usually considerably dehydrated and thereby shrink or collapse, the sporoplasm becomes somewhat refractive and less transparent, and the SBs rather obscure. The ascus vacuole attains its highest volume. Such maximum swollen asci show the highest contrast between spores and ascus vacuole, but are quite rarely seen in preparations.

State 2 (Fig. 25: c–d): A **dead ascus** contains **living spores**. Asci of this state have irreversibly lost their functionality. The ascus vacuole lacks a high percentage of its water due to damage of the plasma membrane. In the most frequent case the ascoplasm becomes refractive and intransparent (state 2a). The sporoplasm is transparent and the SBs are very clearly visible. The spore wall cannot be differentiated from the surrounding ascoplasm due to a similar refractivity index.

Such asci are frequently seen in recently dried material of desiccation-sensitive species, or in a few months or years old collections of desiccation-tolerant taxa, because of the limited tolerance of mature asci. The spores are no longer in their original arrangement but often occupy the whole length of the wider part of the ascus.

In a small number of dead asci the spore wall may nevertheless be clearly visible (Fig. 25: d: state 2b). In this case, the cytoplasm outside the ascus vacuole is apparently so strongly reduced that the area between spores and ascus wall remains transparent despite a high water loss. Asci of this type appear to derive from those which were fully turgescent when still alive (Fig. 25: a–b: state 1b). This would explain why asci of state 2b are only found in a comparatively small number, and also why such asci do not show the glycogen reaction typical of dead mature asci of state 2a and 4a.

State 3: A **living ascus** contains **dead spores**. This situation is very rarely found, especially in desiccation-tolerant species, perhaps due to some stress regarding water or nutrient availability while still in the field. It is in conflict with the general observation that spores exhibit a higher desiccation tolerance than asci do. Such asci may attain full turgescence and eject their functionless spores. A state 3b cannot be distinguished because in the compressed spore cluster the

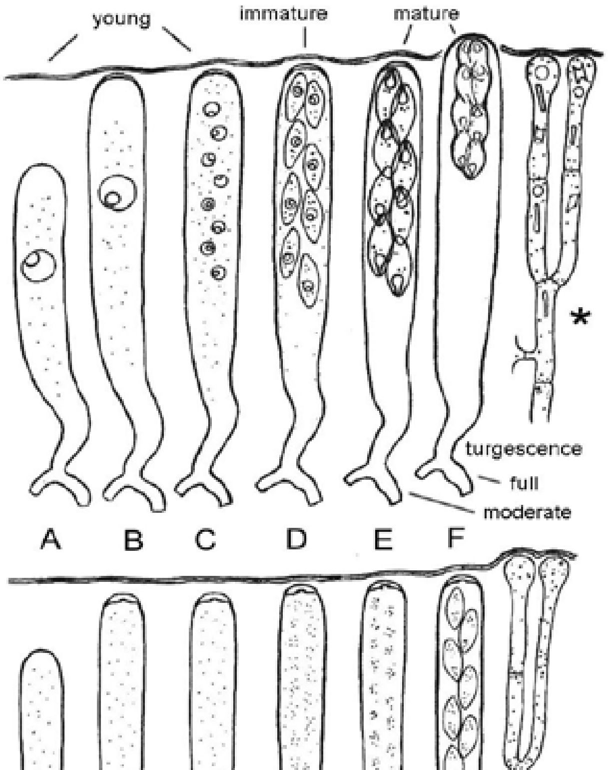

Figure 24: Schematic illustration of ascus ontogeny in the living (above) versus dead state (below).

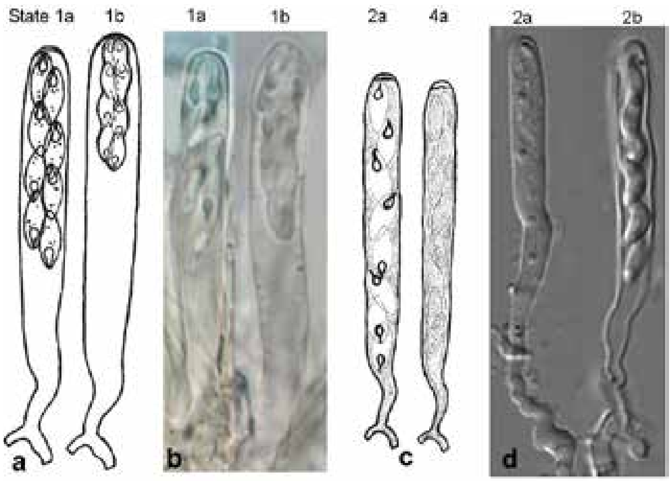

Figure 25: Different states of a mature ascus. — **a–b**. living asci (state 1), **1a**: at moderate turgescence, **1b**: at full turgescence; **c–d**. dead asci (state 2 and 4); 2a–b: containing living spores; 4a: containing dead spores; in 2a the ascoplasm is refractive and only the sporoplasm and SBs are clearly visible, whereas in 2b the ascoplasm is non-refractive, therefore also the spore wall is clearly visible. — **a**, **c**. Schematic drawing of fictive species, **b**. *Orbilia vitalbae* (phot. R. Tena), **d**. *O. neocomma* (phot. Z.F. Yu, DIC).

spore contents are too indistinct to decide whether the spores are alive or not.

State 4 (Fig. 10: d–e, 25: c): A **dead ascus** contains **dead spores**. In the more frequent case (state 4a), both asco- and sporoplasm are refractive. The SBs lost their refractivity and are usually completely invisible. The spores are invisible or very difficult to discern in mountants like H_2O (Fig. 25: c) or KOH, but they usually become clearly visible when applying cytoplasmic stains to a KOH mount, such as IKI, MLZ, CB_L, or phloxine, because the spore wall thereby remains unstained (Fig. 10: d–e). Alternatively, the spore wall may become discernible in some species when staining with CR.

As with state 2b, in a few asci the dead spores may very clearly be visible including their cell walls (state 4b). Asci of state 2b and 4b appear to originate from fully turgescent asci, which can be concluded from the absent glycogen reaction.

Ascus wall, **type of apex**. Light-microscopic observation allows to recognize three main ascus types within the *Orbiliomycetes*, based on external shape and internal wall thickening of the ascus apex (see Fig. 27). These three types often coincide with other features of the teleomorph, which supports their taxonomic value. Our molecular analyses confirm that ascus apex morphology provides a valuable tool in the classification of genera and infrageneric groups within the class (see Tabs 57, 63).

Five electron-microscopic studies (TEM) on the ascus apex of *Orbilia* came to our notice. What can be seen with the TEM in these studies well corresponds to results gained with the LM, and supplies only little additional information. Four of them (Bellemère 1977, Benny et al. 1978, Liu 2006, Kumar et al. 2012) present a comparatively primitive ascus apex, characterized by a continuously thin ascus wall that lacks any clear ring or pore structure. Although each of these authors studied only a single species with the TEM, thin-walled asci were believed to be typical of the genus, which was also supported by LM-studies, e.g., by Bellemère (1968: fig. 50).

In the present study about 73% of the species assigned to *Orbilia* possess asci with such a thin-walled, more or less truncate apex, whereas in the remaining 27% of the taxa the apex is abruptly thick-walled to a varying extent, due to a swollen endotunica that is often provided with an apical chamber. This ascus type was first reported by Baral (1994: fig. 2), and a new subgenus *Hemiorbilia* was proposed for it. In his unpublished TEM study, Müller (1998) treated two species with this ascus type (Fig. 29), besides one with a truncate thin-walled ascus apex.

Although our monograph favours the study of living cells, ascus apical apparati need to be studied primarily in the dead turgorless state (see also p. 50, Influence of ascus turgor). Here the differences in wall thickness and shape between the three main types are much more evident, whereas in living asci neither shoulders nor pronounced wall thickenings can be seen. Nevertheless, living turgescent asci should simultaneously be studied whenever available, in order to recognize the rather strong differences to the dead state, and to avoid misinterpretations in regard to spore discharge.

Ascus wall layers. With the TEM, Bellemère (1977: fig. 7A–B) found the ascus wall of *Orbilia leucostigma* (section *Orbilia*) to be four-layered (Fig. 34: a–b), whereas Benny et al. (1978: figs 6, 8) and Kumar et al. (2012) found in *O. sarraziniana* and *O. tenuispora* (section *Helicoon*) a two-layered wall (see Fig. 34: c–d). Both subgroups of *Orbilia* have an ascus apex of the truncate-shouldered type without apical thickening. Bellemère's two outer layers ('couche a' and 'couche b') appear to correspond to the darker outer layer of Benny et al. and Kumar et al., who found this layer to be comparatively thicker in the shoulder region. Verkley (1992–95) found a two-layered ectotunica (as 'outer layer') in many *Helotiales*, and referred to it as 'outer and inner stratum of the outer layer'. He likewise observed that the endotunica (as 'inner layer') may also be composed of two strata, of which the inner one is often most reactive. Possibly, the four strata observed by Verkley in the *Helotiales* correspond to the four layers described by Bellemère in *Orbilia*.

When transferring these results to our LM observations on more or less thick-walled ascus apices in *Orbiliomycetes*, we conclude that Bellemère's two outer layers correspond to the refractive outer part of the ascus wall here referred to as ectotunica (also termed 'ectoascus', 'exotunica', or 'exoascus', see also Baral 1987a). In species without apical thickening we usually could not clearly differentiate an inner layer (endotunica, also termed 'endoascus') in the apical region, although Bellemère's 'couche c' obviously represents a very thin low-refractive endotunica.

Thick-walled ascus apices occur in most members of subgenus *Hemiorbilia* and in some of section *Ovoideae* (subgenus *Orbilia*). Here the endotunica forms the main part of the strongly swollen apical thickening. Two species with such asci, *O. vinosa* and *O. aristata*, were studied by Müller (1998, see Fig. 69): ecto- and endotunica strongly differ in electron-density, but sublayers within each of the two main layers are not noticeable.

Bellemère's 'couche d' looks on his pl. 7A as if it represents the plasmalemma of the ascus. However, our LM-studies in *Orbiliomycetes* with apically thickened ascus wall show, particularly regarding species with large asci, that the inner boundary of the endotunica is visible in turgorless asci as a thin medium refractive layer, suggestive of Bellemère's 'couche d'. This layer is distinctly enhanced in contrast when stained with CR_{SDS} (Fig. 30: b).

At the ascus apex outside the ectotunica a layer is often found which is currently referred to as 'periascus'. This represents an excretion of the ascus wall and is, therefore, treated here under 'excretions, gel on asci and paraphyses'. In species with black apothecia the periascus may carry an olive-brown pigment.

Concerning the terminology around the apical thickening see also p. 49 (Apical thickening of the ascus wall).

Amyloidity and dextrinoidity. All parts of the ascus wall including the ascogenous hyphae consistently lack a positive (hemiamyloid or euamyloid) iodine reaction in all species of *Orbiliomycetes* examined. Even after KOH-pretreatment, both IKI and MLZ did not provoke any blue reaction at all (see Baral 1987b).

A few literature reports of amyloid (blue) ascus apices in *Orbiliomycetes* are erroneous and some of them might be explained by the presence of yellow pigments in the paraphyses staining blue-green with iodine. Three of the four species of *Orbilia* treated by Thind & Sharma (1980) were said to have amyloid ascus apices (in MLZ). Yet, reexamination of one of their material (*O. curvatispora*, = *O. auricolor*) proved that the asci are inamyloid. Likewise, amyloid ascus apices were reported by Starbäck (1899) for *Orbilia caudata* ('very faintly') and by Cash & Corner (1958) for *O. fici* (= *O. blumenaviensis*), but reexamination of their type material indicated the contrary. Also Vesterholt (in Hansen & Knudsen 2000) stated the asci of *Hyalinia rubella* (= *Orbilia rubella* s.l.) to have an amyloid pore.

In other cases, predominantly in the older literature, reports of blue iodine reactions of asci are coupled with further discrepant features, which indicate that the species belongs to the *Helotiales*. For example, Nannfeldt (1932: fig. 40c, n. 3849) included an unidentified species in *Orbilia*, although he stated on his herbarium label 'Asci I+'. Reexamination revealed that it probably belongs to the genus *Cistella* Quél. (IVV: H.B. 7328).

A faintly reddish reaction was inconsistently observed in a few species of subgenus *Hemiorbilia* section *Lentiformes* (*O. pileosoma*: Pl. 156: 1c), *Hemiorbilia* (*O. junci*: Pl. 389: 1c, *O. vibrioides*, several spp. around *O. myrioobliqua*: Pl. 375: 2e): the comparatively thick apical wall (type A) showed an inconsistent reaction in MLZ (especially when pretreated by heated KOH). In IKI (with or without KOH-pretreatment, or when pretreated by H_2SO_4, Fig. 30: d) no clear reaction could be observed. This reaction fits the definition of dextrinoid (Baral 1987b: 424). In *O. pileosoma* it was very clearly perceptible as a light red stain, whereas in *O. junci* and *O. myrioobliqua* it was only pale red. Only some of the collections of *O. pileosoma* and *O. myrioobliqua* showed the reaction, whereas others were completely negative. Within the discomycetes this reaction seems to be a rare though possibly overlooked feature of inamyloid apical thickenings.

Shape of the pore prior to dehiscence. Bellemère (1977) saw a very minute apical indentation of the endotunica that resembles an apical chamber (Fig. 34: b). This could, however, also be interpreted as a structure that emerged by somewhat irregular, wave-like swelling of the endotunica. A slight apical chamber appears to be visible also on Benny et al.'s (1978) TEM section in front view (truncate-shouldered aspect, Fig. 34: c). What Kumar et al. (2012: fig. 11) reported as electron-light zone (EZ) between apical ascus wall and ascoplasm appears to concern plasma detachment rather than a wall structure.

The presence of an apical chamber was frequently seen under the LM in species with an apical thickening (section *Lentiformes* p.p., section *Hemiorbilia*, section *Ovoideae* p.p.; Figs 28–29). This chamber is formed by an indentation of the endotunica in the central region of the apical thickening. It can also be seen in living asci, but it occurs inconsistently within a preparation, irrespective of the living or dead state (Fig. 31). Since the truncate-shouldered asci are thought to have evolved from ancestors with a hemispherical thick-walled apex, (see p. 254, Plesiomorphic characters in *Orbiliomycetes*), thin-walled apices might well possess some remains of both apical thickening and apical chamber.

Shape of the pore after dehiscence. Benny et al. (l.c.: fig. 7) and Kumar et al. (2012: fig. 13) observed that dehiscence results from a tearing of the thin-walled, flattened apical region between the more thick-walled lateral shoulder areas, but the spatial shape of the pore could not be seen. Our observations with the light microscope showed that the asci of *Orbilia* open by a comparatively large slit- or fissure-like pore. However, although quite clearly visible under the LM, emptied asci with an opening lying in a favourable orientation are not easy to detect. Slit-like pores of emptied asci were so far only seen in a few species of *Orbilia* sections *Lentiformes* (*O. patellarioides*: IVV: H.B. 9173a, *O. atrolentiformis*: Pl. 152: 1c, *O. pileosoma*: Pl. 157: 1n–o, *O. myriolentiformis*: Pl. 177), *O. flavida* (IVV: 23.V.2018), *Hemiorbilia* (*O. junci*: Kohlmeyer et al. 1998: fig. 8, *O. allantoobliqua*: IVV, *O. velutina*: Pl. 282: 1t, *O. occulta*: Pl. 355: 4d, *Habrostictis* (*O. spathulata*: Pl. 640: 1c), and *Orbilia* (*O. renispora*: Pl. 882: 3e). Apparently, the asci of all species of *Orbilia* do open by a more or less large slit-like pore, irrespective of having or lacking shoulders, an apical thickening, or an apical chamber, but this needs confirmation from further taxa from different series.

It is not fully clear whether the slit in truncate-shouldered asci runs from one shoulder to the other, or transversely between the shoulders, neither in *Orbilia*, nor in *Taphrina* (Fig. 39: m–o) and *Neolecta* (Fig. 39: j). However, in *O. renispora* the former appears to be the case when comparing Fig. 3d and 3e in Pl. 882. In *Pseudorbilia* the asci appear to open by a pore, which is ± round in outline and tends to be lateral (Fig. 26: d–f). In *Lilapila* a slit-like apical pore was indistinctly seen, while in *Hyalorbilia* no observations on the apical pore were made so far.

Thakur & Zachariah (1989: fig. 2 E–F) saw with the SEM a round pore with an operculate opening mechanism in the ascus apex of an *Orbilia* (*O.* ?*cardui*) which they obtained in pure culture of *Dactylella rhopalota*. Also Descals et al. (1999: fig. 7, *Orbilia rosea*) illustrated an ascus with an operculum; however, this feature is not further mentioned in the text and seems quite unlikely to represent the typical way of how these asci open during discharge.

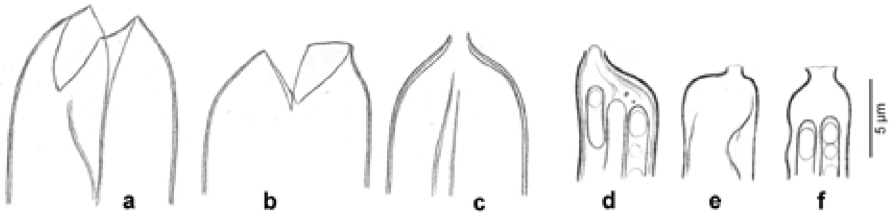

Figure 26: Apex of emptied asci. **a–c**. opened by a large slit-like pore (fissurate, *Orbilia myriolentiformis*); **d–f**. opened by a small, ± lateral, apparently roundish pore (poricidal, *Pseudorbilia bipolaris*).

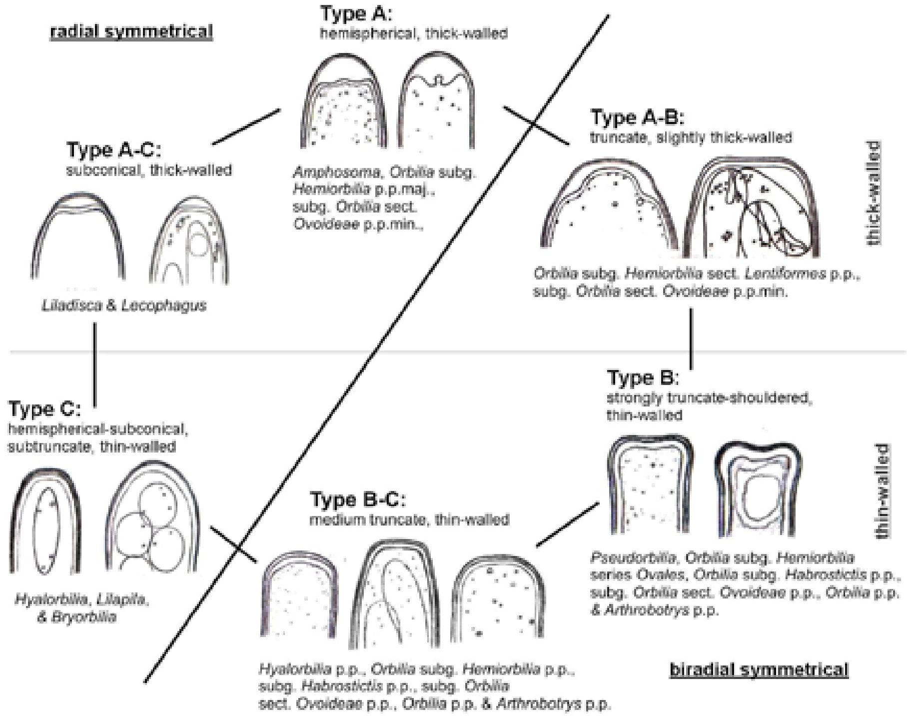

Figure 27: The three main ascus types (**A–C**) known within the *Orbiliomycetes*, and three intermediate types (all in the dead turgorless state).

Type A. **Hemispherical apex with apical thickening** (**Figs 27–32**). Asci of this type occur with a high continuity throughout subgenus *Hemiorbilia*, which represents about 25% of the members of *Orbilia*, but are also present in some members of subgenus *Orbilia* section *Ovoideae*, furthermore in the genus *Amphosoma*. The asci of *Liladisca* and *Lecophagus* (Figs 27 top left) belong to a reduced type that forms a transition to type C. Thick-walled asci are so far only known in the large group of desiccation-tolerant taxa, and their neglection is one reason why they remained unreported in the *Orbiliomycetes*. In other groups of ascomycetes, inamyloid ascus apical wall thickenings comparable to those of *Orbilia* are quite frequent. They are found, for instance, in many genera of *Ostropomycetidae*, or in some of *Leotiomycetes* such as *Calloria*, *Claussenomyces*, *Gelatinopsis*, or *Leotia*. Many of these discomycetes are desiccation-tolerant. Asci of subgenus *Hemiorbilia* resemble also those of the desiccation-sensitive genus *Thelebolus* which, however, differ in a more or less con-spicuous subapical reinforcement of the ectotunica (Fig. 32).

Apical thickening of the ascus wall. In the dead turgorless state the ascus apex of type A is distinctly thick-walled. The ascus wall appears as two-layered when viewing dead asci under the LM (oil-immersion) in water, KOH(+CR), or MLZ. It consists of a thin, firm, refractive ectotunica of quite equal thickness, and a more or less thick, soft, non-refractive endotunica. In the lateral ascus wall the endotunica is often very thin and, therefore, hardly perceptible, but it is abruptly inflated in the apex area. The inflated, thick-walled apex region is referred here to as apical thickening, following the terminology of Verkley (1992: 5). In other studies it was termed 'apical dome' (dôme apical, Bellemère 1977) or 'tholus' by lichenologists. In the present study the term apical dome is used as an equivalent of apical thickening. In the central part of the apical thickening the endotunica usually shows a more or less distinct indentation from below which is termed apical chamber (terminology following Verkley l.c.; in earlier studies also 'ocular chamber' or 'oculus', Bellemère 1977).

Three-dimensional shape. In contrast to the truncate-shouldered type B, one of the characteristics of type A is that the shape of the apex in the dead state does not or only slightly depend upon the viewing direction (Baral 1994: fig. 2). In the living state the ascus apices appear perfectly hemispherical due to the ascus turgor, whereas in the dead state the shape is sometimes broadly conical and/or subtruncate in front view but hemispherical in profile view.

Staining properties. Apical thickenings in *Orbiliomycetes* are unstained in iodine reagents, except for very rare cases of a faint dextrinoidity (see p. 48, Amyloidity). In CR_{SDS} the inner layer which constitutes the main part of the apical thickening, stains distinctly and homogeneously pinkish-red (Fig. 30: a–b). This congophilous reaction seems to occur in all *Orbilia* species with ascus apical thickenings (sections *Lentiformes*, *Hemiorbilia*, *Ovoideae*). It was detected in *O. vinosa* in 2009 by I. Wagner (pers. comm.) when routinely enhancing contrast with Congo red that contained SDS, and was later verified for a number of species of section *Hemiorbilia*. Actually, the reaction requires the presence of SDS, whereas CR alone does not provoke a perceptible stain, even if pretreated with KOH. The reaction is obtained immediately or at least within a few minutes, but only when exposing to a high concentration of CR, either by placing directly in a drop of undiluted CR_{SDS}, or by adding ample solution to a water mount. Presence of KOH strongly diminishes the reaction. Staining of empty, basally opened asci gave the best results.

The region stained by CR_{SDS} is restricted to the endotunica of the apical thickening, which gets entirely and homogeneously red without a perceptible ring-like structure. CRB stains the same region light violet-lilac. When adding KOH to a CRB mount, the stain of the endotunica became very distinct in *O. pleistoobliqua* (Fig. 30: c). A strong stain of the endotunica in CRB was seen also in *Amphosoma macrosporum*. No reaction of the external gel or the ectotunica is obtained in CR_{SDS}, whereas CRB also stains the external gel.

A comparable congophilous reaction could be obtained in the ascus apex of *Neolecta vitellina*. Although thin-walled when mounted in water, pretreatment with heated KOH induced a pronounced apical wall thickening which stained light red in CR (Fig. 39). In comparison with *Orbilia*, where the reaction is usually homogeneous in the entire apical tickening including the region above the apical chamber, the stained area in *Neolecta* forms a distinct apical ring because of a very deep indentation by the apical chamber.

When treated with H_2SO_4, the endotunica strongly swells, also the ascus apex gets more truncate, sometimes even shouldered (*O. aristata*, not so in *O. angustoobliqua*). After neutralizing with KOH, CR$_{SDS}$ stained a ring-like structure ~1 µm diam. deep red, whereas the rest of the endotunica appeared in a pale red (Fig. 30: e). The position of the ring-like structure strongly varied from central to peripheral, or from above to below.

No clear ring structure could be seen with the TEM in *O. vinosa* and *O. aristata* (as *O. occulta*), the two species with apical thickening treated by Müller (1998, Fig. 29). Verkley (1995) observed ring structures by TEM in a few genera of *Helotiales*, in which no amyloid ring structure is visible under the LM (in IKI). Verkley (1995: 17) used the silver-based PA-TCH-SP procedure, which he found to be 'by far the best method for a taxonomic study of the apical apparatus, also because conventional staining procedures (uranyl acetate, lead citrate) do not contrast the walls in ascomycetes'. Müller (1998) used only the conventional method and, perhaps therefore, he did not observe a ring structure in *Orbilia*.

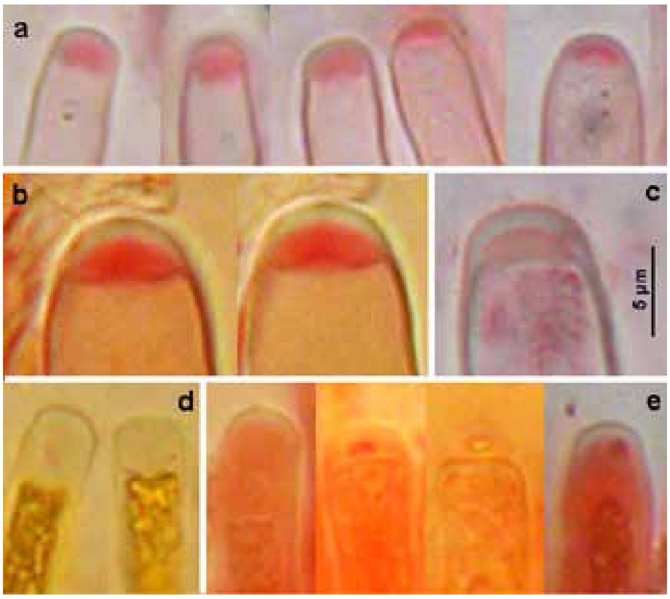

Figure 30 (Type A): Staining of ascus apices in CR$_{SDS}$, CRB, and IKI (dead state). — **a–b**. inner part of apical dome (endotunica) staining directly red in CR$_{SDS}$; **c**. endotunica and thin outer gel layer staining light lilac-violet in CRB+KOH; **d–e**. apical dome strongly swollen after H_2SO_4 treatment (lower end of thickening marked by adjacent ascoplasm), **d**. in IKI (hardly staining reddish), **e**. in CR$_{SDS}$ (partly with irregularly situated ring-like, distinctly red structure, apex sometimes slightly truncate. **a**, **d–e**. *O. aristata* (H.B. 9226a); **b**. *O. angustoobliqua* (H.B. 9050a); **c**. *O. pleistoobliqua* (H.B. 8727c).

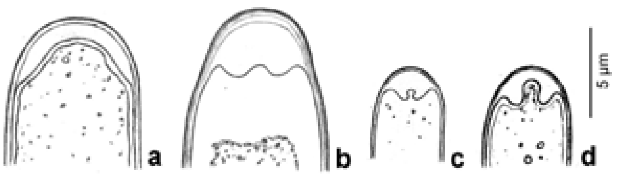

Figure 28 (**Type A**): Young asci with a ± hemispherical apex and an apical thickening with differently shaped apical chamber (dead state). Size and shape of the apical chamber and surrounding annular protrusion strongly varies between and within a species (**a**. *O. megahesperidea*, **b**. *O. myriooblique*, **c**. *O. vibrioides*; **d**. *O. euonymi*, all here assigned to subgenus *Hemiorbilia*).

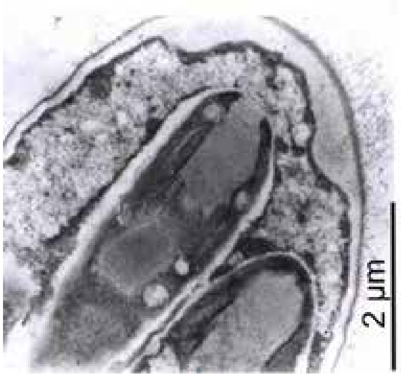

Figure 29 (**Type A**): TEM section of ascus apex showing apical wall thickening with wide apical chamber (dead state). The ectotunica is visible as a dark grey outer line, the endotunica with broad apical chamber as a thick pale grey region below, and the surface of the non-detached ascoplasm as a black irregular inner line (*Orbilia vinosa*, Müller 1998: fig. 13, V.1998, G. Marson, Luxembourg).

Influence of ascus turgor and maturity on the thickness of the apical dome. A frequently overlooked fact is that the ascus apical thickening, or more exactly the endotunica, is an expansible layer that behaves like a sponge (Fig. 31). In living asci the endotunica is comparatively dehydrated due to compression caused by the ascus turgor. For this reason it is rather highly refractive, but easily overlooked because the total wall in the apical region is often not much thicker than laterally. In the dead state the endotunica more or less strongly increases in thickness through imbibition of water and thereby becomes low-refractive. Particularly the inner boundary of the endotunica is highly refractive and rich in contrast in living asci, as opposed to the situation in dead asci. The effect is universal across the *Ascomycota* and was referred to as 'imbibition effect' (Baral 1992: 351).

In sections *Hemiorbilia* the total thickness of the apical wall increases during turgor loss to about 1.5–2.5 ×, e.g., by briefly heating a water mount. Mounting in KOH or H_2SO_4 often results in further imbibition of the endotunica, causing an increase of 2–3 × (KOH) or up to 4–10 × (H_2SO_4) in comparison with the living state (see Fig. 30). The apical chamber often gets narrower during wall imbibition, while its inconsistent presence is perhaps due to different viewing directions.

When comparing dead (or living) asci in the same mountant, the height of the apical thickening varies with the development stage of the asci. Apical thickenings are generally formed at a rather late development stage of the young ascus, i.e., during meiosis of the fusion nucleus or shortly before (see also Verkley 1992–95). At the end of meiosis, when the two unit membranes are formed around each nucleus, the apical thickening attains its maximum height (*Helotiales*, Verkley 1993: 42). This stage of development forms the transition from the young ascus to the immature ascus in Verkley's terminology. During the formation of the ascospore wall in the immature ascus, the apical thickening usually gradually decreases, either only slightly or rather strongly. This phenomenon of decrease in height can be observed in both living and dead asci. In the living asci it can be explained by the increasing ascus turgor, whereas in the dead turgorless asci the phenomenon is thought to be the result of increasing formation of cross-links in the wall matrix, resulting in an endotunica which is less able to swell. In the dead state, the apical wall of immature asci of *Helotiales* and *Orbiliomycetes* is usually about 1.5–2 × thicker than that of mature asci.

Considerable differences in thickness of the apical wall of dead, especially immature asci may occur between different taxa. Those with a thin apical dome (e.g., *Orbilia* subgenus *Hemiorbilia* section *Lentiformes* p.p.) form a transition to the hemispherical thin-walled ascus type, particularly if the apex tends to be truncate. The thickest apical domes known in the *Orbiliomycetes* occur in the immature asci of series *Vibrioides*, measuring immature †(2–)3–4(–6) µm in height. The small apical domes in *Lecophagus* (type A–C) did not show significant height differences between immature and mature, or between living and dead asci.

Difficulties in discerning apical thickenings with the LM. Apical thickenings are easily overlooked or misinterpreted under the LM in water or KOH mountants, due to the often very low refractivity of the endotunica in the dead state. Usually, the dead ascoplasm is more refractive than the endotunica, therefore, care must be taken not to confuse structures of the cytoplasm with those of the ascus wall. Since in dead asci the ascoplasm is usually detached from the wall to a very variable extent, apical thickenings may be reported thicker than they actually are. Because of the detachment, two very close or more or less remote lines can usually be seen: the lower of these two lines constitutes the border of the ascoplasm, the upper the border of the endotunica (Fig. 31: b, d). Drawings showing just one line (usually that bordering the dead ascoplasm which is more conspicuous) are no proof for the presence of an apical thickening.

As will be shown below, plasma detachment in taxa of *Orbilia* with thin-walled ascus apices (ascus type B and B-C) is very often stronger in the apex region compared to the lateral wall, which easily misleads to recognize an apical wall thickening where there is no such thickening at all (see Fig. 36: b). For example, in Spooner's (1987) drawings of species with thin-walled asci [*Orbilia flexispora* (fig. 22C), *O. juruensis* (fig. 24C, E), *O. delicatula* (fig. 21A, E), *O. auricolor* (fig. 19B), *Hyalinia crystallina* (fig. 26C)] the asci appear apically thick-walled, and hardly differ from a drawing of a species with undoubtedly thick-walled ascus apices [*O. vinosa* (fig. 25A)]. It is, therefore, recommended that drawings of apical thickenings indicate these different layers: (1) the outer and inner boundary of the ectotunica in larger asci by two lines, (2) the inner boundary of the endotunica by one line, and (3) the outer boundary of the detached ascoplasm by one line. In doubtful cases, TEM research would help in demonstrating the presence of rather thin apical thickenings, particularly in species with small asci. The inner boundary of the swollen endotunica is best seen when the ascoplasm is strongly detached from the apical wall, e. g., in asci which are broken below. In such a case the ascoplasm may have escaped through the opened base. In unbroken but dead, shrunken mature asci the apical thickenings are often rather compressed and poorly visible due to the closeness and pressure of ascoplasm and spores against the ascus wall, particularly if the spores are still viable and turgescent.

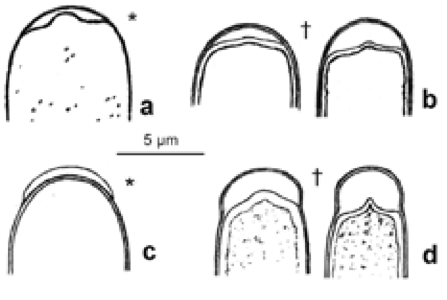

Figure 31 (**Type A**): Apices of immature asci of *Orbilia* subgenus *Hemiorbilia* section *Lentiformes* (*O. euonymi*, **a–b**) and section *Hemiorbilia* (*O. subaristata*, **c–d**). The inner layer (endotunica) of the apical wall strongly swells in dead asci by imbibition due to the loss of ascus turgor. In living as well as dead asci the apical chamber is not consistently seen.

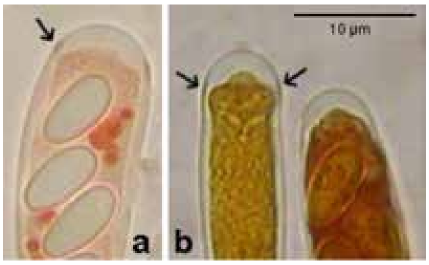

Figure 32 (**Type A**): Asci of *Thelebolus microsporus* (*Thelebolales*, H.B. 8829b) resemble the the hemispherical, thick-walled asci of *Orbiliomycetes*. Note subapical reinforcement of the ectotunica (arrow). Dead state (**a**. in CR, **b**. in IKI).

Intermediate type A-B. **Truncate-shouldered apex with apical thickening** (**Fig**. **27**). In a number of taxa of series *Lentiformes* and *Phanosomates* (section *Lentiformes*, subgenus *Hemiorbilia*) and section *Ovoideae* (subgenus *Orbilia*) both thin- and thick-walled apices occurred within a single apothecium, also truncate asci with distinct apical thickenings were observed. This illustrates the difficulty to draw a sharp limit between the different ascus types.

Type B. **Truncate-shouldered apex without apical thickening** (**Figs 27**, **33–35**). Asci of this type, together with the intermediate type B-C, occur with a high consistency in the two large subgenera *Habrostictis* and *Orbilia* of the genus *Orbilia*. They represent about 73 % of the whole genus. The same type of apex characterizes the small series *Ovales* of section *Lentiformes*, and also the monotypic genus *Pseudorbilia*. Truncate-shouldered, thin-walled asci occur in both desiccation-tolerant and -sensitive taxa. This ascus type is quite extraordinary within the ascomycetes and is otherwise only known from a few non-orbiliaceous genera (*Neolecta*, *Taphrina*, Fig. 39).

Apex shape depending on the viewing direction. This type of ascus apex has a biradial symmetrical shape (Fig. 33) which strongly depends on the viewing direction. In front view the apex appears truncate, often shouldered and centrally indented, whereas in profile view it looks hemispherical or subconical. During a rotation by 90° around the longitudinal axis of an ascus a truncate shape changes to a rounded shape. Therefore, only about half of the asci in a preparation look truncate. The orientation of the asci is obviously accidental in the context of the hymenium, therefore, asci with truncate and rounded apices are found in close association and equal frequency.

The simultaneous presence of truncate and rounded ascus apices may be misinterpreted at first glance as a morphological variation. Instead, every turgorless ascus has two shoulders, which is recognizable from those asci being oriented intermediate between front and profile view. Such asci show the phenomenon that, during focusing, the wall segment being in focus 'moves' from one shoulder to the other.

The biradial symmetry of the truncate *Orbilia* ascus was illustrated by Baral (1994, see Fig. 33: b) and Descals et al. (1999, Fig. 33: a), also by Liu (2006, Fig. 34: e). If only the truncate-shouldered aspect is shown, the ascus apex can easily be misinterpreted as a crater with a slight central depression. Instead, the ascus apex forms an obtuse ridge that runs from one shoulder to the other. This ridge is often somewhat depressed (indented) in the middle to form a saddle. In some asci or taxa the truncation is only slight so that the ridge is convex and the shoulders are less distinct, or the shoulders may project laterally. Such lateral protrusion provokes an abrupt widening at the ascus apex (Figs 34: c, 35: b), which is in contrast to most groups of ascomycetes in which the asci are apically narrowed.

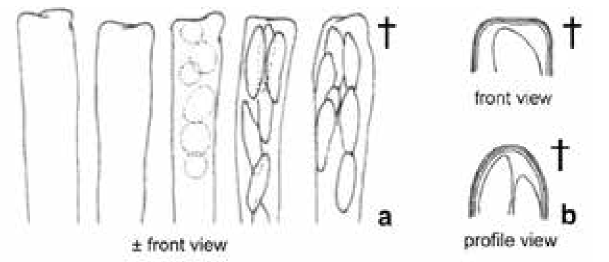

Figure 33 (**Type B**): Ascus apices in *Orbilia* subgenus *Habrostictis* as seen with the light microscope (dead state). Shoulders are visible only in front view. — **a**. *O. rosea* (Descals et al. 1999 fig. 8 A–F, as *Orbilia* sp.); **b**. *O. trapeziformis* (Baral 1994: 119: fig. 3d–e).

The two shoulders are the most prominent feature of this ascus type. Since central indentation and shoulders are only visible in front view, we have consistently figured the front view in our illustrations of this ascus type, but only exceptionally the profile view in addition.

Three of the five TEM-studies which treat this type of ascus apex each report the asci only in one viewing direction: Bellemère (1977, see Fig. 34: a–b) observed the asci in profile view and, therefore, figured an obtuse apex, whereas Benny et al. (1978: fig. 6, 8; see Fig. 34: c–d) and Kumar et al. (2012: figs 3, 9–11) found the apex to be truncate, sometimes slightly indented and with two shoulders, hence they observed the asci in front view. The biradial symmetry of the ascus is easily overlooked since TEM images are based on the study of ultra-thin sections, and spatial information is often not presented with this technique. Benny et al. (l.c.) mentioned the biradial symmetry of the ascal tip only indirectly by describing it as 'truncate with rounded shoulders'. SEM micrographs which show the spatial aspect of the shouldered ascus tips are unknown to us within *Orbiliomycetes* (two SEM-images in Pfister 1997: fig. 2 concern *O. blumenaviensis*, a species that lacks distinct shoulders), but were published for the genus *Neolecta*, which has a very similar type of ascus apex (see Fig. 39).

Apex shape depending on ascus turgor. Besides the fact that only those asci look shouldered which are oriented in front view, the shape of the apex highly depends on ascus turgescence (Fig. 35). Changes in ascus apex shape during the loss of turgor are generally observed in ascomycetes and, similar as with the shrinking effect, this feature is overlooked by many workers.

When studying recently collected specimens in water mounts, truncate apices are often only exceptionally found. The reason for this phenomenon is easily explained: due to their turgescence, living asci are much less truncate than dead asci, at any stage of development. The effect is provoked by the ascus turgor and the elasticity of the ascus wall. Only a very slight biradial symmetry can be noted in the living state, in which lateral inflation as well as central indentation are completely absent (Fig. 35: a, see also Baral 1994: fig. 3). The aspect of the taxonomically important truncate-shouldered apex is a result of ascus shrinkage in combination with an apparently higher wall rigidity in the shoulder region. The truncate-shouldered apex is most developed in basally broken (opened) asci. Sometimes only such artificially emptied asci are laterally inflated and apically indented. Moreover, the shoulders may be more prominent in water mounts compared to KOH.

Are the shoulders and the central indentation to be considered as artifacts of herbarium material? They become apparent indeed only when the asci lose turgor, either when they die prior to spore discharge or when they burst during discharge. However, shoulders are undoubtedly present also in the dry dormant state. Living asci lose all of their free water when apothecia are air-dried and thereby become laterally flattened (compressed) in their upper part. In order to study such asci, a section of an apothecium of *O. trapeziformis* was mounted in water and subsequently dehydrated by adding 96% ethanol, which changed the ascus apex from rounded to strongly truncate. However, the asci die in that medium, and a proper method to study the shape of dormant asci was not found. Asci of desiccation-tolerant species survive in a dry dormant state for a long time. Upon rehydration the shoulders instantly disappear with the increasing ascus turgor.

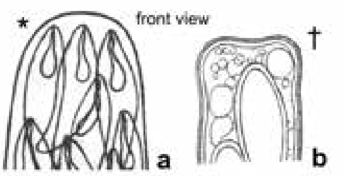

Figure 35 (**Type B**): Apex of mature ascus (**a**. living, **b**. dead state, both in front view). Shoulders appear only when asci lose turgor (*O. multidelphinus*).

When rehydrating dead, strongly flattened asci, they do not necessarily become circular in cross section, not even when heating a KOH mount, therefore, their width depends on the viewing direction, whereas dry living asci immediately reattain their circular outline in optical cross section when water is added (see also p. 9–11, Microscopic measurements).

Apex shape depending on maturity. In addition to the striking effect caused by turgescence, the shape of the ascus apex may slightly depend on ascus maturity: shoulders and indentation were sometimes found to be less developed in mature dead asci. In addition, living turgescent spores inside a dead ascus may prevent the elastic ascus wall from complete

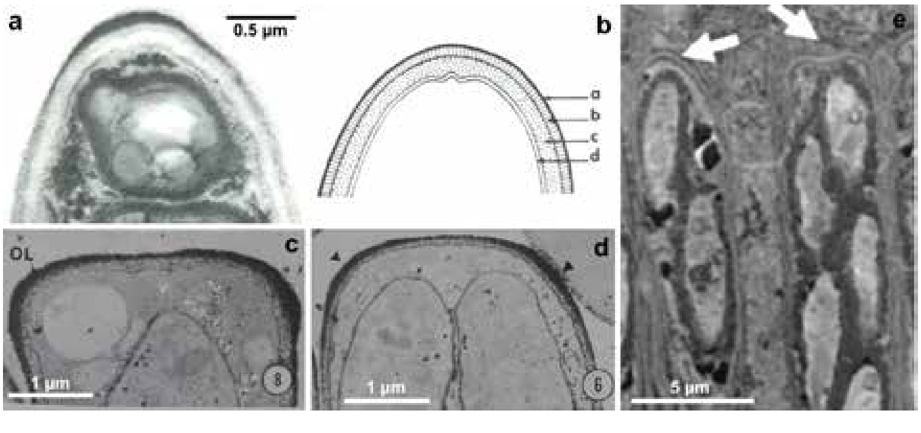

Figure 34 (**Type B**): Ascus apex in *Orbilia* as seen with the transmission electron microscope (TEM, dead state). — **a–b**. *O. leuco-/xanthostigma* s.l. (section *Orbilia*) in profile view (Bellemère 1977: 249, fig. 7 A–B, as *Orbilia* sp.); **c–d**. *O. sarraziniana* (section *Helicoon*), in front view (Benny et al. 1978: fig. 8, as *O. luteorubella*); **e**. *O. sarraziniana* (Liu 2006: 22, pl. 1 fig. C), showing the view-dependent aspect of the ascus apex (**left**: obtuse, in profile view; **right**: shouldered with indentation, in front view).

loss of its tension, resulting in the absence of either distinct shoulders or apical indentation.

Apex shape variation between taxa. Besides the three parameters vitality, maturity, and viewing direction, the apex of dead immature, tension-less asci differs between taxa with this ascus type: it varies from slightly truncate (with a convex apex) over strongly truncate (with a flattened apex) to more or less indented (Fig. 27, types B and B–C). Also the abrupt lateral inflation of the apex was not observed in every species. For instance, some taxa consistently lack both central indentation and lateral inflation irrespective of ascus maturity or other parameters, and are referred to as 'intermediate type B-C' here. On the other hand, prominent shoulders are sometimes only seen in a few asci of a preparation which contains only dead elements, therefore, their taxonomic value is limited.

Wall thickness of truncate ascus apices. One of the crucial characters of type B is that the ascus apex is thin-walled. Even in dead asci there is no apical thickening perceptible at any stage of development, whether studied under the LM (oil-immersion) or the TEM. The apical border of the detached ascoplasm can usually be seen in dead asci under the LM as a thin line a short distance from the ectotunica (Fig. 35: b). Under the LM the endotunica seems to be in total absent, whereas under the TEM a thin layer can be seen that does not expand in the apical region (Fig. 34: a, c–d).

Benny et al. (1978: figs 4, 6, 8, see Fig. 34: c–d) emphasized that the ectotunica is slightly thickened at the shoulders, compared to the central top and the sides of the ascus. This slight wall thickening was generally not seen by us under the LM in species with asci of type B, or rarely only very indistinctly. Bellemère's (1977) micrograph in profile view (Fig. 34: a–b) shows an apically thickened ectotunica, possibly because the section hits one of the shoulders. On his schematic drawing no such apically thickened ectotunica (layers a+b) is figured, and the endotunica (layers c+d) bears a very minute apical chamber that is not seen on the micrograph. Perhaps this drawing refers to a section across the centre of the ascus apex rather than the shoulders.

Intermediate type B-C. **Medium truncate apex without apical thickening** (**Figs** 27, **36**): Dead asci with medium truncate apices lacking apical indentation and often also lateral inflation may be considered as intermediate between type B and C. This type of apex is widespread within *Orbilia* subgenus *Orbilia*, and also occurs in some taxa of subgenera *Hemiorbilia* (series *Lentiformes* and *Phanosomates* of section *Lentiformes*), and *Habrostictis.* In some groups this type predominates (series *Abutilones* of section *Aurantiorubrae*, series *Microsomates* of section *Orbilia*, series *Dactylellina* of section *Arthrobotrys*). Rarely, type B-C is found in *Hyalorbilia*.

The dead ascoplasm is here often more detached from the apical wall than from the lateral wall (Fig. 36: b), and pretends a slight apical wall thickening. A thickened endotunica could, however, never be confirmed with certainty under the LM. However, in several species of section *Ovoideae* the apical endotunica of some of the dead immature asci was distinctly swollen, therefore, the present type can also be interpreted as intermediate between type A and type C.

Type C. **Hemispherical apex without apical thickening** (**Figs** 27, **37**): This rather primitive type of ascus apex characterizes the genus *Hyalorbilia* (Baral 1994: fig. 1), but is also found in *Bryorbilia* and the otherwise very different genus *Lilapila*. It is, however, not sharply differentiated from the intermediate type B-C.

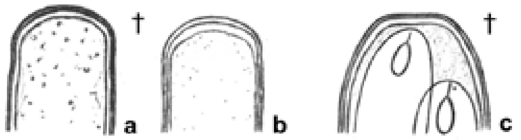

Figure 36 (**Type B-C**): Apices of dead asci in front view. — **a–b**. *Orbilia* section *Ovoideae* (*O. polyspora*, immature, slightly truncate); **c**. *Orbilia* section *Lentiformes* series *Phanosomates* (*O. tremuloidis*, mature, conico-truncate).

The ascus apex is more or less hemispherical in both the living and dead state. However, in the dead state it often tends to slightly or distinctly truncate (Fig. 37: b, h, resembling type B-C) or conical (Fig. 37: d, g, j). Whether the shape of the apex here also depends on the viewing direction is not clear. The apical wall is devoid of a thickened low-refractive endotunica, but sometimes the wall is thicker in the apex region compared to the lateral ascus wall (Fig. 37: b).

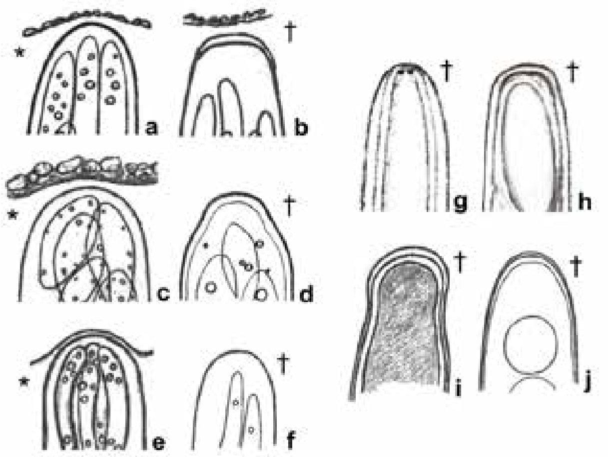

Figure 37 (**Type C**): Ascus apex in *Hyalorbilia* (living vs. dead state). — **a–b**. *H. juliae*; **c–d**. *H. latispora*; **e–f**. *H. helicospora*. Dead asci vary between truncate, conical, and hemispherical; **g–h**. *Bryorbilia arenicola*; **i**. *Lilapila oculispora*; **j**. *L. oculisporella* (**g** & **i**. immature asci).

Intermediate type A-C. **Subconical apex with a small lens-shaped apical thickening** (**Figs 27**, **38**): *Lecophagus* has subconical ascus apices (in the living state more hemispherical or slightly mammiform) with a rather small-sized, lens-shaped central apical thickening. The otherwise very different genus *Liladisca* shows quite a similar type of ascus apex which is, however, more distinctly conical.

In both genera the apical thickening appears to be devoid of a distinct apical chamber when viewed with the LM. Contrary to ascus type A, the apical thickening in *Lecophagus* scarcely gets thicker in the dead state, also it does not clearly decrease in thickness at maturity. Since *Liladisca* is only known from the old type collection, the situation in living asci could not be studied.

Non-orbiliaceous genera with a truncate biradial symmetrical ascus apex (**type B**, **Fig. 39**): Biradial symmetrical truncate ascus apices also occur in another subdivision of *Ascomycota*, the *Taphrinomycotina*. In the two genera *Neolecta* and *Taphrina*, which are assigned to two different classes within

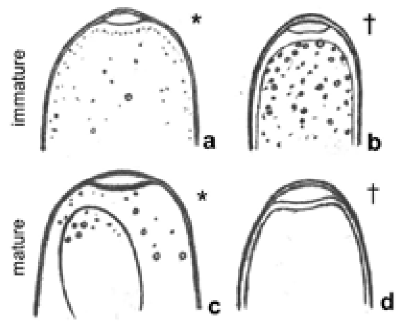

Figure 38 (**Type A-C**): Apex of immature (**a–b**) and mature (**c–d**) asci in *Lecophagus ellipsoideus*. Size and shape of the apical thickening scarcely depends on vitality or maturity.

this subdivision, the ascus apex is strikingly similar to that of type B of *Orbilia* (see also Landvik et al. 2003, Syrop & Beckett 1976: fig. 15). Landvik et al.'s SEM micrographs show for *Neolecta* two 'laterally-opposed horn-like protrusions' (Fig. 39: i) which, however, do not extend laterally. Their TEM micrograph in profile view (Fig. 39: k) shows a rounded-subconical ascus apex and a slight subapical thickening of the endotunica, but no shoulders. Shoulders could unexpectedly not be obtained in any of her TEM-sections, and even under the SEM the shoulders were rather rare and mainly seen in immature asci (S. Landvik pers. comm.). Shoulders were frequently seen by us under the LM in *N. vitellina* (Fig. 39: c), but are, as in *Orbilia*, only present in the dead turgorless state.

According to Landvik et al. (2003), ascospores in *Neolecta* are released through a slit across the thin-walled central region of the apex (fissurate type of dehiscence, Fig. 39: j). The subapical wall thickenings might prevent too irregular splitting during discharge (similar as the ring-shaped subapical wall thickening in the *Thelebolales*), but the authors mentioned also rupture at the subapical thickening (Landvik et al.: fig. 12). Since the shoulders are not further recognizable in opened asci, it remains unclear whether the slit runs from one shoulder to the other or transversely between the two shoulders.

We must be aware that this subapical wall thickening in *Neolecta* is only present in the dead state as a swollen endotunica, but of equal thickness with the adjacent wall in living asci. This is confirmed when studying fresh *N. vitellina* with the LM: the endotunica strongly imbibes water only when treated by heated KOH, and hereafter a ring-like structure that stained ± bright red in CR could be demonstrated (Fig. 39: e–h). This structure obviously corresponds to the subapical thickening reported by Landvik et al. (2003), who did not see a differentiated annular structure in their micrographs (Fig. 39: k). Increase in thickness of the endotunica when treated with KOH or H_2SO_4 and a more or less distinct congophily also occurs in ascus type A of *Orbiliomycetes* (see Fig. 30).

Like *Neolecta*, the genus *Taphrina* has a truncate to saddle-shaped ascus apex very similar to type B in *Orbilia*, judging from a TEM-study by Syrop & Beckett (1976, *T. deformans*) and an LM-study of a fresh collection of *T. pruni* (Fig. 39: l–o). Also in *Taphrina* the two shoulders are only present in dead asci. Similarly as in *Orbilia* the dead asci are widest at the apex when seen in front view. The ascospores are forcibly ejected through a very wide apical slit that runs laterally up to about 10 µm down on both sides (fissurate type of dehiscence, see also Syrop & Beckett l.c.: fig. 16). Again, the shoulders are not further recognizable in opened asci.

Landvik et al. (2003) compared the simple ascus apex types of *Neolecta* and *Taphrina* with their overall slightly thickened apical wall and a similar fissurate type of dehiscence with that of *Pertusaria* as described by Chadefaud & Galinou (1953), an ascus type reported also for various *Lecanoromycetes* by Chadefaud (1973: figs 9, 15, as 'déhiscence bivalve'). A similar fissurate opening mechanism was reported by David (1987) for *Epigloea* Zukal, but here an abrupt apical wall thickening with apical chamber and 'nasse apicale' was observed, although Döbbeler (1984) illustrated mature asci with an overall thin wall. Schoch et al. (2009) referred to this fissurate discharge mechanism as 'nonporicidal', in contrast to the poricidal mechanism through a round apical ring. Slit-like pores are also known from some other inoperculate ascomycetes, e.g., *Helicogonium* (*Phacidiales*, Baral 1999: fig. 5b) and *Deltopyxis* Baral & G. Marson (*Ostropales*, Baral & Marson 2012: fig. 5g).

Since the spatial shape of the biradial symmetrical truncate ascus apex (type B) is easily overlooked, it might well occur in some other groups of *Ascomycota*. Members of *Pezizales* or *Sclerotiniaceae* (*Helotiales*) are usually characterized by a more or less truncate ascus apex in the dead state (see, e.g., Van Brummelen 1981, Bellemère 1977, Verkley 1993). In *Coprotus* and *Kimbropezia* the truncate asci even appear to have shoulders or horns (Van Brummelen 1998a: fig. 12; 1998b: 261). The apex in *Desmazierella* is distinctly laterally inflated (Eckblad 1968: 115; see also IVV) very similar to type B of *Orbilia*. However, all these taxa with a truncate ascus apex are, to the present knowledge, radial symmetrical, i.e., they look truncate

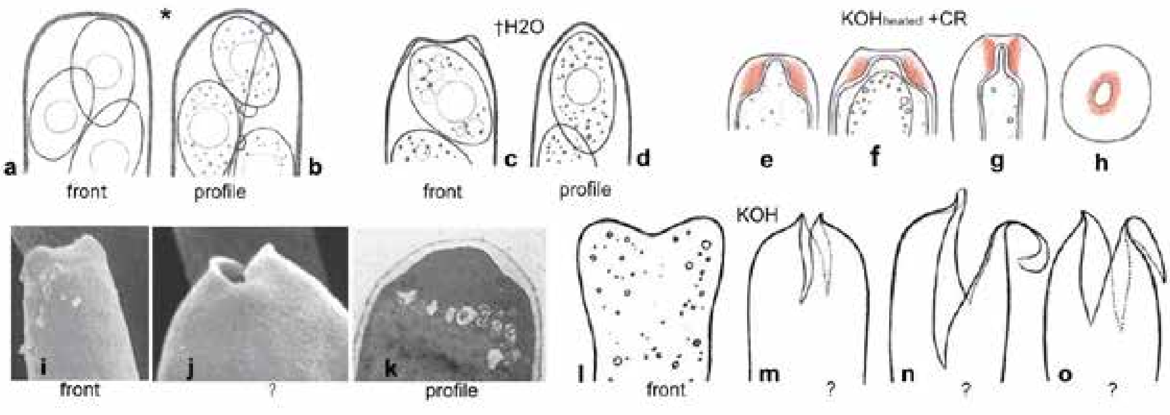

Figure 39 (**Type B**): Ascus apex of the shouldered type, with a fissurate opening mechanism. — **a–k**. *Neolecta vitellina*, **l–o**. *Taphrina pruni*. **b**. a tractus is visible in the living state; **e–h**. unopened asci in which pretreatment by heated KOH induced an apical wall thickening reminiscent of type A-B, enclosing a congophilous ring structure; **h**. top view; **j**, **m–o**. asci opened by a slit, in all of them the viewing direction (front or profile) is unclear. — **a–h**, **l–o**. after LM studies by H.O. Baral (ined.); **i–j**. SEM/**k**: TEM after studies by Landvik et al. (2003: figs 6–9).

irrespective of the viewing direction. However, the truncate ends of the ascospores of *Sarcoscypha* resemble the truncate asci of *Orbilia* in their pronounced biradial symmetry (especially in the dead state). Various authors thought that they vary between rounded and truncate but, in fact, they are saddle-shaped (Baral 1984: 126).

Phylogeny of the ascus apex. Asci with rather primitive apices, in which ring-like structures are absent and inner wall thickenings only slightly developed, represent either the original situation (plesiomorphy) within a group, or should have arisen by reduction as an apomorphy from a more complex structure.

The phylogenetic origin of asci with thick-walled apices within the *Orbiliomycetes* is difficult to determine. Their occurrence in different clades of *Orbilia* (sections *Hemiorbilia*, *Lentiformes*, *Ovoideae*) leaves the question open whether asci with thin-walled, truncate apices, which characterize subgenus *Habrostictis*, section *Orbilia*, and section *Arthrobotrys*, evolved by regression from the former, or represent a plesiomorphy within *Orbilia*. The striking similarity of the thin-walled, truncate apices of *Orbilia* with those of *Taphrina* and *Neolecta* led Kumar et al. (2012) to consider it as an ancient, plesiomorphic character. However, in *Neolecta* a distinct wall thickening with a congophilous ring structure could be induced by heating a KOH-mount (Fig. 39: e–g). The uniform and primitive ascus apex in *Hyalorbilia*, a genus which diverged rather early in the evolutionary history of *Orbiliomycetes*, would argue against the truncate ascus apex as a plesiomorphy within the class. However, also the small genus *Amphosoma* forms a rather basal group, judging from its predominant growth on coniferous substrate, the bipolar SB arrangement, and phylogenetic data. It unites characters of both *Hyalorbilia* and *Orbilia*, and might have maintained some morphologies of the common ancestor of the two genera, which would support our hypothesis that hemispherical, thick-walled apices are primary (Fig. 40). The ascus apices of *Liladisca*, *Lilapila*, and *Lecophagus* are rounded or conical and never with shoulders, either thin-walled or with a small wall thickening. The two former grow on conifers and all three undoubtedly represent rather basal groups. The similarity of the shouldered ascus of *Taphrina* and *Neolecta* could, therefore, be a feature which the common ancestors of *Orbiliomycetes* did not have but which has been reinstalled in some of its subgroups. The genus *Pseudorbilia* is interesting in this regard as it possesses shouldered asci but otherwise closely resembles *Hyalorbilia*, e. g., in having croziers and bipolar SBs.

Within the *Leotiomycetes*, some families consistently possess inamyloid asci (*Helicogoniaceae*, *Cordieritidaceae*) or almost so (*Tympanidaceae*). Species of *Orbiliomycetes* with black apothecia resemble some genera of *Tympanidaceae* not only macroscopically but also from their ascus structure, suggesting an evolutive connection between the two classes. However, molecular data indicate that the *Orbiliomycetes* are more related to the *Pezizomycetes* where they occupy a rather isolated position.

When adopting this regression hypothesis to the *Orbiliomycetes* in which amyloid asci are unknown, taxa with thin-walled apices could have evolved in different lineages from taxa with apically thick-walled asci. In some of these lineages the thin-walled asci are coupled with desiccation-sensitivity of the apothecia, whereas thick-walled asci were so far exclusively observed in desiccation-tolerant taxa.

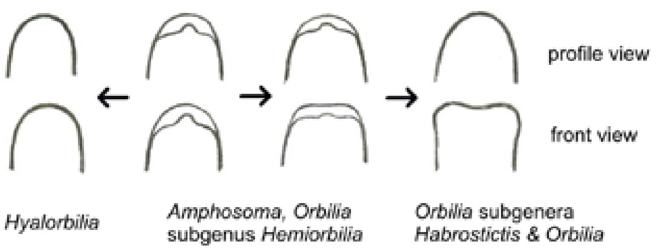

Figure 40: Hypothetical phylogeny of the ascus apex in *Orbiliomycetes* as seen in the dead state.

Wrinkling of the ascus wall or the ascoplasm. In dead asci mounted in H_2O or low-concentrated KOH (up to ~2%), the ascus wall in *Orbilia* rarely appear more or less strikingly transversely wrinkled, so that the asci look like warted, shrivelled or striate. The phenomenon was exclusively observed in very old herbarium material, e. g., in nearly all asci and even some paraphyses of the type material of *O. fibriseda* and *O. serpentina* (Pls 574: 2; 651: 2). This wrinkling may easily be mistaken for a taxonomic character. However, it depends on the mountant: when mounting in 3% or 5% KOH (unheated) the walls promptly turned smooth, whereas mounting in 2% KOH, even when very briefly heated, did not remove the striation. Of course this wrinkling is never seen in hydrated living asci.

The present observations with the LM leave some doubt about the origin of the phenomenon. At least in *O. serpentina* the observed wrinkling appears to result from a transversal folding of the peripheral ascoplasm (which is sometimes secondarily pigmented) rather than a wrinkling of the ascus wall. Due to the rarity of the phenomenon, the true nature of the striation could not be clarified, as it was never observed in any of the more recently collected specimens.

A similar wrinkling of the wall of dead asci is known in the genus *Sarcoscypha* (*Pezizales*, Van Brummelen 1975, Baral 1994). Here the asci get wrinkled during loss of ascus turgor, either after spore discharge or when the apothecia are dried, whereby the asci do not survive. That the observed wrinkling is provoked by shrinkage is obvious from the fact that living hydrated asci have always a smooth wall due to their internal turgor. Our observations in *Orbilia* and *Sarcoscypha* suggest that this wrinkling occurs only in some of the herbarium specimens of a given species and has little taxonomic value.

Amyloidity of the ascus wall. Since amyloid ascus walls have never been observed in any taxon of the *Orbiliomycetes*, a common ancestor with inamyloid asci can be postulated. The question whether an earlier ancestor of *Orbiliomycetes* possessed asci with amyloid walls remains up to now speculative. Molecular studies have shown that the *Orbiliomycetes* have early separated from the remaining *Pezizomycotina* (see Fig. 114). However, in the genus *Neolecta* which diverged even earlier and which belongs to the most basal groups of *Ascomycota* (*Taphrinomycotina*, Landvik et al. 1993, Schoch et al. 2009), the entire wall surface of the asci reacts hemiamyloid (IKI pale red, type RR, KOH-pretreated IKI pale blue; negative in MLZ, blue in MLZ after KOH; Redhead 1977, Landvik et al. 1993: 109, Baral ined.). Amyloid ascus structures are otherwise unknown in the *Taphrinomycotina* and *Saccharomycotina*. Hence, two possibilities seem plausible: (1) a common ancestor of all *Ascomycota* possessed amyloid ascus walls, or (2) amyloidity developed independently in different groups. We are unable to decide which of the two is the more probable scenario. The first option means that the *Orbiliomycetes* separated from the lineage leading to the remaining *Pezizomycotina* while still having amyloid ascus walls, but it is then difficult to understand why none of them survived. The second option would imply that hemiamyloidity, i.e., the KOH-provoked change in reactivity from red to blue, independently developed in different groups.

Spore number within asci, **polyspory**. Polyspory of asci, i.e., spore numbers higher than 8, was found in the present study to be a fairly frequent feature within the genus *Orbilia*, which occurred in about 30% of the taxa. Other genera of *Orbiliomycetes* displayed consistently 8-spored asci, with one exception, the 16-spored *Hyalorbilia pleioerythrostigma*. Regularly 4-spored asci, whether by an omitted mitosis or by abortion of spores, have never been noted with certainty in the class.

Within a given population, the number of spores of an ascus is highly constant, which indicates that spore number is genetically fixed. The observed spore numbers quite exactly follow the formula 2^n. The ascospores in *Orbiliomycetes* were found to be consistently uninucleate in the rare cases when nuclei could be seen. Polyspory in *Orbilia* is certainly always a result of mitotic nuclear division prior to spore formation, which can be concluded from the fact that neither yeast-like budding nor fragmentation of ascospores could be observed. In the terminology of Martens (1932), adopted e.g. by Barr (1991), this case is termed 'true polyspory'. Martens provided a detailed survey on polysporous ascomycetes, according to the three recognized types of polyspory (true polyspory, budding, fragmentation). Yet, in this systematic survey Martens did not mention the very sparse literature reports of polysporous taxa in the genus *Orbilia* known at that time.

Polysporous asci have been described in only four species of *Orbilia*. Two of them are 16-spored: *O. serpentina* (Patouillard 1892, 14–16 subulate spore bodies were seen in the asci) and *O. junci* (Kohlmeyer et al. 1998, 16-spored but often up to 8 spores aborted), and two are 32-spored: *O. paradoxa* Ade (1924, ?= *O. flavida*, '16–24-spored') and *O. polyspora* Grelet (1926; 'usually 24-spored'). Variation in spore number or numbers between 16 and 32 as indicated by the authors can be explained by the difficulty in counting the spores, particularly inside dead asci, but also by irregular abortion of spores or omission of mitoses. Polyspory in *O. serpentina* was obviously not fully understood by Patouillard (1892) since he stated the asci to be 'finally 8-spored'. The report of polysporous asci in *O. myriospora* (W. Phillips & Harkn.) Sacc. turned out to be erroneous: it refers to lipid bodies inside immature asci of a member of the *Calloriaceae* (*Helotiales*, see p. 1679). On the other hand, polyspory has been overlooked in several taxa (*O. coccinella*, *O. euonymi*, *O. flavida*) which were described as 8-spored, either in the protologue or in the current interpretation, but are, in fact, 16- or 32-spored.

Difficulty in counting the spores. Polyspory of asci in *Orbilia* has almost completely been neglected in the past, for the following reasons: (1) when dealing with dead material, the spores are difficult to discern within the asci (see Figs 24, 25: b); (2) if only some of the spores are still viable within a dead ascus, the living spores are much better visible, and the dead spores are easily neglected (see Fig. 7: d); (3) spore numbers of species with very elongate spores are often not easy to evaluate; (4) workers did not pay attention to spore numbers because they did not expect any deviation from the current situation of octospory.

When dead and living spores occur mixed within a dead ascus (case 2), the dead spores are often invisible because they do not contrast with the ascoplasm (Fig. 25: c). Mounting in lethal media such as MLZ, KOH+IKI, or KOH+CR may reveal the full spore number in such asci (Figs 10: d–e, 92: a). In any case, the study of dead herbarium material, perhaps in combination with inadequate preparation methods, was the reason why the three polysporous species were described as 8-spored in the literature. However, another possibility to explain different results of spore numbers is a mixture of several species in a collection (see p. 146–148).

High spore numbers are often difficult to count, especially if the spores are small and/or elongate. The presence of living spores (irrespective of whether mature or immature, or whether inside living or dead asci), enormously facilitates counting. Evaluating spore numbers is also often easier when counting the spore bodies instead of the spores, especially if the SBs are not very elongate and narrow. Such counting is further facilitated by selectively staining the SBs with CRB. Artificial flattening of the living or dead asci by pressure on the cover slip, e.g., through water evaporation, rearranges the included spores in ideally two layers which may aid in evaluating exact spore numbers of 64- or 128-spored taxa.

For species identification it is sufficient to roughly estimate spore numbers. E.g., when counting distinctly more than 32 spores, a sample may be classified as 64-spored. Another method evaluates spore numbers from the volume of the pars sporifera and that of the individual spores (see p. 9, Polyspory).

Spore numbers deviating from 2^n. Spore numbers that regularly deviate from the formula 2^n have never been observed in *Orbiliomycetes*. However, a small number of aberrant asci can sometimes be found within an apothecium, showing slightly reduced spore numbers, although all spores are in the living state and clearly visible. In such a case, one or several oversized spores can be found among the normal-sized ones. For example, in a species with regularly 16-spored asci, 1 or 2 spores inside a mature ascus may show a larger size, resulting in spore numbers of 15 or 14, respectively. Such larger spores contain also distinctly larger SBs. Rarely, such reduction results in a complete step downwards, e.g. from 32- to 16-spored asci. In this case, both types of asci are usually found in one apothecium, together with some asci with intermediate spore numbers and with the higher-spored asci distinctly prevailing. The opposite case, that a minority of asci of an apothecium deviate in a spore number higher than the majority, we have never observed.

Whether the oversized spores contain two nuclei or are formed by the occasional omission of a mitosis, could so far not be clarified. We consider problems in nutrition, or other external parameters, such as water supply or temperature, as possible factors that might disturb the regular process of mitosis and spore wall formation.

Taxonomic value of spore numbers. A lot of species here recognized in *Orbilia* are mainly or solely distinguished by their spore number. This raises the question whether such variation in the number of mitoses is a reliable character to be applied at the species or perhaps better at some infraspecific level. Species concepts become even more dubious in cases in which taxa with different spore numbers occur in close association on the same piece of substrate. However, we have found spore numbers to be generally highly constant within single apothecia and usually also within a population. Therefore, a high taxonomic value is attributed to spore numbers in the present study. It was also a practical reason at an early stage of this monograph, that populations with different spore numbers were consistently distinguished at some taxonomic level.

Barr (1991) discussed the question as to whether (true) polyspory in *Capronia* should be recognized at the genus level by separating 8-spored from polyspored taxa. She thereby relied, e.g., on results from members of *Valsaceae* (by Kern 1957 and Hubbes 1960, both cited in Barr) who reported that 'polyspory was a constant character in the specimens that they examined and cultured, that is that it was at least a character of specific value'.

Similar variation in spore numbers between closely related taxa is known from various groups of ascomycetes. Spore numbers are usually believed to be a constant character at the species level, though this seems not always to be the case in the genus *Thelebolus*, in which spore numbers of 8 up to > 2000 occur. De Hoog et al. (2005: 57) accepted, apart from three 8-spored species, only one multispored taxon, *Th. stercoreus*. Within a single sample of this species, spore numbers of 24, 32, 48 and 64 occurred, although spore numbers within a sporocarp appeared to be constant. In a monospore isolate of another population referred to the same species, spore numbers ranged from 128 up to 264, with an optimum close to 246.

Within *Orbilia*, the consistency and taxonomic value of spore numbers is supported by cultural results in a single species, *O. flavida*. This is the only polysporous taxon for which we obtained apothecia in pure culture (by adding sterilized natural substrate). The apothecia that developed there (H.B. 6716, Pl. 172: 4) fully concurred in their microscopic features with those that had grown in the field, e.g., concerning the consistently 32-spored asci and the spores with their lens-shaped SBs. This result confirms our hypothesis that features like spore numbers are generally not seriously affected by environmental conditions but are instead genetically determined.

A rather well-explored example is series *Microspermae* of *Orbilia* section *Lentiformes* (Fig. 41). The type species *Orbilia euonymi* has 32-spored asci and a wide and dense distribution within Europe, but also occurs in North America. A much rarer 16-spored European species (*O. pleioeuonymi*) differs in subglobose spores and wider SBs. A 64-spored species was discovered in Australia and China, and a 128-spored species rarely occurs in Europe. The spores of the latter two taxa do not markedly differ from *O. euonymi*, nevertheless, we preferred to attribute all four taxa specific rank, although their characters coincide to a high rate with those of the 32-spored populations. Even the anamorphs were found to show only little differences among the four species, apart from a slight reduction of conidial width with increasing spore numbers. Our species concept was confirmed when molecular data became available.

We have recorded quite a few similar cases of more or less similar species with deviating spore numbers, mainly from more or less desertic areas. In contrast to series *Microspermae*, the number of available collections of each species was here usually too low to explore their variation and to see which of the spore numbers are the predominant ones. Most of these mainly extra-European taxa described from just one or a few collections must be considered under this point of view. In the worst case, a here described taxon will turn out to represent a rare marginal derivative of a more common taxon which has escaped our notice.

Polyspory in *Orbilia* was found to be strictly confined to desiccation-tolerant taxa, but even among the 8-spored taxa about 75% are desiccation-tolerant (Tab. 5). Higher-than-average frequency of polyspory was encountered in samples from semiarid to arid regions (~70%, ca. 94 out of 137 polysporous taxa), while only 32 polysporous taxa (~23%) were observed in humid, mainly temperate climates, and 26% in each subhumid and semihumid regions. The 32 polysporous taxa in the humid zone are mainly from sections *Lentiformes* and *Habrostictis*. The proportion of polysporous to 8-spored taxa decreases significantly from arid to humid regions (1.8 in arid, 1.2 in semiarid, 0.6 in subhumid, 0.32 in semihumid, and 0.12 in humid regions). The number of 8-spored taxa in the two main humidity zones is about 325 out of 388 (84%) in humid and semihumid regions and 108 (28%) in arid to subhumid regions. Concerning the frequency of polysporous ascomycetes in arid climates see also p. 64, Advantages of spore cluster.

The occasionally observed variation in spore number within a single apothecium, which in some asci provokes a reduction down to half the typical values, appears to have a non-genetical basis as mentioned above. In apothecia of *O. euonymi* such abnormal 16-spored asci contain subglobose instead of ellipsoid spores with wider SBs, reminiscent of *O. pleioeuonymi*. Such cases of strong variation in spore number within an apothecium were only infrequently met in our study, therefore, the application of those names which are mainly defined by spore number was almost never a serious problem.

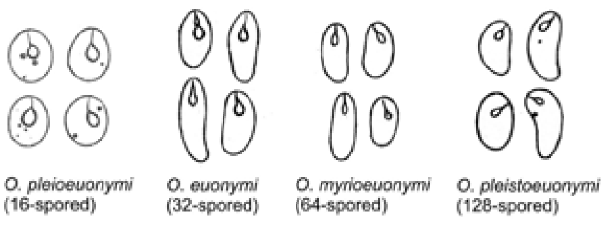

Figure 41: The four taxa recognized in series *Microspermae* differ mainly in spore number.

Because of the frequent absence of further distinguishing characters in taxa with a deviating spore number, one could

Table 5. Frequency of polyspory in *Orbilia* in relation to ascocarp desiccation tolerance and aridity of the geographic region. The table indicates the approximate number of species recognized in the present study, including undescribed (aff./cf.) taxa. Desiccation tolerance among the polysporous taxa was always medium (min. 1–2 months) to high (min. 0.5–1 year), whereas 8-spored taxa comprise a continuum from sensitive to highly tolerant. The number of tolerant 8-spored taxa in this table includes also those with a slight tolerance; subhumid includes a savannah climate.

	8-spored	16-spored	32-spored	64-spored	128-spored	total
desiccation-tolerant	294	58	42	30	7	431
desiccation-sensitive	94	–	–	–	–	94
arid	27	22	16	10	–	75
semiarid	58	26	19	21	4	128
subhumid	60	17	14	4	1	96

assume that only slightly differences in the DNA exist between them, which might be restricted to the control of ascospore numbers. However, we generally found a rather high distance in the ITS region. For instance between *O. pleioeuonymi* and *O. euonymi* 6.5%, between *O. euonymi* and *O. pleistoeuonymi* 13–13.5%, between *O. flavida* and *O. ocellata* 7%, and between *O. sphaerospora* and *O. canadensis* 5%. Sometimes we observed populations with deviating spore numbers co-occurring on the same piece of substrate, and considered the possibility that they belong to a single species. From their different rDNA data, however, we must conclude that such mixed populations originate from independent colonization of the substrate.

Our molecular data on closely related polysporous species are rather sparse, and usually only a single sequence of each taxon was available for comparison. Future research on a wider scope of gene regions will perhaps answer the question whether closely related species with different spore numbers evolved by singular changes in spore number or by repeated changes in a polyphyletical process. Not only progression in spore numbers but also regression from higher to lower numbers probably occurred during evolution.

A system of prefixes was often applied when creating new names for closely related species (Tab. 6). For example, *Orbilia euonymi* has 32-spored asci, and a series of allied species is named *O. pleioeuonymi* (16-spored), *O. myrioeuonymi* (64-spored), and *O. pleistoeuonymi* (128-spored).

Inverse orientation of spores. Ingold (1954, 1971: 45) stated that the inverse orientation of a heteropolar ('bipolar-asymmetrical') spore 'never appears to occur'. Likewise Nannfeldt (1982: 165) thought that 'heteropolar spores (almost?) invariably are oriented in one way only' (with the wider spore end above). We can actually agree to these observations for the majority of hygrobiotic ascomycetes. Ingold's and Nannfeldt's statements are incorrect, however, regarding many xerobiotic ascomycetes but also many hygrobiotic *Orbiliomycetes*.

Inverse spore orientation in *Orbiliomycetes*. Particularly in the genera *Orbilia*, *Lecophagus* and *Liladisca*, inverse spore orientation is quite a consistent feature. In all the numerous species of *Orbilia* in which spore length exceeds ascus width, a varying percentage of the spores within an ascus is oriented inversely, i.e., with the 'lower' end towards the ascus apex, whereas the remaining spores are 'ordinarily' oriented. This is not only so in species with a heteropolar spore shape, but also in those in which the 'upper' end of the spore is only recognizable by the presence of a spore body (see p. 69 ff., SBs). But even in the genera *Hyalorbilia* and *Amphosoma*, in which the spores are predominantly homopolar in shape and the SBs occur at both spore ends, inversely oriented lower spores of a heteropolar shape were sometimes seen.

The number of inversely oriented spores in asci of a given apothecium varies to a more or less high extent, but some differences between taxa are obvious. In most of the species, about 35–65% inverted spores represent the general case [series *Phanosomates* and *Hesperideae*, subgenus *Habrostictis*, sections *Orbilia* and *Arthrobotrys*]. For species with 8-spored asci this means that 3–5 spores are inverted, while 1–2 or 6–7 inverted spores exceptionally occur. In contrast to this, many taxa of series *Lentiformes* and all of series *Hemiorbilia* show a more or less strong preference for only 1–3 spores inverted (except for the possibly misplaced *O. megaocculta*). Very exceptionally, a few asci were observed in which all 8 spores had an ordinary (*O. patellarioides*, *O. lentiformis*, *O. spermoides*, *O. aviflagellata*, *O. aviaristata*, *O. pseudoaristata*) or an inverse orientation (*O. lentiformis*, *O. ovoidea*, Pl. 766: 1b). In two species (*O. fimbriata*, *O. pseudoflagellispora*) the asci contained all spores with an ordinary orientation (Pl. 352: 1b), except for a few asci in which the lowermost spore was inverted. A maximum variance of (0–)1–5(–8) inverted spores was noted in *O. lentiformis*, and (2–)3–6(–8) inverted spores in *O. ovoidea*. In 16-spored taxa about 6–10 spores are usually inversely oriented, and also in 32-, 64- and 128-spored taxa many inverted spores occur in every ascus (Fig. 42: c).

In most taxa the inversely oriented spores tend to be grouped at the lower end of the pars sporifera, whereas the upper spores are those with an ordinary orientation (Fig. 42: a). In a rather small number of 8-spored species, the upper spores are those which are inversely oriented, either consistently (*O. pseudobrevistipitata*, *O. bomiensis*, *O. spirillospora*), or predominantly (*O. sarraziniana*, *O. spathulata*, *O. wannerooensis*). In these species usually all 8 spores point with their 'upper' (SB-containing) ends towards the middle of the pars sporifera (Fig. 42: b). Benny et al. (1978) figured this situation with the TEM in *O. sarraziniana* (Fig. 71: a). The authors were obviously fascinated by this striking arrangement of the SBs. However, they had only a slight idea of the widespread occurrence of SBs in *Orbiliomycetes*, and accidentally studied a species with an unusual spore arrangement. Also Liu's (2006) TEM-image of the same species (Fig. 71: b) shows inverse orientation of the upper spores and their SBs. So far this rare case never occurred in asci with more than 8 spores.

The inverse spore orientation is often rather regular not only within an apothecium but throughout the populations of a species. However, particularly in species with polysporous asci and/or a homopolar spore shape there is often slight if not considerable disorder, so that the inverted spores are not strictly confined to the lower part of the pars sporifera but occur more irregularly distributed within an ascus (Fig. 42: c). In the descriptions this case is referred to as 'mixed orientation'.

In those species in which ascus width exceeds spore length, the spores may be oriented in all directions, i. e., some of the spores have a more or less horizontal or oblique orientation (Fig. 42: d). Yet, an orientation parallel to the longitudinal axis of the ascus may also here be predominant if the spores are elongate, which forces them to lie more or less parallel in order to facilitate formation of the spore cluster (Fig. 42: c). So, even in this example, in which the rather short spores are homopolar in shape and the asci multispored, a majority of the lower spores tend to be inversely oriented.

Spore orientation is completely irregular in those species in which the spores have a more or less circular outline, or their length/width ratio is distinctly below 2. If such spores are more or less flattened, either by their semicircular shape (e. g., *O. leucostigma*) or when round spores are laterally flattened (*Lilapila* spp.), they may be arranged like coins in a pile, the SBs thereby pointing sideways (horizontal orientation). Likewise, in *O. corculispora* with heart-shaped spores (Fig. 42: d) the spores are oriented in such a way that the SBs tend to point in lateral direction.

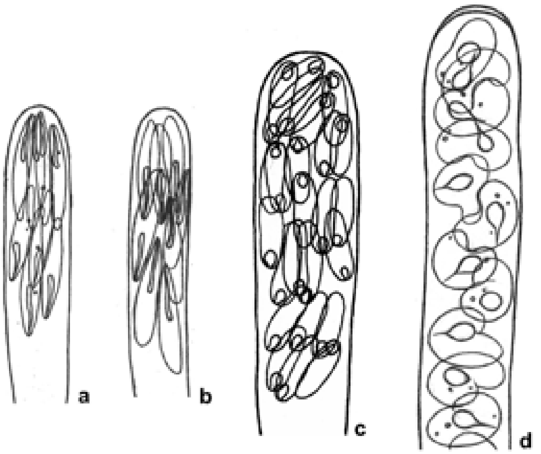

Figure 42: Spore orientation in living asci. — **a–b**. spores longer than ascus width, inverse orientation of lower (**a**. *Orbilia rosea*) or upper spores (**b**. *O. sarraziniana*); **c–d**. spores shorter than ascus width, orientation inverse for lower spores (**c**. *O. multiaustrocylindrica*) or irregular (**d**. *O. corculispora*).

Spore orientation in herbarium material, literature reports. The situation of inverse spore orientation is easily seen when studying living spores, due to the very conspicuous SBs in the spore apices. In dead herbarium material, spore orientation is often very difficult to evaluate in species with a homopolar spore shape, and even if the spores are distinctly heteropolar, the shape of the spores is not always clearly observable inside dead asci (see p. 29). Hence, literature reports of inverse spore orientation are rare due to the current method of studying herbarium specimens.

Only a few reports of inverse spore orientation in *Orbilia* prior to 2000 came to our notice. Three refer to living specimens: Patouillard (1892b) depicted subulate SBs in 16-spored asci of *O. serpentina*, some of them clearly inversely oriented (Fig. 151: 1). Baral (1989: pl. 4) figured an 8-spored ascus of *O. septispora* with 3 inverted lower spores (see Pl. 683: 2) and (in Rubner 1996: 94, fig. 48d) an 8-spored ascus of *O. elegans* (as *O. auricolor*) with 5 inverted lower spores (see Pl. 961: 1). Four reports refer to dead specimens (all with 8-spored asci): Drechsler (1937a: 458, fig. 18 R) described and figured inverse orientation of 1–4 lower spores in an unidentified *Orbilia* (possibly section *Arthrobotrys*). Ellis & Ellis (1985: fig. 1202) illustrated three lower of seven figured spores in *O. comma* inversely oriented. Galán et al. (1994: fig. 60) depicted three of six spores with an inverse orientation in *O.* (*Hyalinia*) *flagellispora*. In Pfister's (1994) illustration of a collection referred to *O. fimicola* (= *O. auricolor*), ~3–5 lower spores are somewhat indistinctly drawn with their acute lower ends pointing upwards.

When illustrating asci of *Orbiliomycetes*, authors have repeatedly figured all spores of an ascus with ordinary orientation. For example, Rolland (1901, three asci of *O. hesperidea*) and Chenantais (1918, one ascus of *Hyalinia ulicis*) illustrated all 8 living spores with their SBs oriented upwards (see Fig. 151: 2–3). Likewise, Starbäck (1899, *O. caudata*), Spooner (1987: 185, fig. 25 A, *O. vinosa*), Graddon (1977: fig. 17, *O. comma*), Birken (1984, *O. sarraziniana*) and Pop (1994: pl. 1 fig. 5) figured all (7–)8 dead spores with their tapered ends pointing downwards. In Spooner's drawing of *O. auricolor* (1987: 165, fig. 19 B), only one of the seven figured spores (above the lowermost spore) looks like being inversely oriented. Although asci without inverted spores occur only in a very small number of 8-spored species of *Orbilia*, we may assume that the above-mentioned illustrations were carried out with the belief that heteropolar spores are consistently oriented with their broader ends upwards. This was demonstrated when restudying the type material of *O. hesperidea*, *O. caudata*, and *O. comma*: all asci examined contained a varying number of inverted spores.

Inverse spore orientation in *Leotiomycetes* and *Pezizomycetes*. The phenomenon of inverse spore orientation in *Orbiliomycetes* strikingly coincides with that reported by Döbbeler & Poelt (1974) for *Bryodiscus* B. Hein et al. and by Döbbeler (1984: 208) for *Epigloea*. In *Epigloea*, Döbbeler found inverse orientation to be characteristic of all known species, though in some of them the feature is not easy to observe because of indistinctly heteropolar spores. Every ascus showed this phenomenon, without exception, and always the lower spores were those being inverted. The number of inverted spores in 8-spored species varied among the asci: mostly 4, but often also 2 or 3, rarely more. Döbbeler (1984) emphasized this peculiarity as extraordinary within ascomycetes, and could only refer to one further genus (*Bryodiscus*) in which the long, filiform-clavate ascospores in two of the three known species are in part inversely oriented.

Both *Epigloea* and *Bryodiscus* are obviously very distantly related to the *Orbiliomycetes*. In *Epigloea* the outer ascus wall layer reacts hemiamyloid. The spores are provided by large amounts of lipid and in some species by polar setulae. No SBs could be observed in a fresh collection of *E. urosperma* Döbb. (IVV: H.B. 6148b). In *Bryodiscus* the asci are gradually thicker-walled towards apex and react faintly euamyloid, while contents of the living spores are unknown. *Epigloea* stands in a family of its own with unclear relationship within the *Ascomycota*, and *Bryodiscus* is considered as a synonym of *Sphaeropezia* Sacc. in the *Stictidaceae* (Jaklitsch et al. 2016).

In the *Pezizales* the rarity of inverse orientation is mainly due to the rarity of heteropolar spores, besides the rarity of desiccation-tolerant taxa. Döbbeler (2004) reported inverse spore orientation in the desiccation-tolerant *Octosporella erythrostigma* (Mont.) Döbbeler. In this species the spore base is provided with an abrupt narrow tail, similar as in series *Hemiorbilia*. Our observations on this *Octosporella* confirm that mostly the lower spores are inverted. However, there is no distinct tractus to be seen in the living asci and the spores do no cluster near the apex, instead, they are distributed down to the base also at maturity. Moreover, neither Döbbeler nor we were able to detect any apical ascus structure like an operculum. Instead, the ascus wall seems to disintegrate with age. Apparently, the species is unable of forcible spore discharge and, therefore, does not require uniform spore orientation within the asci.

In *Leotiomycetes*, desiccation-tolerant taxa with slightly to distinctly heteropolar spores, such as *Patellariopsis dennisii* (I. Focht ined.; N. Matočec pers. comm.) or *Helicogonium* (*H. cyathiculae*, *H. mollisiophilum*, Baral 1999), may show a few of the lower spores with the narrower end directed towards the ascus apex. Also in *Durella atrocyanea* and *Patinella abietina* a few of the basal spores were found to be sometimes heteropolar and distinctly inverted (Baral ined.). *Ascocoma eucalypti* (*Phacidiales*) as described and illustrated by Swart (1986) has clavate ascospores with strongly eccentric septum and shows 3–7 of the lower spores inverted. On the other hand, other genera with desiccation-tolerant apothecia and distinctly heteropolar spores, such as *Patinellaria* (*Helotiales*) or *Patellaria* (*Patellariales*), never showed the phenomenon of inverse spore orientation.

Spore discharge. According to Landvik et al. (2003: 1029), active ascospore discharge is an ancient feature within *Ascomycota*, being first found in *Taphrinomycotina*. Spore discharge is a universal feature of various groups of discocarpous ascomycetes, such as *Orbiliomycetes*, *Leotiomycetes*, *Pezizomycetes*, or *Lecanoromycetes*. Exceptions are very rare and only known in taxa with more or less closed sporocarps, such as *Tuberales* and *Octosporella* (*Pezizomycetes*), or *Bicornispora* and *Unguicularia unguiculata* (*Leotiomycetes*). The phylogenetically oldest subdivision of *Ascomycota* in which active spore discharge occurs are apparently the *Taphrinomycotina* (*Taphrina* and *Neolecta*). Also many of the pyrenocarpous ascomycetes show active spore discharge, but various groups have lost this ability.

Our study showed that apparently all taxa of *Orbiliomycetes* are capable of forcible ascospore discharge. In a fairly large number of species of both *Hyalorbilia* and *Orbilia*, but also in *Lilapila*, we have observed fully turgescent asci in water mounts, and we saw active spore discharge from such asci into the water medium. Forcible instant spore discharge was observed in taxa with apically thick-walled as well as thin-walled ascus types. However, the process of spore discharge happens comparatively seldom, because fully turgescent asci occur usually in small number. But even if they occur abundantly, which is frequently the case in *Hyalorbilia*, spore ejection was only exceptionally seen in water mounts.

Spore discharge is used when obtaining pure cultures. Spores of *Orbiliomycetes* were forcibly ejected through the air within the Petri dish over the short distance between lid and agar in virtually all species of *Amphosoma*, *Hyalorbilia*, *Lilapila*, and *Orbilia* that we have tried to culture. The orientation of the apothecia was generally downward or laterally, but some inoculations were made with an upward orientation and likewise succeeded to land spores on agar.

The force that propels the spore cluster through the apical ascus pore originates from the osmotically generated hydrostatic pressure (ascus turgor) which increases during ascus maturation. Turgor is promptly released by bursting of the apical wall, obviously due to a preformed weakness zone. Complete ejection of all spores takes place in the blink of an eye (perhaps within 1/1000 sec) and cannot, therefore, be recorded with normal video cameras.

Active spore discharge requires a number of obligatory features, namely: (1) the ascus wall must be elastic, allowing volume increase during turgor increase; (2) the whole ascus wall must be permeable for water to enable water intake by the ascus vacuole; (3) water uptake is assumed to result from the transformation of osmotically inactive glycogen (see p. 96, Glycogen) in the ascoplasm to soluble sugar molecules; (4) the spores must be crowded at the top of the ascus (Baral 1992: figs 8–10).

Spore dehydration prior to discharge. In species with thin and/or elastic spore walls a further phenomenon supports discharge: the spores decrease in volume, either via shrinkage or collapsing. This is effected by partial dehydration, i.e., translocation of water from the sporoplasm to the surrounding ascus vacuole. The result of this process is a low spore volume in relation to a high ascus volume which is essential for an effective spore discharge. Shrinkage and collapsing of spores is caused by the raised osmotic pressure of the ascus vacuole that withdraws water from the spores.

If the spore walls are more or less elastic, the spores shrink to some extent prior to discharge during dehydration inside asci, particularly in width. This is quite a commonly observable feature in helotialean taxa (see also p. 28, Shrinking effect), which facilitates passage of the spores through the apical ring.

If the spore walls are more rigid, spore shrinkage is hardly noticeable, instead, the spores collapse inside the living asci when full turgescence is attained. Collapsing of spores is quite a frequently observable effect in *Orbiliomycetes*, especially in *Orbilia* (Fig. 43: a, c-d). It is not an artifact but a physiological process: the spores obviously cannot shrink to the required extent because their thin walls possess a too low degree of elasticity. The effect was particularly observed in species with globose or ellipsoid spores, and could not so far be seen in sections *Aurantiorubrae*, *Hemiorbilia* and *Arthrobotrys* in which the spores are mainly elongate and narrow. In *Hyalorbilia* deformed or collapsed spores were only seen in species with subglobose spores (*H. multiguttulata*), also spore shrinkage inside living asci could hardly be observed here. On the other hand, the subglobose spores of *Lilapila* were so far never seen to collapse.

Formation of a spore cluster. As a further peculiarity of *Orbiliomycetes*, the spores of an ascus stick together in the course of ascus turgor increase, apparently by adhesive remains of the ascoplasm around each ascospore. The resulting spore cluster forms a more or less compact projectile (Fig. 43: b, d), even in multispored asci. Thereby, collapsing of the spores allows a more tight packing which evokes that the pars sporifera is distinctly reduced in length and often also width. The refractive spore cluster exhibits an increased contrast to the large non-refractive ascus vacuole in which it is enclosed. The individual spores are often more or less indistinguishable within the cluster, also the SBs may become masked. The tight packing of the spores enables the spore cluster to be violently ejected as

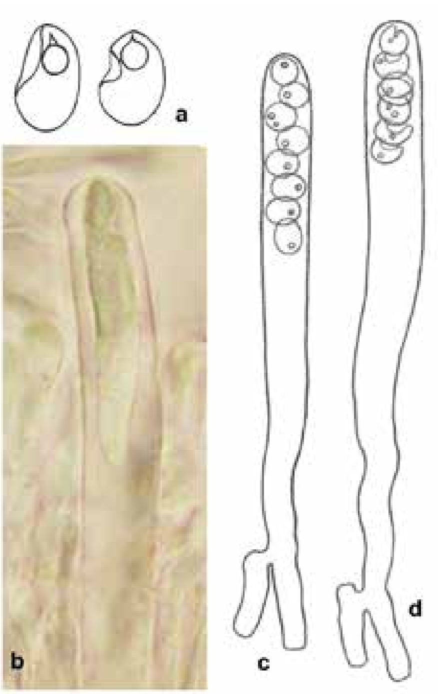

Figure 43: **a**. *O. octosporoides*, collapsed living spores inside fully turgescent ascus shortly before discharge; **b**. fully turgescent ascus of *O. vinosa*, with cluster of 8 dehydrated spores; **c–d**. *O. liliputiana*, mature living asci at moderate (**c**) and full turgescence (**d**), here with shortened pars sporifera and collapsed spores.

a single entity. This is confirmed when obtaining pure cultures, whereby each spore cluster produces a discrete spore heap on the agar (Fig. 44: a–b).

This peculiarity was observed in all our cultures of *Orbilia* and most of the other genera of *Orbiliomycetes*. *Lilapila* forms a very indistinct spore cluster inside turgescent asci, with a thin mucilage between the ± uniseriately arranged spores (Pl. 30: 1g). Also in *Hyalorbilia* the cluster is only indistinctly formed, but similar as in *Orbilia* the spores remain loosely coherent after discharge in a water mount (Fig. 44: d). Only in *Lecophagus* the spores were found singly or in pairs on the agar (*L. ellipsoideus*), and also spore clusters have not been seen in this genus, except for *L. subglobosus*: photos made by B. Coué (pers. comm.) suggest that the spores stick together and collapse somewhat prior to discharge (Pl. 50: 1g).

We conclude that in *Orbilia* the mature asci undergo two morphologically very different stages of development: (1) the stage of moderate turgescence with clearly visible individual spores, and (2) that of full turgescence in which individual spores are often hard to see (Fig. 24). Due to the absence of vital studies, literature reports do not account for the spore clusters in *Orbilia*. Because of the opposed orientation of the acute ('apiculate') spore ends in *O. sarraziniana*, Benny et al. (1978) assumed that the spores are discharged as a single entity. However, the authors did not study living asci under the LM, therefore, they could not prove their assumption.

When observing spore discharge from high-turgescent asci in a water mount, the spore cluster is brought to a halt at a distance of about 20–40 µm away from the ascus tip, due to the density of the medium. Shortly after discharge into water, the spores swell by water uptake and separate a bit form each other, though remaining loosely coherent for at least some minutes, apparently due to remains of ascoplasm (Fig. 44: c–e). These remains do not appear to consist of a mucilage as is infrequently observed in *Helotiales* ascospores, because such mucilaginous sheaths usually stain lilac in CRB, whereas the surface of ascospores of *Orbiliomycetes* did never stain in this basic dye.

Spore clusters are probably formed in every species of *Orbilia*, although we have seen them in only ~10% of the taxa recognized here. Photos or drawings of spore clusters in fully turgescent asci exist for the following sections: *Lentiformes* (*O. euonymi* Pl. 207: 1), *Hemiorbilia* (*O. aprilis* Pls 289: 1; 290: 1e, *O. breviclava* Pl. 322: 1e, *O. clavuliformis* Pl. 315: 6b, *O. graminis* Pl. 373: 2e, *O. myrioauris* Pl. 306: 2a, *O. octocorculispora* Pl. 296: 2m, *O. vinosa* Fig. 43: b; Pl. 262: 1b), *Aurantiorubrae* (*O. xanthoguttulata* Pl. 444: 10a, *O. pseudoaristata* Pl. 524: 5, *O. scolecospora* Pl. 464: 2b), *Helicoon* (*O. rosea* Pl. 529: 5, *O. sarraziniana* Pl. 538: 4c), *Habrostictis* (*O. gambelii* Pl. 721: 7d, *O. multihamulata* Pl. 590: 2f, *O. paravitalbae* Pl. 490: 2d), *Orbilia* (*O. battenii* Pls 840: 1; 841: 2a, *O. dryadum* Pls 870: 1–2; 871: 3a, *O. eucalypti* Pl. 857: 7, *O. fabacearum* Pl. 888: 1, *O. tremulae* Pl. 861: 5, 6, *O. xanthostigma* Fig. 45, Pls 875: 5, 15; 878: 4a, 7, *O. liliputiana* Fig. 43: d), and *Arthrobotrys* (*O. asomatica* Pl. 931: 1l, *O. multiformis* Pl. 958: 1a).

The particular phenomenon of a tight spore packing in combination with the partial invisibility or collapsing of individual spores could not be observed so far in any other class of *Ascomycota*, and appears to represent one of the unique characteristics of *Orbiliomycetes*. In all the many non-orbiliaceous inoperculate discomycetes which we have studied, the individual spores remain always clearly visible prior to discharge, and the spores are usually not ejected as a single entity but one after the other, frequently through an expansible amyloid apical ring. The difference between moderate and full turgescence in such taxa is only a gradual one, but also involves increase in ascus size, decrease in spore width, and also contraction of the pars sporifera.

Spore clusters similar as in *Orbilia* occur in multispored asci of some genera such as *Deltopyxis*, *Sarea*, and *Symbiotaphrina*. However, the spores do not collapse or become obscure prior to discharge here. As in *Orbilia* the asci open by a large slit-like pore, and the spores are ejected as a single entity by forming discrete heaps on the agar (for *Deltopyxis* see Baral & Marson 2012: fig. 5h–i). In ascoconidia-forming members of *Claussenomyces* s.auct., *Tympanis*, and *Helicogonium*, the conidia are included in 8 'balls' within the living asci, which are similarly ejected by forming 8 conidial heaps on the agar. Also

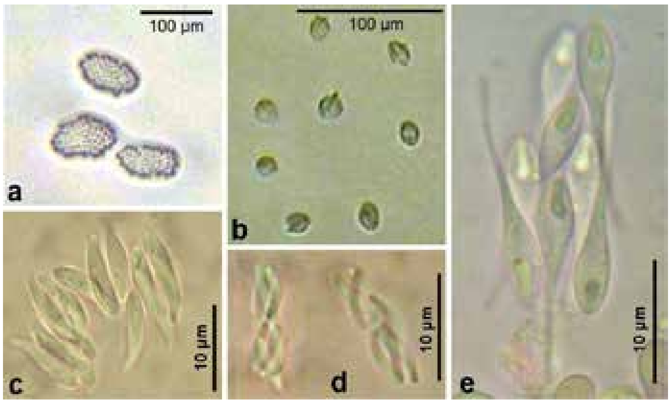

Figure 44: **a–b**. Spore clusters shot on agar, **a**. *Orbilia myriosphaera* (64-spored, H.B. 6679a), **b**. *O. obtusispora* (8-spored, H.B. 8691); **c–e**. loosely cohering clusters of 8 spores a few minutes after discharge from high-turgescent asci in water mounts, **c**. *O. quaestiformis* (H.B. 7592a). **d**. *Hyalorbilia tortuosa* (H.B. 7576), **e**. *O. aristata* (P.P. 20071028).

scolecosporous genera of *Ostropomycetidae* eject their very long, filiform spores as one entity in the form of an agglutinated parallel bundle, according to an unpublished observation in *Karstenia* sp. (IVV: H.B. 9272a).

In contrast to this, we have observed in various species of *Helotiales* with an amyloid ring that the spores arrive more or less singly on agar. This is also the case in those taxa with inamyloid asci in which the spores are successively ejected (e.g., *Durella connivens*, *D. atrocyanea*). Comparable observations were made by us in *Sclerococcum* (= *Dactylospora*, *Lecanoromycetes*), *Rhizodiscina lignyota*, and *Patellaria atrata* (*Dothideomycetes*).

The spore cluster in *Saccobolus* Boud. (*Pezizales*) differs from those of *Orbiliomycetes* in the eight individual spores firmly sticking together at a rather early immature development stage, i.e., prior to formation of the episporial pigment (Van Brummelen 1967: 40). The spores remain agglutinated during further maturation, also in the dead asci and after discharge.

Spore clusters similar to those of *Orbiliomycetes* were described for the 8-spored *Thelebolus microsporus* (*Thelebolales*), in which the spores are ejected as a single projectile (De Hoog et al. 2005: 64). A fresh specimen of this species showed a strikingly refractive, irregularly shaped gluing substance between the spores which stains bright rose-red in CR. With the help of this glue the spores may remain agglutinated after ejection in the same obliquely biseriate order as inside the living asci. However, dehydration and collapsing of the spores inside the high-turgescent asci was not observed. It appears that the spores are successively pressed through the pore and rearrange thereafter by means of the glue. Similar spore clusters held together after ejection by some gel sheaths or ascoplasm are known in *Podospora*, *Sordaria* (*Sordariales*), and *Dasyobolus* (*Pezizales*) (see Ingold 1933), also in *Unguiculella tityri* (Baral ined.). All these species are coprophilous, and the frequent occurrence of spore clusters in this ecological group might be indicative for a need for spore dispersal at high distances.

Tractus and nasse apicale. Neither of these cytoplasmic structures could be discovered with the LM (oil immersion) or the TEM in the mature asci of any member of *Orbiliomycetes*. This seems to support the isolated position of the class within the *Ascomycota*. Nevertheless, a structure must exist that draws the spores towards the ascus apex. Apparently this task is taken on by the remains of ascoplasm around the spores which hold them together in a cluster in the fully turgescent ascus. At earlier stages of ascus maturity these plasma remains cannot be seen, perhaps because they are more hydrated by connecting the spores only loosely together.

Tractus and nasse apicale are best seen in living asci. A nasse apicale is typical of various *Dothideomycetes* (e.g., *Gloniopsis*, *Patellaria*, *Pleospora*, *Rhopographus*, *Tubeufia*; Chadefaud 1942: figs 49–50; 1973: figs 8, 17, 19; Baral 1992: fig. 7). It was also reported for some groups of *Helotiales*, viz. *Belonidium*, *Incrucipulum*, and *Vibrissea* (Bellemère 1960, as 'manchon épiplasmique'; Baral 1987a: figs 17, 25; Leenurm & Raitviir 2000, as 'apical cap'). A tractus occurs as a general feature in the *Pezizales* (Chadefaud 1942: figs 56–66, 70–80), but was also observed in, e.g., *Leotia* (Chadefaud 1944: figs 15–18), *Lecanora* (Baral 1992: fig. 9a), and *Neolecta* (Fig. 39: b). A similar structure was seen in *Trichoglossum* by Verkley (1994). The tractus is affixed at the ascus tip and to each ascospore; it drags the spores upwards and holds them close to the ascus apex, while the nasse apicale perhaps functions as a reinforcement of the plasmalemma in the apex region that aids during spore passage. The presence of a tractus in *Neolecta* could indicate that the *Orbiliomycetes* early lost this microstructure. In polysporous asci a single tractus would actually seem unsuitable.

Frequency of fully turgescent asci. In desiccation-sensitive members of *Helotiales* and *Pezizales*, fully turgescent asci are often seen in mature apothecia in great number. Likewise, mature apothecia of *Hyalorbilia* often contain hundreds of fully turgescent asci. In contrast, in desiccation-tolerant discomycetes such asci are usually more sparse. Also asci of *Orbilia* that show the characteristic spore cluster are only infrequently seen, usually only a few in a section, although every successful ascus inevitably undergoes this stage of development.

The rarity of fully turgescent asci in *Orbilia* might be explained by the frequent desiccation tolerance of the apothecia, which are generally collected during dry weather. Immediately after rewetting they contain abundant mature asci at moderate but not full turgescence. Only when kept wet for some hours, a few asci may attain full turgescence and thereby project beyond the hymenium. However, even in those species of *Orbilia* which do not survive drying, full turgescence is often only observed when a section is kept for about 10–20 min in a water mount. Even if apothecia are submerged under water for some hours or days, the number of fully turgescent asci did not noticeably increase (tested with *O. sarraziniana*). Turgescent asci occurred in greater abundance only in a few cases, for instance in *O. xanthostigma* (Fig. 45).

In *Hyalorbilia* the difference between moderate and full turgescence is not as clear as in many species of *Orbilia*. Nevertheless, the abundance of fully turgescent asci in *Hyalorbilia* is a frequent feature and seems to correlate with the observation that the apothecia are comparatively short-lived, i.e., they survive only a short period of time in the dry state.

The paucity of fully turgescent asci in *Orbilia* is the reason why apothecia often shoot their spores rather sparsely on agar. It seems to be a general feature of desiccation-tolerant taxa including lichens, that 'comparatively few asci discharge at any one time' (Sherwood 1981: 32). But also in *Hyalorbilia* the obtained spore heaps on agar were often comparably few. Desiccation-sensitive members of *Helotiales* and *Pezizales* often discharge their spores in much higher quantities under the same conditions. The macroscopically visible 'puffing',

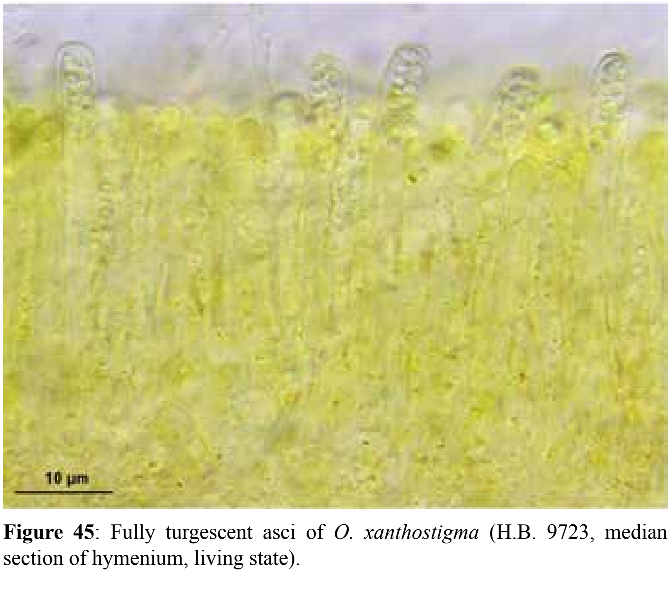

Figure 45: Fully turgescent asci of *O. xanthostigma* (H.B. 9723, median section of hymenium, living state).

whereby numerous asci simultaneously explode, being triggered by external influence (see Buller 1934), was never observed in the *Orbiliomycetes*.

The function of apical thickenings and truncate apices. Desiccation-tolerant ascomycetes grow in direct exposure to air currents or sometimes in the narrow interspace behind slightly detached bark of standing trees, therefore, long distance discharge does not seem to be important in this ecological group of fungi (Sherwood 1981). Amyloid apical rings are undoubtedly essential for long distance spore discharge due to their enormous elasticity (Baral 1987b: 432). Their absence in many desiccation-tolerant *Helotiales* can apparently be explained in such a way. Therefore, it is surprising that, among the desiccation-tolerant members of *Orbilia*, two very different types of ascus apices occur: those with apical thickenings and apical chamber, and those with truncate, thin-walled-shouldered apices. Judging from morphology, the former type appears to be more efficient in regard to active spore discharge than the latter type. However, the consistent absence of apical thickenings in desiccation-sensitive members of *Orbilia* is in conflict with this assumption. Experiments that assess discharge distances should be undertaken on representatives of the different ascus apex types.

A theory that tries to explain apical or lateral thickenings of ascus walls as an adaptation to a xeric environment in combination with long-lived apothecia (Nannfeldt 1932: 27; Chadefaud 1942: 59, 1973: 135f.; Dughi 1957), was considered as not convincing by Baral (1992: 353). Within *Orbilia*, however, this theory seems to be supported by the fact that all species with thick-walled ascus apices showed a more or less pronounced desiccation tolerance over several months or even years. On the other hand, many taxa with thin-walled ascus apices survive about the same periods of time in the dry state.

Theories that try to reconstruct the process of spore discharge are usually based on the morphology of the dead mature ascus as seen under the LM, TEM, or SEM, in comparison with the emptied ascus. Yet, in most orders of *Ascomycota* living turgescent asci differ greatly from dead asci. This is also the case in the two main types (A and B) of *Orbilia* asci (Figs 31, 35): asci with apical thickening are much more thin-walled in the living state, and truncate asci are almost hemispherical or only slightly truncate, without any trace of shoulders. This means that types A and B look rather similar in the living state and can hardly be distinguished. The strong difference in wall thickness and apex shape in the dead state might involve different pore structures of the emptied ascus. Yet, the few available observations in *Orbiliomycetes* disprove this possibility (see p. 48).

In *Orbilia* the apical chamber of the thick-walled ascus apex is often not perceptible in the turgescent state. One could conclude from this that the wall above the apical chamber is less expansible than the wall around, so that both wall areas have about the same thickness when compressed. However, in *Orbilia euonymi* (Fig. 31: a) the apical chamber could be seen in the living state, and also in the *Lecanorales* with a similar shape of apical thickening this chamber is very clearly visible in living asci, though lower and much wider compared to the dead state (Baral 1992: fig. 9).

During ascus explosion, the wall around the preformed apical fissure must be stretched in order to allow passing of the large spore cluster. Thereby, the apical thickening (the endotunica) probably elongates upwards. Such extensibility, sometimes in combination with a separation from the ectotunica, is known from groups with strongly expansible apical walls, such as the *Lecanorales* with a rostrate type of emptied ascus, but is also believed to occur, e. g., in *Thelebolus* (De Hoog et al. 2005: fig. 12f). Stretching and elongation of the thickened endotunica is probably a universal phenomenon in the ascomycetes, most developed in the fissitunicate ascus of the *Dothideales*, and appears to be the main function of this structure (see Baral 1987a: 127, 1992: 353).

Due to their elasticity and expansibility, apical thickenings appear to serve in preventing loss of water from the ascus when the spore cluster passes the pore. If this holds true, asci of the truncate-shouldered type should be less efficient in this respect so that the spore cluster is less forcibly ejected. The firm subapical wall of the thin-walled ascus type (Fig. 34: c–d) might restrict the apical opening to a short slit and thus avoid too much water loss. On the other hand, part of the ejected vacuole water undoubtedly remains attached to the spore cluster after discharge and increases its weight and, therefore, the distance to which the cluster is shot. Thick-walled ascus apices might be able to withstand a higher ascus turgor, but this has to be demonstrated experimentally.

Function of the inverse spore orientation. The inverse orientation of some of the spores within an ascus seems to support a more tight packing within the spore cluster. This applies, however, only to species with a heteropolar spore shape, with one end tapered or tailed. In species with long and thin spore tails there is a strong tendency of only 1–3 basal spores being inverted. Some asci of these species may even lack any inverted spores, and a few species (*O. fimbriata*, *O. pseudoflagellispora*) showed predominantly asci in which all spores were oriented with their tails downwards. Hence, the formation of a spore cluster does not seem to depend on inverse spore orientation. The orientation of all spores in the same direction probably represents a higher evolutionary level and becomes obligatory in species which eject their spores one after the other through an elastic apical ring.

Döbbeler (l.c.) imagined that the phenomenon of partial spore inversion in *Bryodiscus* resulted in cylindrical instead of clavate spore fascicles and, therefore, cylindrical instead of clavate asci which might serve in a more efficient spatial exploitation of the hymenium in concave (cup-shaped) hymenia, but in *Epigloea* he admitted that spore inversion could not be explained this way. We must remember, however, that Döbbeler's remark refers to dead shrunken asci in which the spores fill most of the ascus lumen. Considering the fact that living asci usually have ample water around the spores, we doubt that the shape of the spore fascicles in *Bryodiscus* necessarily influences the shape of the turgescent asci.

Whatever the advantage of spore inversion in *Orbilia* may be, the formation of a compact spore cluster appears to be a prerequisite for the evolution of a high diversity of different spore shapes, particularly concerning strong curvature. Inverse spore orientation might be a plesiomorphic character of a common ancestor of ascomycetes. Then it would now represent a relict which had not been abandoned with the emergence of heteropolar spores because of the ability to form a spore cluster.

Spores of desiccation-sensitive *Helotiales* are often slightly to strongly heteropolar in shape. When successively discharged, a heteropolar spore achieves greater initial velocity and consequently greater range during discharge (Ingold 1954). With its rather motionless air, the sheltered habitat of such fungi was suggested by Sherwood (1981) to require a more efficient spore discharge, and one could speculate that fungi of this habitat have abolished the unfavourable inverse spore orientation. But the opposite case, the loss of uniform spore orientation, could likewise have happened during evolution. This may well be so in those *Helotiales*, in which an amyloid ring is considered to be primary (Baral 1987b: 438), and inverse orientation could so far only be observed in genera with inamyloid asci.

Advantages of the spore cluster. The advantages of the spore cluster and the involved dehydration of the spores appear to be as follows:

1) A large compact cluster of spores is shot to a much greater distance compared to comparatively small single spores (Ingold 1933: 183 ff.).

2) A broad range of spore shape diversity could evolve in the *Orbiliomycetes*, because the individual spores do not require an aerodynamic design. The spore cluster has a concordant cylindric-fusoid shape, regardless of the individual spore shape.

3) All spores of a cluster are still held together when landing on the substrate. This kind of dispersal might avoid single spore mycelia during substrate infection, and provide a higher probability for an efficient colonization in case that species is homothallic.

The spore clusters of *Orbilia* appear to represent a strategy to achieve similar distances compared to those desiccation-sensitive *Helotiales* which eject single spores through an elastic amyloid ring. In desiccation-tolerant *Helotiales* with inverse spore orientation, spore clusters have never been observed in the living asci. Vital studies should clarify whether genera like *Epigloea* or *Bryodiscus* form spore clusters in the living asci. The *Orbiliomycetes* have possibly developed this type of discharge mechanism because the group as a whole has never possessed or very early lost amyloid ascus wall structures (see also p. 129–135).

Sherwood (1981: 31 ff.) postulated that discomycetes growing on branches exposed to air currents do not need efficient discharge mechanisms compared to those growing at the ground, followingly they were not subjected to strong selection pressure for aim or long distance trajectories. According to Sherwood, desiccation-sensitive ascomata are faced with problems of still air surrounding the substrate, whereas desiccation-tolerant ascomata are directly exposed to turbulent air and, therefore, need minimal distance trajectories for efficient spore dispersal. The situation found in *Orbiliomycetes* is in conflict with Sherwood's hypothesis. Desiccation tolerance is probably a plesiomorphic feature within the genus *Orbilia* (see p. 160). Nevertheless, the group appears to have developed an elaborate capacity of long distance discharge, and maintained this capacity also in desiccation-sensitive species. Since desiccation-tolerant species possess on average larger spores and also larger spore clusters due to the frequent polyspory, they are expected to achieve larger distances than desiccation-sensitive taxa.

Sherwood (1981: 25, 32) noticed the frequency of large, filiform or muriform spores as well as polyspory in desiccation-tolerant ascomycetes, combined with the absence of apical ring structures. Yet, she appears to have underestimated the efficiency of spore discharge in these fungi. Colonization of new substrate is possibly supported by invertebrates as vectors, for instance in semideserts with very scattered plants. Forcible discharge of a sticky spore cluster during moist periods should also be considered under this point of view.

Ingold (1933) drew attention to the efficiency of spore clusters ('spore masses') in long distance dispersal. Among the pyrenomycetes, the 128-spored *Podospora curvicola* attained 45 cm in vertical direction as maximum distance of discharge, whereas 8-spored species of *Podospora* and *Sordaria* attained 6–30 cm. In comparison, pyrenomycetes ejecting single spores attained a maximum of only 1–1.2 cm. Ingold also noted a correlation between the formation of 'spore masses' and coprophily: three very different groups of coprophilous fungi have independently evolved spore clusters, in which the spores are held together by gel sheaths, gelatinous appendages, or by the surrounding sporangial wall: *Dasyobolus* (*Pezizales*, maximum distance 30 cm), *Podospora* and *Sordaria* (*Sordariales*), and *Pilobolus* (*Mucorales*, maximum distance 200 cm).

The direction of discharge is governed in the three groups by a phototropic mechanism either of the individual ascus, the perithecial neck, or the sporangiophore. In the *Pezizales*, the protruding part of the asci is often bent towards the direction of light (Buller 1934: 264, Van Brummelen 1967: 36). No such phototropism of asci or ascomata could ever be observed in the *Orbiliomycetes*.

Ascospores

Ascospores of *Orbiliomycetes* provide the most diagnostic characters for species delimitation, which involves not only their size and shape, but also size and shape of the included spore bodies (SBs). In contrast to other ascomycetes, lipid bodies (LBs) turned out to have a rather low taxonomic value in this group. Due to their refractivity, SBs are very conspicuous cytoplasmic inclusions in the living ascospores when viewed under oil immersion, whereas they are hardly or mostly not at all discernible in dead herbarium material, irrespective of which staining agent is applied. Ascospores of *Orbiliomycetes* exhibit an extraordinary high diversity in shape, which appears unique among the *Ascomycota*. A similar diversity can be attested to SB morphology, which was found to better reflect phylogenetic lines than spore shape does. The high taxonomic value of ascospores lies in the combination of both characteristics. Many species or groups of species can readily be recognized merely by morphology of their living spores. Therefore, collections of *Orbiliomycetes* generally remain unidentified if no spores are found.

Spore size and shape. – Size. Ascospores of *Orbiliomycetes* are currently perceived as being extraordinarily small. However, there is actually a wide size range across the taxa. Living spores may range from *(1.8–)2.5–3.5 up to 20–25(–30) µm in (actual) length and from *(0.6–)0.7–0.9 up to 4–5(–6) µm in width. This diversity corresponds to a volume range of around 2–5 up to 150–250 µm^3, which means a maximum difference of over 100×. Desiccation-sensitive species tend to have rather small spores whereas those of desiccation-tolerant taxa comprise the full range of spore size, with a tendency to larger spore volumes if 8-spored and to smaller volumes if polyspored.

Curved spores pose a methodological problem when measuring their length. The direct distance from end to end (in situ) is easier to evaluate but subjected to higher variation,

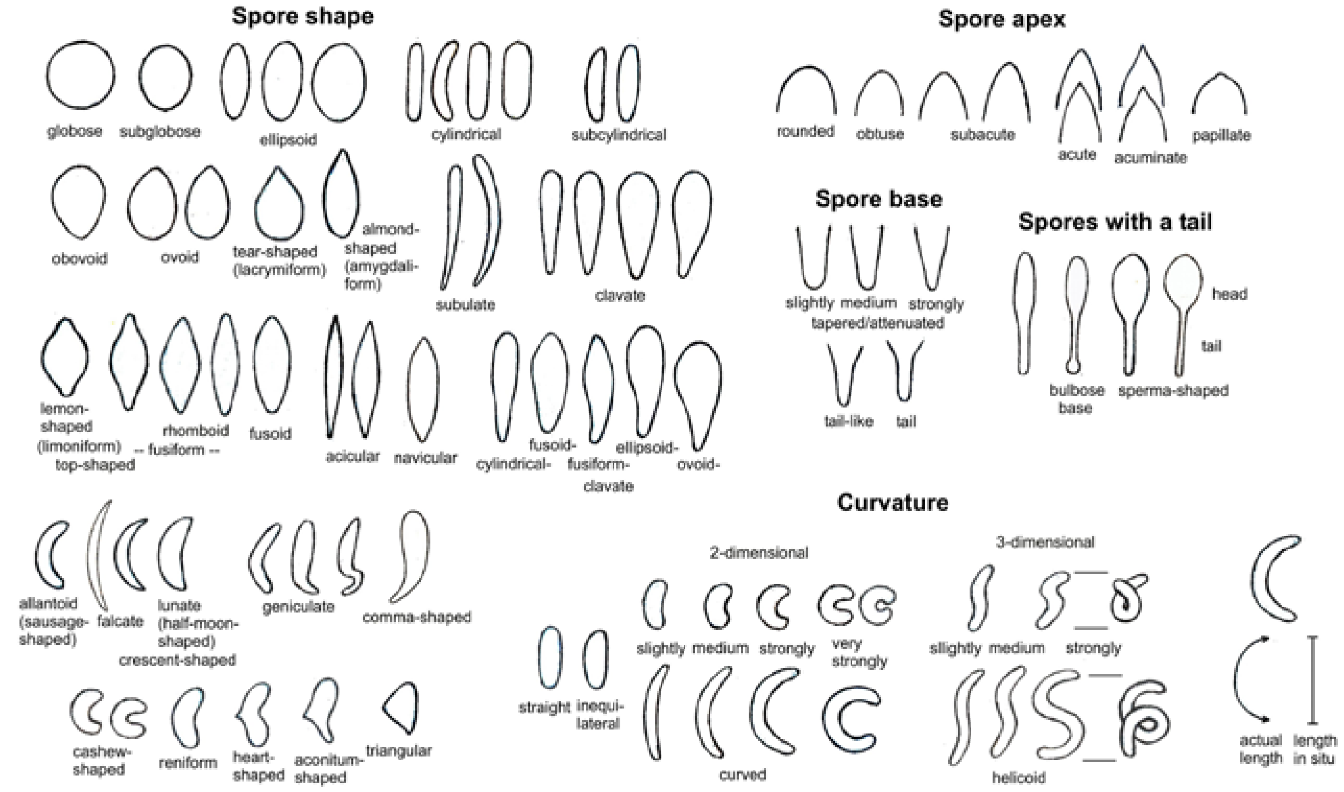

Figure 46: Different types of ascospore shapes occurring in *Orbiliomycetes*. Terminology following in parts De Hoog & Guarro (1995) and Hawksworth et al. (1996).

however, the actual length along the curvature yields more reliable information but can only be estimated or calculated by respecting spatial spore shape. The best is, therefore, to separately evaluate spore length in both ways (see p. 10, Microscopic measurements).

Shape. Spore diversity within *Orbiliomycetes* comprises virtually all types of spore shapes known in ascomycetes: globose, ovoid, ellipsoid, fusoid, rhomboid, clavate, sperm-shaped, tear-shaped, cylindrical, subulate, falcate, helicoid, comma-shaped, sausage-shaped, cashew-shaped, triangular, heart-shaped etc. (Fig. 46). This high diversity within the class as opposed to a rather low intraspecific variability suggests that spore shape diversity reflects some kind of ecological adaptation, rather than representing an accidental evolutionary product.

Many species of *Orbilia* possess more or less ellipsoid ascospores. Besides species with globose and subglobose spores they represent the more primitive type of spore shape (see Fig. 55). A more complex morphology is achieved when the spore ends become attenuated or pointed, which results in a fusoid or fusiform (rhomboid or navicular) shape. These types of spore shape often occur in very distant groups of *Orbiliomycetes*, therefore, confusion at the sectional up to generic level may occur when dealing with dead herbarium material, in which the spore bodies are invisible (see Fig. 3), also if ascus characters are neglected.

Similarly, vermiform to acicular ascospores occur in various, more or less distant taxa. For instance, falcate spores are typical of section *Arthrobotrys*, but also occur in sections *Helicoon* and *Hemiorbilia*, and even in *Hyalorbilia* (Fig. 47). Such spores may sometimes show a very slight helicoid twist. In other species the spores are distinctly helicoidally twisted (within the living asci but also after discharge). Helicoid spores are typical of series *Aurantiorubrae*, *Hyalinia*, and *Xanthoguttulatae* (section *Aurantiorubrae*, Fig. 48: a–d), but also occur in sections *Hemiorbilia* and *Orbilia*, and even in *Hyalorbilia* (Fig. 48: e–g). Helicoid spores in *Orbiliomycetes* are predominantly twisted like a right-hand thread. In this way they are tightly intertwined inside the asci. Only in three rather distantly related species (*O. spirospora*, *O. bomiensis*, *O. helicovinosa*) the spores are consistently twisted like a left-hand thread. Such helicoid spores are often incorrectly termed 'sigmoid' (e.g., by Spooner 1987) or 'spirally twisted' (e.g., by Velenovský 1934), terms which should better be restricted to spores curved in one plane, though the letter sigma resembles helicoid spores seen in side view. Falcate and helicoid spores are heteropolar in most species of *Orbilia*, i.e., their two ends deviate in shape and contain a spore body only in one end, whereas in *Hyalorbilia* they are homopolar in shape, and their SBs occur near both spore ends.

Sausage- to cashew-shaped spores exist in a few species of two rather distant sections (*Hemiorbilia* and *Orbilia*, Fig. 49: a–e). Such spores often form semicircles, and even almost complete circles occur (*O. subfabacearum*, Fig. 49: c). The rare case of warted spores occurs only in this spore type (Fig. 49: d).

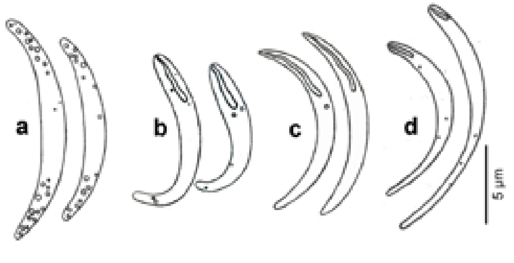

Figure 47: Falcate (sickle-shaped) spores as occurring in quite distant groups of *Orbiliomycetes* differ markedly in the living state by their SBs, while in the dead state they are easily confused. — **a**. *Hyalorbilia berberidis*, **b**. *Orbilia multicurvula* (section *Hemiorbilia*), **c**. *O. arcospora* (section *Helicoon*), **d**. *Orbilia* cf. *rubrovacuolata* (section *Arthrobotrys*).

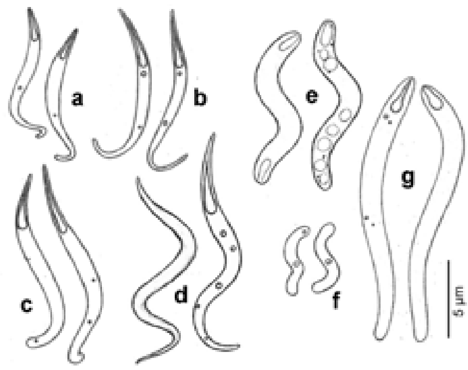

Figure 48: Also helicoid ascospores occur in very different groups of *Orbiliomycetes* (living state except for **e–f**). — **a**. *Orbilia pseudobrevistipitata*, **b**. *O. nemaspora*, **c**. *O. jugulospora*, **d**. *O. spirillospora* (**a–d**. section *Aurantiorubrae*), **e**. *Hyalorbilia macrohelicospora*; **f**. *O. spirospora* (section *Orbilia*), **g**. *O. helicovinosa* (section *Hemiorbilia*).

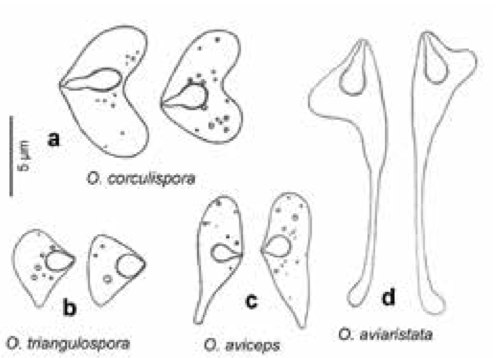

Figure 50: Extraordinary types of bilaterally symmetric spore shape (heart-shaped to triangular, SBs apically to laterally inserted). — **a**. series *Hesperideae*, **b–d**. series *Hemiorbilia*.

Spores with more or less long basal tails constitute quite a frequent type of spore shape. The tails are sometimes swollen and curved at their basal end. Such spores are typical of series *Hemiorbilia* (Figs 49: f, i; 50: d), but very similar spores occur in several more or less distant sections and series of *Orbilia* (Fig. 49: g, h, j–l). All these spore tails possess a lumen that contains cytoplasm along their entire length.

In an extraordinary type of ascospores the shape is asymmetrical and the spore apex with its large tear-shaped spore body is either in an apical or lateral position, resulting in heart-shaped or triangular spores (Fig. 50: a–b) or spores resembling more or less a bird's head (Fig. 50: c–d). Such spores occur in series *Hemiorbilia* and *Hesperideae* and appear to have evolved from symmetrical spores with apical SBs (see also under Spore body, p. 72). *O. aviaristata* and *O. aviflagellata* with their asymmetrical spore heads (Fig. 50: d) but apical SBs form a transitional type.

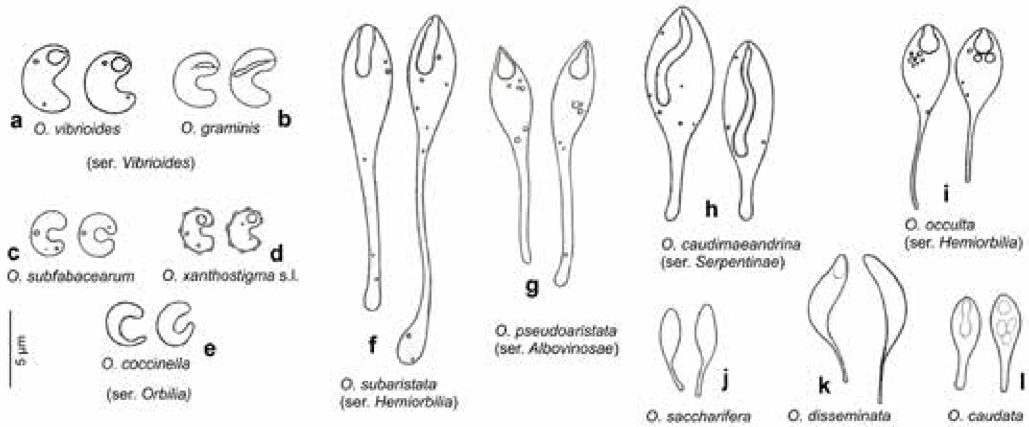
In quite a few species of *Orbilia* the spores have a seemingly aerodynamic shape. Their apex is tapered, often acute, and their base gradually attenuated or even provided with a tail, the widest part of the spore being above the middle. Yet, some of the spores are usually inversely oriented within the asci, and all spores are ejected as a compact cluster (see p. 60, Spore cluster). This provides sufficient evidence that the function of spore shapes in *Orbilia* must be explained differently (see p. 144–145, Preying on invertebrates).

Variation. Ascospore size and shape are usually quite valuable characteristics of a species, Yet, spore characters are sometimes overestimated in regard to species delimitation, and thought to be constant within a species. In our experience, variation in both size and shape seems to be a common phenomenon in many groups of ascomycetes. A more or less pronounced intraspecific variability was noted in almost every species of *Orbiliomycetes*, particularly between populations but also within.

Deviations in size and shape were particularly observed between collections from very remote areas, but sometimes also within a narrow area. They might in some cases be the result of external conditions rather than having a genetical basis. Frequently, however, such deviating populations raise the question as to whether they represent different species. For example, an extraordinary case of variation was observed between populations of *O. corculispor*a. Typically this species has heart-shaped spores, but sometimes it occurs in a form with more or less subglobose spores (see Fig. 65: b); intermediate spore types sometimes occur and would make a separation into two species difficult. In addition to this, typical populations vary among another between distinctly heart-shaped and kidney-shaped. Striking differences were sometimes also observed between parts of a single collection (Fig. 51: b–c). Whether such populations represent one variable or two separate species could not be clarified (see also p. 16 ff., Taxa concepts).

Spores may vary in size even within a single ascus. Such heterospory is known to occur commonly in the *Helotiales*: the lower spores of an ascus are slightly or even considerably longer than the upper ones. This phenomenon could be thought to provide a balanced discharge distance to all spores by compensating the declining turgor pressure during spore release. This assumption is based on Ingold's (1933)

Figure 49: Similar spore shapes in different series and sections of *Orbilia* (living state except for **e**, **k–l**). — **a–e**. reniform to semicircular spores; **f–l**. spores with tails.



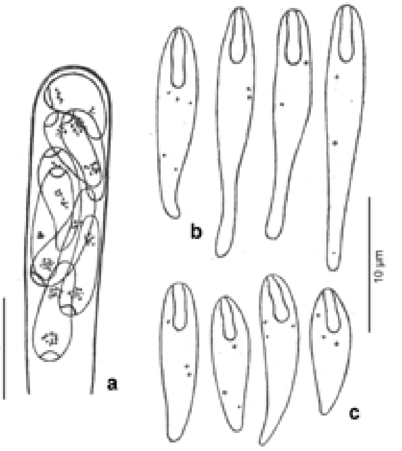


Figure 51: Variation in spore size and shape within an ascus (**a**) or a population (**b–c**). — **a**. Uppermost spore consistently shorter and wider and more curved than lower spores (*O. ocellata*); **b–c**. differences in spore length and shape observed in different subpopulations within an Australian collection of *O. hesperidea.*

observation that spores with a higher mass attain a higher distance. The lower, larger spores thereby compensate for loss of ascus turgor during spore discharge by a greater mass. In the *Orbiliomycetes* no such distinctly larger basal spores can usually be observed, instead, larger and smaller spores occur more or less scattered within the ascus. This is not surprising since here all spores of an ascus are ejected as a single cluster. It would not make any sense for an efficient dispersal to place the longer spores near the base of the pars sporifera. However, in series *Lentiformes*, and here particularly in 8-spored taxa, the uppermost spore is very frequently distinctly shorter and thicker and, furthermore, often strongly curved (Fig. 51: a). As this situation can regularly be seen in this series, such deviating spores are included in the description.

These deviations are considered to belong to the normal scope of variation, however, spores of abnormal size or shape may occasionally occur inside the living asci due to some possibly external influences. This concerns (1) spores of an abnormally large size but normal shape, which arise in asci with reduced spore numbers (see p. 56), or (2) spores of abnormal shape, generally more primitive than the typical spores of the species, for instance, normally ellipsoid spores are instead ovoid to globose, or spores with a tail or or tail-like base lack these markers. Both phenomena have occasionally been seen in a number of taxa, but usually only inside a few of the asci of an apothecium. In the case of abnormal shape, usually all spores of an ascus show this abnormity. Whatever causes such regression is unclear. We have consistently excluded abnormal spores from our species descriptions and keys if they occurred only exceptionally. In *O. eucalypti*, however, broadly ellipsoid to subglobose spores may occur in rather high frequency or sometimes strongly predominantly compared to the normal ellipsoid spores.

In those species of *Orbilia*, which mainly deviate from each other in spore number, the spores tend to be smaller with increasing spore numbers. However, exceptions confirm the rule: for instance, in series *Microspermae* a difference in spore volume is only seen between the 16-spored *O. pleioeuonymi* and 32-spored *O. euonymi* (Fig. 41). On the other hand, closely related species may markedly differ in spore size though having the same spore number (examples: *O. vinosa* and *O. aprilis*, or *O. pleiolentiformis* and *O. flavida*).

Terminology of spore ends. The partial inverse orientation of the spores in asci of *Orbiliomycetes* poses the problem of how to name the two spore ends. In most species the inversely oriented spores (with the SBs pointing downwards) are the lower spores of an ascus. In comparison with the *Helotiales* in which inverse orientation of some lower spores was rarely noted (see p. 59), we conclude that the SB-containing end of the spore, which is usually closer to the widest part of the spore, represents the 'upper' or 'apical' end, and the opposite the 'lower' or 'basal' end.

Of course, the terms 'upper' and 'lower end' applied to ascospores are somewhat incorrect because (1) ascocarps on the natural substrate often occur oriented in all directions, and (2) the spores within an ascus may also be oriented in two opposite or sometimes in all directions.

In order to avoid the first mentioned conflict, Domínguez de Toledo (1994) in her 'suggestions for describing and illustrating fungal spores' proposed the terms 'distal' and 'proximal' in order to characterize the poles of a spore. In her definition, the spore ends in fungi are determined either by their formation on sterigmata or conidiophores, or by their orientation within the asci, but not by their shape. 'Proximal pole' means the spore end by which a basidiospore or conidium is attached, or that end of an ascospore directed towards the ascus base. 'Distal pole' means the spore end directed away from the attachment. It must be noted, however, that some workers on pyrenomycetes, notably Eriksson (1967: 342), but also Webster et al. (1998) in *Orbilia*, conversely used 'proximal' for the broader ascospore end being oriented towards the ascus apex, and 'distal' for the narrower end pointing towards the ascus base (in pyrenomycetes with heteropolar spores we have so far never observed inversely oriented spores).

The second conflict mentioned above, the phenomenon of inverse spore orientation within asci, was obviously unknown to Domínguez de Toledo. However, she mentioned the case of rather short and wide spores, in which the spores do not show any regular arrangement within the asci. For this case Domínguez de Toledo concluded that the terms 'distal' and 'proximal' cannot be applied.

In our opinion, a clear reference to the two different poles is necessary for spores that are distinctly heteropolar in shape and/or cytoplasmic structure, even if the spores are irregularly arranged in all directions within the ascus. Based on the justified hypothesis that the differently shaped spore bodies in *Orbiliomycetes* are homologous organelles, we conclude that SBs provide a valuable tool for recognizing spore ends in *Orbiliomycetes* (see also p. 71–72).

We decided to continue the current usage of the terms 'upper/apical' and 'lower/basal' in reference to the terms 'ascus apex' and 'ascus base'. Thus, the 'upper end' contains the spore body. Thereby we refer to spores that point with their SBs towards the ascus apex as oriented 'ordinarily or upwards', and we name those spores as oriented 'inversely', 'inverted', or 'downwards' which point with their SBs towards the ascus base. In the case when SBs are absent or occur at both spore ends, the broader spore end is named 'upper end'. We also recommend arrangement of the spores on plates consistently with their upper end pointing upwards. In cases of homopolar spores with laterally inserted SBs (*O. corculispora*, *O. beatricis*, *O. fabacearum*) or when the spores are globose or flattened like a lens, no distinction can be made between upper and lower spore end, and also a distinction between ordinarily and inversely oriented spores is then more or less impossible. In such cases spore end terminology (including SB attachment) and spore orientation become ambiguous.

Shrinkage and collapsing during dehydration. Shrinkage and collapsing are universally observed effects of the living

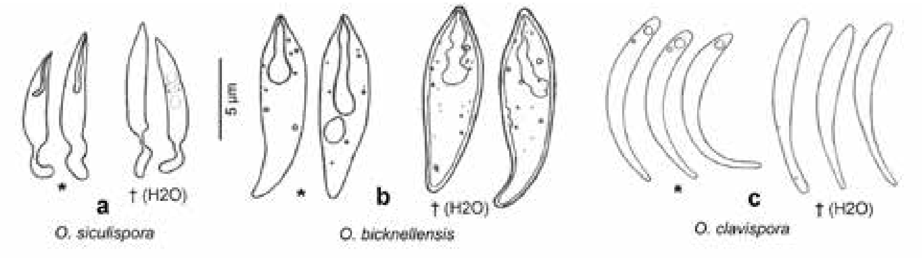

Figure 52: Spore shape may differ between the living (*) and dead state (†). — **a**. the basal constriction gets more pronounced; **b**. no change observed; **c**. falcate spores usually become distinctly less curved.

fungal spore and represent two types of response to dehydration (Baral 1992: 350, fig. 11). The two effects depend on whether the spore wall is elastic or not. Shrinkage and collapsing instantly disappear upon rehydration with water, if the spores are still alive. Due to the rapidness of the rehydration process, these effects of living spores are easily overlooked. The phenomenon has a general occurrence in ascomycetes with thin or thick but not too rigid spore walls, and is due to the high permeability of the spore wall to water (Baral 1992: 379). Shrinkage and collapsing is also observed when the asci attain full turgescence and the living spores thereby shrink or collapse (see p. 60).

The collapsed shape of dry dormant spores can be observed under the LM, either in air as medium, or when mounting dry spores in oil. Also the cells of conidia of *Orbiliomycetes* collapse in the dry state. This phenomenon was already observed with the first compound microscopes, according to a report by Loew (1867) who described the dry conidia of '*Arthrobotrys oligosporus*' as wrinkled and irregularly edged, with the protoplasm retracted from the cell wall. Collapsing is also often observed in SEM spore images.

Differences in shape between living and dead ascospores. When adding lethal media to water-mounted living spores, slight shrinkage and/or changes in shape usually occur (see p. 28). In *Orbiliomycetes* the spore wall shows quite a low elasticity, in strong contrast to the ascus wall. This can be concluded from the rather low values of spore shrinkage observed in this class, and from the phenomenon of collapsing. Nevertheless, minor changes in shape can be noted so that characteristic spore profiles may become enhanced or obscured in the dead state. For instance, spore tails or constrictions often become thinner (Fig. 52: a), and acute spore apices may either change to acuminate or subacute. In other cases spore size and shape remain quite unchanged (Fig. 52: b). Another, rather striking phenomenon concerns spore curvature: dead spores are frequently less curved than living spores (Fig. 52: c). This effect can be explained by a higher elasticity of the dorsal spore wall compared to the ventral wall.

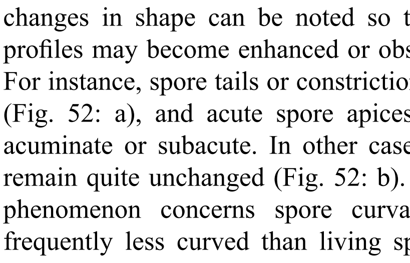

Figure 53: Collapsing of dead spores of *O. lentiformis*. — **a**. living spores, **b**. dead flattened spore, **c**. same spore after a 90° turn (all in H_2O). Living spores in the dry dormant state look quite similar as in **b–c**.

Living hydrated ascospores in *Orbiliomycetes* are usually more or less perfectly circular in optical cross section. In the dry state, however, they are more or less flattened or collapsed due to complete water loss, irrespective of being alive or dead. After rehydration in water, living spores reattain their original shape within a few seconds, while dead spores usually remain strongly compressed, and rehydration in KOH may but must not inflate them to their original shape. The width of such flattened spores in water was, e. g., 4.5–4.7 µm (Fig. 53: b) and after adding KOH it changed to 3.5–4 µm. Flattening of spores is easily overlooked under the LM, but becomes apparent when spores are floating in a water mount: after a turn for 90° the strongly collapsed middle part of the spores in the above example showed a width of only 1–2 µm (Fig. 53: c).

Lateral flattening was reported by Spooner (1987: fig. 26 D) for the narrow, somewhat subulate spores of *O. crenatomarginata* (as *Hyalinia crystallina*). Because of the helicoid spore shape, this flattening is only seen as a local constriction, the place of which depends on the viewing direction. However, such flattening apparently occurs quite rarely in such spores, as we have never observed it in series *Hyalinia* in the herbarium specimens studied.

Septation and germination. *Orbiliomycetes* have earlier been characterized as possessing non-septate ascospores, until a species was discovered with regularly (0–)1(–3) transversal septa while still within the living asci (*Orbilia septispora*, Baral 1989; Fig. 54: a). Until now, this species remains the only exception within the class, apart from very occasional spore septation within the living asci in one further species (*O. lentiformis*, Pl. 158: 2b).

During the process of germination, however, some species were found to produce one or sometimes up to three transsepta. Overmature spores can usually be obtained from senescent apothecia that had been affixed to the lid of the Petri dish and left for a few weeks. Except for *O. septispora*, spore septation was only observed in free spores or those inside dead asci. Septate overmature spores were noted in *Amphosoma* (*A. macrosporum*, *A. atroolivaceum*), *Orbilia* sections *Lentiformes* (*O. patellarioides*, *O. lentiformis*, *O. pleiolentiformis*, *O. phanosoma*, *O. cercidicola*), *Hemiorbilia* (*O. corculispora* Fig. 70: d), *Habrostictis* (*O. obtusispora* Figs 54: b, 70: c, *O.* cf. *quaestiformis*, *O. mesaverdiana*), and *Orbilia* (*O. austropleiomicrosoma*, *O. eucalypti*). Overmature stages of spores were mainly observed during such culture studies, because in *Orbiliomycetes* the spores frequently do not germinate in senescent apothecia on the natural substrate, even when kept in a moist chamber for some time. Only very rarely (e. g., *O. eucalypti*, P.P. 20061028–6, P. Perz pers. comm.; *O. austropleiomicrosoma*) abundant spore germination was observed on the natural substrate.

Phylogeny of spore shape. Globose to ellipsoid, homopolar spores probably represent the plesiomorphic type of ascospore within the *Orbiliomycetes*, whereas heteropolar spores as well as curved spores appear to be advanced, apomorphic features, particularly spores with a basal tail or a helicoid curvature. Nannfeldt (1982: 164) was similarly convinced that 'the change from radial symmetry to biradial or bilateral means a step of high

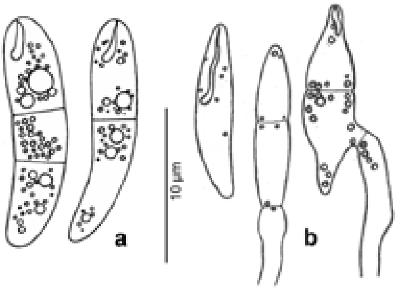

Figure 54: Septate ascospores in *Orbiliomycetes*, depending on maturity. — **a**. mature 1–2-septate spores of *O. septispora*; **b**. mature non-septate (left) and overmature, germinated, 1-sepate spores of *O. obtusispora*. Spores of *O. obtusispora* become septate only during germination, whereas those of *O. septispora* possess septa already during ejection, and do not get further septa during germination.

taxonomic and phylogenetic importance, a step from a more unspecialized and 'primitive' stage to a more specialized and 'advanced'. However, reverse evolutionary lineages may also have taken place. For instance, Rogers (1979) and Nannfeldt (l.c.) believed that the *Xylariaceae* which are characterized by homopolar non-septate ascospores developed from ancestors that had heteropolar 1-septate spores. We suspect that evolutionary steps in both directions (advance and reduction) have occurred within the genus *Orbilia*.

Spore wall, **surface and colour**. The ascospore wall of *Orbiliomycetes* is always thin (~0.1–0.2 µm), and varies only slightly in thickness among the taxa. Its surface is consistently smooth when observed under the LM at 1000–1500×, with a remarkable exception: the minute, cashew-shaped spores of the *xanthostigma-leucostigma* complex including the closely related *O. aureocrenulata*, possess a number of distinct warts on their dorsal but also laterally. These warts were described for the first time by Spooner (1987: fig. 21). Their presence was confirmed by us from numerous collections, and can quite easily be demonstrated on microphotographs (Fig. 56: e–f). Research with the TEM (Müller 1998) showed that they are protuberances of the spore wall which include the sporoplasm (Fig. 56: a–b). With the SEM a spatial image was obtained by Pfister (1997, Fig. 56: c–d). Mainly here it became evident that these protuberances also occur on the lateral side of the spore. For a possible function of these warts see p. 144–145, Infection by ingestion.

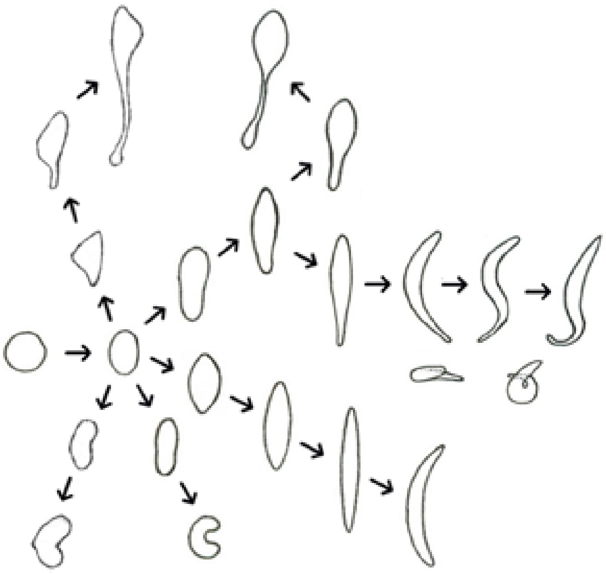

Figure 55: Hypothetical phylogeny of ascospore shape in *Orbiliomycetes*.

Non-cellular appendages such as setulae (previously called 'cilia') or slime caps have never been observed in the *Orbiliomycetes*. A peculiar spore sheath (a membrane that is shed when the spores are ejected into water, Baral 1992: 356, fig. 14) is rather frequently observed in the *Helotiales* but could never be seen in the *Orbiliomycetes*. There is not even a thin gel layer on the spore wall, as can be concluded from the absence of any colouration upon treatment with CRB. This is surprising since in all other elements of the holomorph, including often also the conidia, the wall surface is covered by a thin gel that stains faintly to intensely purplish-lilac in CRB (see p. 97–99).

The ascospores of *Orbiliomycetes* are always hyaline. Even during ageing and germination no natural colouration of the spore wall or the sporoplasm in the living or dead state was ever noted.

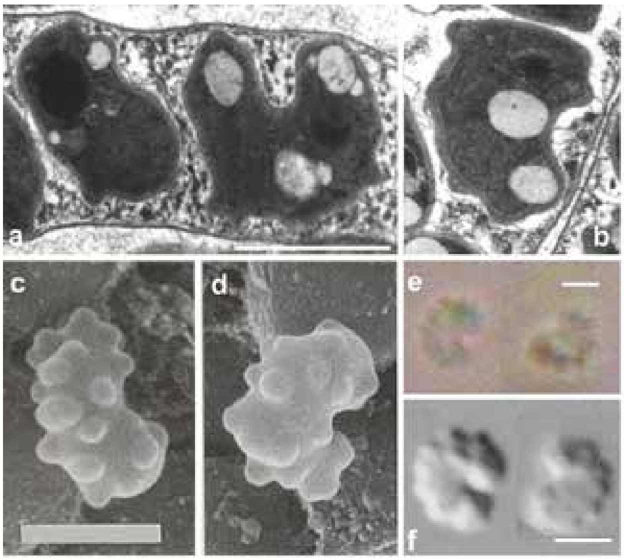

Figure 56: Warted ascospores of *O. xanthostigma* s.l., a rare case in *Orbiliomycetes*. The warts are caused by protuberances (bulging) of the spore wall and include sporoplasm. — **a–b**. Spore body (SB)

Mature living ascospores contain conspicuous, hyaline, more or less strongly refractive cytoplasmic inclusions when viewed in water mounts under oil immersion, usually one per spore (Fig. 57). This curious organelle is consistently present in almost every species of *Orbiliomycetes*. No other group of ascomycetes is known so far to possess such a spore inclusion, which is referred to as 'spore body' (SB) here, a term introduced in an ultrastructural study by Benny et al. (1978).

SBs become invisible in media such as IKI in chloral hydrate (MLZ), lactic acid, Cotton blue in lactophenol (CB_L), KOH etc. by completely losing their refractivity. Frequently, no trace of the SBs can be discerned in dead spores with any of the methods that we have tested in the present study.

Only in a few, mainly small-spored taxa (*Hyalorbilia herbicola* p.p., *H. hergiswiliana*, *H. pleioerythrostigma*, *H. rotifera* p.p., *H. texensis*, *Orbilia asomatica*, *O. eucalypti* p.p., *O. subfabacearum* p.p.), the SBs are either absent, or too small to be discerned under the light microscope, or difficult to recognize among the similar-looking LBs that often accompany them. SBs are undoubtedly absent in *Orbilia asomatica* (section *Arthrobotrys*), a species which forms a rare exception within the large genus *Orbilia*: no trace of a spore body could be seen in the fully mature, rather large viable spores, whether ejected or in the living asci.

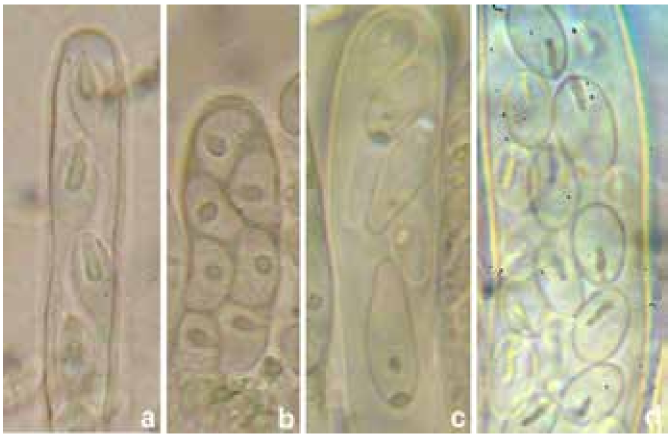

Figure 57: Four examples of different types of spore bodies (LM, oil immersion, bright field). — **a**. *O. aristata* (H.B. 8269b), **b**. *O. corculispora* (H.B. 8087a), **c**. *O. ocellata* (3.VIII.2008, phot. P. Perz), **d**. *O. multimacroasca* nom. prov. (#756). Living state, except for asci in **a–b**.

Size and shape. The size of SBs ranges among the species at (0.2–)0.4–2 in diameter for ± globose SBs and 2–10(–12) µm in (actual) length and 0.2–0.4 up to 1(–1.5) µm in width for elongate SBs. This diversity corresponds to a volume range of about (0.008–)0.05–10 µm^3, which implies a maximum divergence of up to ~200 × (or exceptionally 1.000)× between the smallest and the largest known spore bodies. Similar as ascospore size and LB diameters, SB dimensions have high taxonomic importance and, therefore, need to be included in descriptions. Similar as in curved spores, the length of curved SBs should be evaluated in two ways, i. e., straight length (in situ) and actual length (see p. 10, Microscopic measurements).

In addition to their size, SBs differ among taxa in a number of parameters which dictate their shape. These involve (1) length/width ratio, (2) width of upper end where they are attached, (3) width below attachment, (4) width of middle part, (5) width of lower end, (6) ratio between length of inflated and not inflated parts, (7) strength of curvature, and (8) place of attachment (apical, subapical, lateral). The ratio between SB volume and spore volume also varies considerably among the genera, subgenera, sections, and series. For instance, section *Orbilia*, but also *Hyalorbilia*, include taxa with very small SBs in relation to spore volume, despite the often comparatively small spores, whereas in series *Lentiformes*, or sections *Habrostictis* and *Hemiorbilia*, much higher SB volumes occur, and also the ratio between SB and spore volume is usually higher.

One of the main criteria to characterize the taxonomic groups within *Orbiliomycetes* is the shape of SBs (Fig. 58, see also p. 25). Lens-shaped SBs occur almost exclusively in *Orbilia* series *Lentiformes*, but also in *Lilapila*, *Pseudorbilia*, and *Amphosoma*, also in two species of section *Ovoideae* and in one of series *Microsomates.* Ampulliform to dumbbell-shaped or cylindric-subulate to tear-shaped, usually straight SBs occur in section *Hemiorbilia*. Elongate tear-shaped (subulate), straight SBs are typical of series *Hyalinia*, *Aurantiorubrae*, and *Xanthoguttulatae*, and tear-shaped SBs of series *Albovinosae*. Strongly elongate, worm-shaped to filiform or subulate, often flexuous to helicoid or uncinate SBs (sometimes resembling a question mark or a pig tail) are typical of subgenus *Habrostictis.* Stomach- to sausage-shaped or note- to lantern-shaped SBs mainly occur in series *Phanosomates* and *Microspermae.* Minute plug-shaped SBs are typical of series *Microsomates*, and ampulliform to christmas ball-like SBs of section *Ovoideae* and *Lecophagus*. Small globose SBs characterize series *Regales* and *Orbilia*, section *Arthrobotrys* p.p., and *Hyalorbilia*. Small rod-shaped SBs occur in series *Dactylellina*, *Gamsylella* and *Drechslerella* of section *Arthrobotrys*.

Attachment. Although sometimes seemingly unconnected, SBs are apparently always attached to the spore wall, either broadly as in the lens- or plug-shaped type, or by a more or less narrow connecting part. Often the connecting part is an extremely fine, tractus-like thread which is called ‘filum’ here.

SBs can be apically, subapically or laterally attached to the spore wall. Irrespective of their position in the spore and the position of the spore within the ascus, the point of attachment is referred to as the apical end of the spore body, which coincides with the spore apex in the majority of species, and the opposite as the basal end. As a consequence, in the case of lateral attachment the spore body apex points in a lateral direction.

Lens-shaped SBs may easily be mistaken for a thickening of the wall at the spore apex, due to their close and very broad connection to the spore wall. However, adding KOH to a water mount promptly makes the structure invisible, and the spore looks thin-walled at the apex, even if stained with CR afterwards.

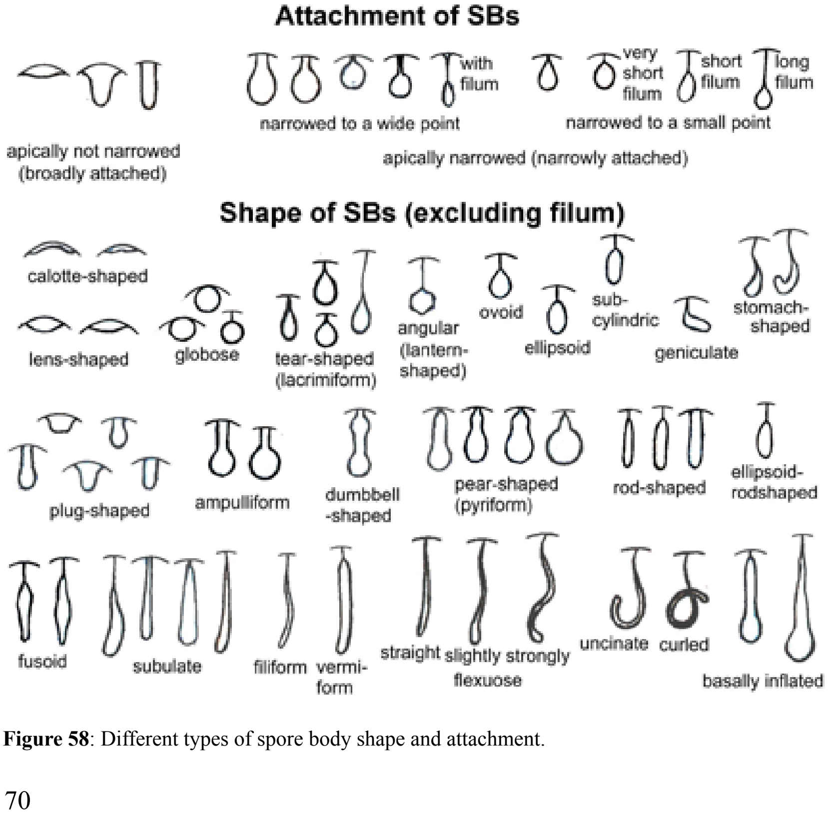

Figure 58: Different types of spore body shape and attachment.

However, the SBs are still present in the dead spores, though difficult to recognize. In water mounts the contrast is better (Fig. 67: j, o), and when cytoplasmic stains such as iodine or CRB are applied, the sporoplasm takes up the dye whereas the region of the SB remains unstained (Fig. 66: f).

SBs of section *Hemiorbilia* are apically often only slightly narrowed to a short and thick connecting part. Rarely the SBs are short-cylindrical to plug-shaped and broadly connected to the spore apex without any obvious constriction, e. g., in some species of series *Microsomates*. By far the major part of *Orbiliomycetes* have SBs with a more or less narrowed connecting part between inflated part and spore apex, thereby the thickness and length of this connecting part strongly varies between the series. In series *Phanosomates* (Fig. 59: a–c) and in some species of section *Habrostictis* the SBs consist of an abrupt basal inflation and a long and fine filum. Similar globose to ellipsoid SBs but with a shorter filum are predominantly found in series *Regales*, sections *Ovoideae* and *Arthrobotrys* (Fig. 59: d), and series *Orbilia*. In these four groups the filum is so fine that it is only exceptionally visible. In cases of a seemingly absent connection a very fine filum may sometimes become visible when staining with CRB. In *Hyalorbilia* a filum could only exceptionally be demonstrated (*H. erythrostigma*, *H. subfusispora*).

Ascospores containing a single SB. In the great majority of species only a single spore body is found in each spore, mostly at one of the two spore ends (Figs 57, 59). The SB-containing spore end is here consistently referred to as the ‘upper’ spore end (see p. 67). Such spores can be termed heteropolar with regard to their sporoplasm, although the spores may be homopolar in shape. Five genera of *Orbiliomycetes* include species with a heteropolar, asymmetrical sporoplasm: *Hyalorbilia* p.p.min. (*H. anonyma*, *H. erythrostigma*, *H. orbiliicola*, *H. ulmi*), *Lecophagus*, *Lilapila*, *Liladisca*, and *Orbilia*. Rarely the SBs are subapically to laterally inserted (Figs 50: a–c; 57: b).

Ascospores containing more than one SB. Contrary to the normal situation in *Orbilia*, the ascospores of the three genera *Amphosoma*, *Hyalorbilia* p.p.maj., and *Pseudorbilia* contain symmetrically arranged spore bodies, with one or up to about five SBs near each spore end. Such spores can be termed homopolar with regard to their sporoplasm, and also their shape is often homopolar in these taxa.

Species with a heteropolar sporoplasm may, as a rare abnormity, form two SBs, one at each spore end. Such exceptions were, however, only noted in about one out of a hundred spores, and so far only in a few desiccation-tolerant species, viz. two of series *Lentiformes*: *O. lentiformis* (Fig. 60: c) and *O. pleiolentiformis* (H.B. 7231d), one of section *Habrostictis*: *O. macrotrapeziformis* (H.B. 7284m), and several of section *Hemiorbilia*: *O. hesperidea* (Fig. 60: d), *O. aprilis* (P.P. 20060310), *O. montigena* (H.B. 9137b), *O. clavuliformis* (21. II.2010), and *O. myriofusiclava* (H.B. 8923b). In *O. lentiformis* two of the studied asci contained one abnormal and seven normal spores, while in the other species only free spores with this abnormity were seen. This phenomenon of abnormal spores appears to represent an evolutionary regression, supporting the idea that taxa with a heteropolar sporoplasm evolved from taxa with a homopolar sporoplasm (see Fig. 74).

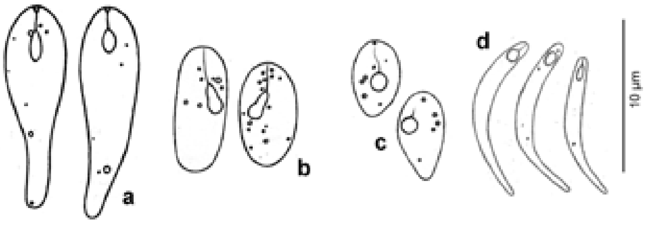

Figure 59: Spore bodies with a filum (**a–c**. series *Phanosomates*, **d**. series *Arthrobotrys*). — **a**. *O. magnifica* (with funnel-like attachment), **b**. *O. multiphanosoma*, **c**. *O. myriosphaera*, **d**. *O. auricolor*.

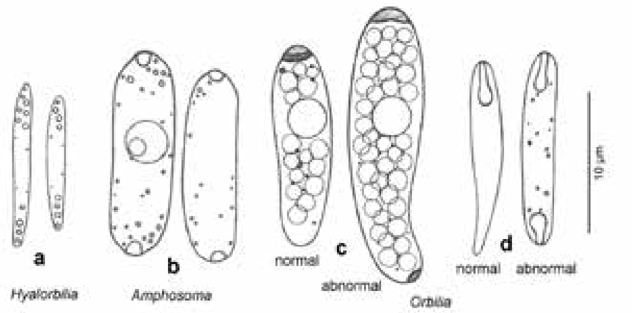

Figure 60: Homo- vs. heteropolar sporoplasm: SBs of *Amphosoma* and *Hyalorbilia* occur near both spore ends (**a–b**), whereas SBs of *Orbilia* occur at one end only (**c–d**, left), but abnormal spores may contain SBs at both ends (**c–d**, right). **a**. *H. juliae*, **b**. *A. macrosporum*, **c**. *O. lentiformis*, **d**. *O. hesperidea*.

SBs in ascospores with a heteropolar shape. In many species both the spore shape and the sporoplasm is heteropolar. In this case, the widest part of the spore is usually not exactly in the middle, and the SBs are mostly attached to that end which is closer to the widest part of the spore (Fig. 61 normal case).

Spore bodies provide a valuable means for defining the apical spore end (see p. 67). However, there are some exceptions to this rule. In a small number of species the phenomenon was observed that rare abnormal spores of an apothecium contained the SB in the ‘wrong’, i. e., narrower end of the spore (Fig. 61 abnormal case; observed also in *O. ovalis* Pl. 181: 4a and *O. coniferarum* Pl. 687: 2a).

A few further species or aberrant populations break this rule (Fig. 62: a, c, e): their SBs are consistently found in the acute end, whereas the opposite end is ± obtuse, with the widest part of the spore being predominantly closer to the obtuse end. In such a case, the spore shape misleads from an aerodynamical point of view to consider the obtuse end as the upper spore end and to arrange spore illustrations with their acute ends pointing downwards. The interpretation of the SB-containing spore end as the upper end is confirmed by closely related populations (Fig. 62: b) or species (Fig. 62: d), in which the widest part of the spore is closer to the SB-containing end. Obviously, spore shape is less important in regard to spore polarity than SB position.

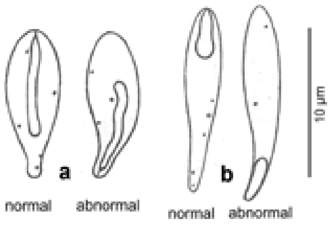

Figure 61: In species with a heteropolar spore shape the SBs are generally attached to the wider end of the spore, and only in abnormal spores they are attached to the narrower spore end. — **a**. *O. caudimaeandrina*; **b**. *O. pleionavajoana*.

SBs in ascospores with a homopolar shape. In ascospores with a homopolar shape, the upper spore end can only be recognized by the spore body that it encloses (Fig. 63). In such taxa, heteropolarity and inverse spore orientation is usually

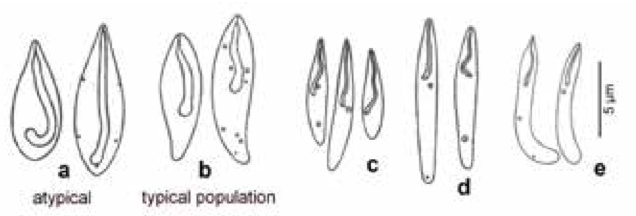

Figure 62: In a few taxa (**a**, **c**, **e**) the SBs are partly or predominantly attached to the narrower spore end. In closely related taxa or different populations (**b**, **d**) the SBs are predominantly attached to the wider spore end. In dead spores the two spore ends usually cannot be correctly addressed. — **a–b**. *O. maeandrina*; **c**. *O. sarraziniana*; **d**. *O. rosea*; **e**. *O. suberis*.

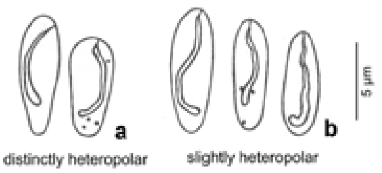

Figure 64: The spores of *Orbilia myrionamibica* are often distinctly heteropolar, but sometimes almost homopolar, SBs are attached to the wider but sometimes to the narrower spore end (right spore); in the dead state the upper spore end and consequently the spore orientation within the asci is quite impossible to determine in this species.

completely masked in the dead state (compare, e. g., Spooner 1987: fig. 20: *O. cunninghamii*, fig. 24: *O. juruensis*, fig. 28: *Habrostictis decipiens*; Haines & Egger 1982: *O. piloboloides*; see Figs 155–156), except for species with lens-shaped SBs in which the SBs often remain more or less perceptible in the dead state.

Frequently, not all spores of an apothecium are homopolar in shape. The lower end is often more or less variably shaped, whereas the upper end is generally more consistent in shape. As a consequence, spores which are ± strongly heteropolar in shape occur mixed with spores which are almost homopolar (example: *O. myrionamibica*, Fig. 64).

In a few species of *Orbilia* the definition of the upper spore end becomes more or less obscure because the SBs tend to be laterally attached (Fig. 65). In some of these species the SBs vary between apically, subapically or laterally attached (Fig. 65: a, c), while closely related species are known which have apically attached SBs. It can be assumed that the ancestors of species with laterally or subapically attached SBs possessed spores with apically attached SBs.

Such 'evolutionary migration' of SBs appears also obvious when comparing typical species of section *Hemiorbilia* with axially symmetric spores and apical SBs (e. g., *O. aristata*, *O. flagellispora*) with more rare cases of slightly (*O. aviaristata*, *O. aviflagellata*, Fig. 50: d) to strongly (*O. corculispora*, *O. triangulispora*, *O. aviceps*, Fig. 50: a–c) bilaterally symmetric spores with a subapical to lateral SB insertion.

The latter three species show a remarkable case of tripolarity in spore shape. The SB is affixed to a slight lateral projection of the spore which is predominantly oriented sideways within the asci. We see two possible explanations for this peculiarity: (1) the lateral projection represents the former upper spore end, or (2) the SB moved away from the spore apex to a lateral position. Surprisingly, both cases appear to exist, but in different series of *Orbilia*.

Case (1) is represented by species of series *Hemiorbilia* with strongly bilaterally symmetric spores (Fig. 48: b–c): the spore apex including the SB is pushed to a lateral position by a large, now apically positioned protuberance. This view is supported by the similarly but less strongly asymmetrical spores of *O. aviflagellata* and *O. aviaristata* (Fig. 50: d), in which the protuberance points in lateral instead of apical direction, whilst the acute spore apex with the SB still points upwards.

Case (2) is represented by members of series *Hesperideae* (*O. corculispora*, *O. octocorculispora* and *O. myrioauris*, Fig. 65: b–c), and similar cases occur in series *Orbilia* (*O. fabacearum*), ?series *Microsomates* (*O. beatricis* Fig. 65: a, e), series *Vibrioides* (*O. myriooobliqua*, Fig. 65: d) and others. In most of these species a migration of the SBs in whatever direction is beyond doubt. For instance sibling species of the latter three species (*O. cylindrospora*, *O. leucostigma*/*xanthostigma*, *O. paraobliqua*) have spores of a very similar shape but with the SB consistently positioned at the spore apex. In *O. fabacearum* and *O. myrioauris* we observe variation within apothecia (Fig. 65: a, c): usually, the SB is positioned at the lateral wall of the spore, but in a few spores the SB is attached more subapically, or even at the spore apex. Therefore, we assume that in these series the SB changed during evolution its place from the spore end towards the middle part.

In *O. corculispora*, evolutionary SB migration is suggested by rarely encountered atypical populations with ± ellipsoid to subglobose spores which usually more or less entirely lack the shape of a heart (Fig. 65: b): in these spores the SBs are either apically, subapically, or laterally attached, with a trend towards a lateral position in those spores with a slight bilateral symmetry. We presume that the ancestor of *O. corculispora* had subglobose spores which, during evolution, became more and more inequilateral and eventually got a deep indentation at one side and a protrusion at the opposite side, which resulted in the characteristic kidney- or heart-like shape. This process was accompanied by a lateral migration of the spore body.

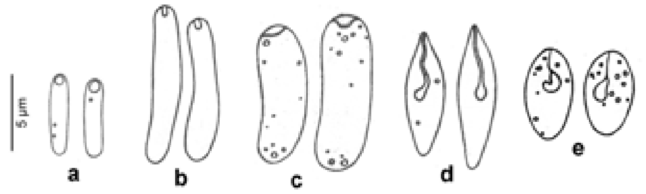

Figure 63: Spores with a homopolar shape but a heteropolar sporoplasm (**a**. *O. cylindrospora*, **b**. *O. microsoma*, **c**. *O. pleiolentiformis*, **d**. *O. carpoboloides*, **e**. *O. pluristomachia*).

Behaviour of spore bodies during killing. From their refractive appearance under bright field illumination, SBs resemble lipid bodies, particularly when they are globose. Confusion with LBs is then easily possible, especially in species of series *Orbilia*, or in *Hyalorbilia*. Several small droplets are often found in the living spores of *Orbiliomycetes*, either scattered or near the ends, and only the use of a dye or a test with KOH reveals which of the droplets represent spore bodies.

When treated with KOH or CRB, SBs behave in a similar way as refractive vacuolar bodies (VBs) do, therefore, they have been included in the scope of this type of organelle by Baral (1992: fig. 37). The KOH test has been applied in the present study to a rather high number of species from various genera and subgroups of *Orbiliomycetes*, and also CRB was tested in quite a few taxa. The result was always the same, therefore, it can be assumed that SBs of all species behave this way.

KOH of different concentration (0.5–10 %) applied to a water mount rapidly kills the spores by destroying the semipermeability of the plasmalemma. SBs promptly and irreversibly become invisible under the LM by losing their refractivity, whereas LBs remain unchanged. The behaviour of SBs in acids is similar to alkali: if adding strong acids like nitric or formic acid, the plasmalemma is destroyed and the refractivity of the SBs disappears in the blink of an eye. In weak acids like diluted acetic acid (~5 %), the spores remain viable and the SBs unaltered for some time. Likewise, weak alkali such as diluted NH_4OH kill the spores only tardily when applied to a water mount. Mounting in CB_L (containing lactic acid or lactophenol) or MLZ (containing chloral hydrate) also promptly kills the spores and masks the spore bodies completely and irreversibly. Only SBs of the lens-shaped type may still be faintly perceptible in CB_L or MLZ.

The loss of refractivity, i. e., the optical disappearance of SBs, is not bound to the application of a chemical. When the spores die in the desiccated state during a longer period of dryness, e. g., in the herbarium, or when they die by briefly heating a water mount, also when strong pressure is applied to the cover slip, SBs and also VBs optically disappear in the same way, perhaps due to a raised pH when the plasmalemma, including the membrane around the SBs, loses its semipermeability. Therefore, VBs and SBs can properly be studied only in living cells mounted in water or other non-lethal media such as aqueous CRB (see also p. 31, Conservation of vital characters). Future TEM studies will undoubtedly greatly increase our knowledge on SB ultrastructure but the risk for obtaining artifacts is high with this technique, unless modern methods of cryofixation by high-pressure freezing are applied which conserve turgescence of the cells and their organelles.

Staining of SBs in living spores. Staining by metachromatic basic dyes (CRB or TB) yields a selective, spectacular, deep blue to violet or in some species at first turquoise stain to the SBs due to accumulation of the dye, whereas the rest of the sporoplasm remains unstained (Fig. 66). The same result of selective staining is obtained with VBs in vegetative cells, and probably the mechanism of accumulation of the dye is the same (see also p. 90–92). Aqueous Methyl blue (CB_a) and Neutral red (NR) likewise selectively stain SBs in the living spores (deep blue or bright orange-red, respectively), whereas Methyl blue in lactophenol (CB_L) kills the spores and destroys the SBs by staining the sporoplasm (similar as in Fig. 66: f).

The membrane that surrounds the refractive matrix of the SB is undoubtedly semipermeable and might have a composition similar to that of the plasmalemma, or to the tonoplast of vacuoles. VBs differ from SBs in the absence of a connection to the plasmalemma, and in staining more greenish-blue (turquoise) even at high concentration of CRB (see p. 90–92). CRB stains lens-shaped SBs (Fig. 66: e) much more quickly (within about a second) in comparison with narrowly attached SBs (often only after several minutes). The reason for this is probably that the stain intrudes through the spore wall into the matrix of lens-shaped SBs without passing any plasma membranes, whereas the delayed staining of narrowly attached SBs is due to a retarded intrusion, either through the fine attachment or through two membranes, plasmalemma and SB membrane. Staining of VBs in living paraphyses and excipular cells is similarly delayed, and here the cause of delay is unquestionably the passage of plasmalemma and tonoplast.

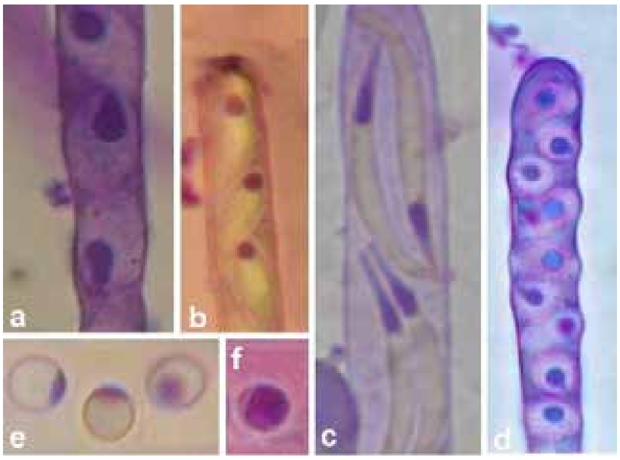

Figure 66: **a–e**. Living spores with spore bodies stained with Cresyl blue: SBs stain violet- to turquoise-blue, while the sporoplasm remains unstained; **f**. dead spore in KOH+CRB: SB remains unstained but sporoplasm stained deep purplish-violet. — **a**. *Orbilia arizonensis* (H.B. 8002a), **b**. *O. pilifera* (H.B. 8076a), **c**. *O. aurantiorubra* (phot. M. Hairaud, H.B. 8076b), **d**. *O. corculispora* (phot. J.P. Priou, J.P.P. 23138), **e–f**. *Lilapila oculispora* (H.B. 9162a).

SBs are formed by the invagination of the plasmalemma (see p. 74, Ontogeny of spore bodies). Therefore, the matrix of spore bodies is more or less exposed to the environment because it is mainly delimited by the spore wall but apparently not by a membrane. It is, therefore, possible that the SB matrix does not differ in its pH from the surrounding medium, and the accumulation of CRB in SBs could follow a mechanism different from that in vacuoles. However, the loss of refractivity of the SB matrix is probably due to a severe change in the pH inside the SB. SB refractivity gets irreversibly lost when destroying the semipermeability of the plasma membrane by applying acids or alkali, but also by applying heat or during long-term storage in the herbarium. This suggests some stabilizing influence of the intact enclosing membrane of the SB matrix on its refractivity and pH, or a closing membrane at the point of attachment.

Staining of living cells by IKI never caused a distinct accumulation of iodine in SBs, whereas VBs, particularly those in the *Helotiales*, frequently show a faint to strong red-brown reaction (Baral 1987b: 424, 1992: 364). VBs sometimes contain a pale to bright yellow or orange vacuolar pigment, whereas SBs are always hyaline. Moreover, hyaline VBs frequently turn yellowish to reddish-brown when the cells die, apparently through oxidation of phenolic compounds (Baral 1992). No such secondary pigment could ever be seen in dead spores of *Orbiliomycetes*.

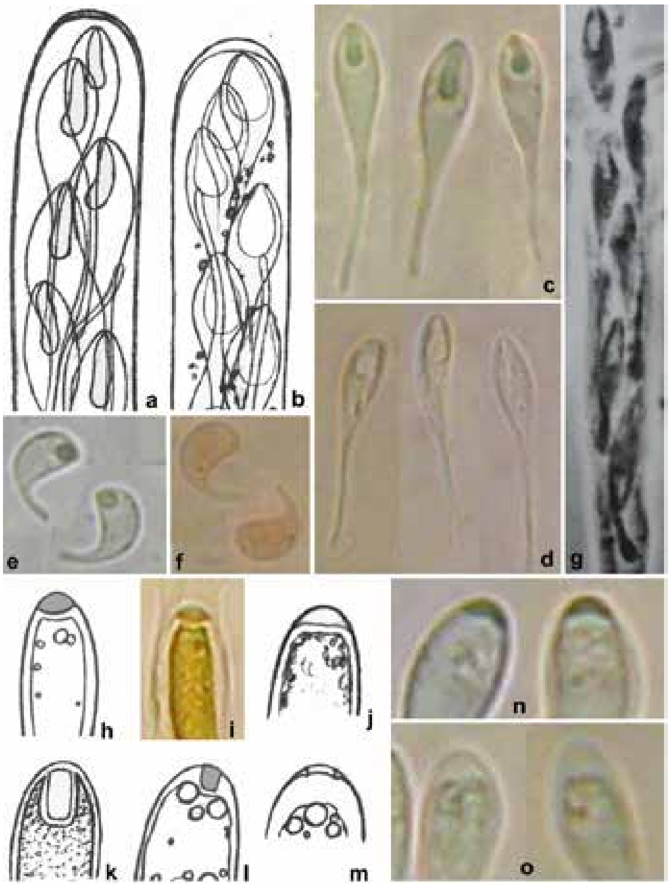

Figure 67: SBs in ascospores of *Orbilia* and *Amphosoma* in the living (**a**, **c**, **e**, **n**) and dead state (**b**, **d**, **f–m**, **o**); **f**. The reason for the turquoise colour of CRB when accumulated in SBs or VBs is not fully understood. Possibly, chemical properties of the refractive matrix influence the colour of CRB (metachromatic effect) more than the pH of the water in the matrix does. The accumulation of CRB in SBs and VBs is not necessarily due to the ion trap mechanism of vacuoles: broadly attached (lens-shaped) SBs sometimes remain refractive although the spores are dead, and they were found to stain blue-violet irrespective of whether the spores are alive or not.

Shrinkage during osmosis. When adding a drop of high-concentrated sugar solution to a water mount that contains living asci and spores, not only the asci and spores shrink, but also the spore bodies. In *O. myriomuscula*, a shrinkage of the globose-ampulliform SBs by ~12–15% in both length and width was observed, resulting in ~30–40% volume decrease. This result demonstrates semipermeability of the SB membrane, and some kind of liquid nature of the refractive matrix. In the above sugar solution the width of a living ascus decreased by 18%. Observation of SBs in high-concentrated media is difficult, however, because of a strongly diminished contrast.

Spore bodies in dead spores. SBs are usually completely invisible in dead spores in any of the tested mountants (e.g., Fig. 67: f). However, in some species they could be seen as inconspicuous, non-refractive, transparent regions within the more refractive sporoplasm, sometimes in water mounts (Fig. 67: d), or when mounted in KOH, CR (Fig. 67: b), CRB, CB_L, phloxine, or MLZ (Fig. 67: g). This transparent region is not stainable by any of the tested staining agents. Despite a somewhat altered shape, the region clearly corresponds to the area of the refractive spore body. In water mounts the sporoplasm is more or less refractive and the transparent region of the SBs may sometimes be quite distinct by looking 'empty' (Fig. 67: d). Plasmatic stains, but also cell wall stains, preferably added to alkali-pretreated material, may sometimes improve the visibility of SBs in dead spores. Contrary to the living state, these dyes stain the dead, often somewhat granular sporoplasm (e.g., purplish-violet in CRB) whereas the region of the SBs remains completely unstained (Fig. 66: f). In cases of narrow or small SBs, however, often no trace of the previously so conspicuous SBs remains discernible, with rare exceptions (e.g., lectotype of *O. eucalypti*, Pl. 858: 1a).

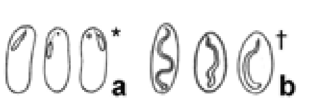

Figure 68: *Orbilia orientalis* (**a**. H.B. 7379, **b**. holotype), in H_2O: **a**. Living spores with short rod-shaped SBs with a delicate filum; **b**. dead spores with a worm-shaped helicoid structure of coagulated sporoplasm (SBs invisible).

In taxa with elongate SBs, the transparent region in dead spores is often shorter and wider than in living spores (see Fig. 67: a–d). This must be taken into account when comparing dead spores of one collection with living spores of another. A similar change in SB shape is observed when living spores get overmature (Fig. 70).

Our tests to preserve the refractivity of SBs in permanent slides or other voucher specimens were unsuccessful (see also p. 31, Conservation of vital characters). As a rare exception, however, some or all of the dead spores still contained SBs of the very same shape and refractivity as the living spores. This peculiarity was noted in some collections of species with broadly or narrowly attached SBs: *Lecophagus ellipsoideus* (Pl. 45: 2a), *Amphosoma macrosporum* (Fig. 67: l), *O. ocellata* (Fig. 67: h–i, see also Pl. 164: 3a), and *O. olivacea* (Pl. 806: 2a). Application of KOH irreversibly destroys refractivity of such SBs, and CRB stains them blue-violet similar as in the living state. Frequently, however, broadly attached SBs are low-refractive in the dead state (Fig. 67: j–k, o). In one case (*A. macrosporum*) the apical wall of a dead spore showed a pore-like aperture at the place where the SB was attached (Fig. 67: m).

The cytoplasm of dead spores is often coagulated by dehydration, showing an increased refractivity and a more or less strong detachment from the spore wall. In some cases the protoplast was so strongly dehydrated that it simulated SBs by forming rather regular, filiform, often flexuous structures. The effect was especially striking in the holotype of *O. orientalis* (Fig. 68: b). In many asci, all eight spores contained such a long, filiform, flexuous structure. However, undoubtedly conspecific fresh collections showed completely different, much shorter, rod- to tear-shaped SBs (Fig. 68: a). It can safely be concluded, therefore, that the observed filiform structure represents an artifact of the dead sporoplasm.

Ontogeny of spore bodies. In the course of spore maturation, SBs gradually increase in size and develop to their individual, species-specific shape. The ontogeny of SBs can rather easily be observed under the LM in living material (see the drawing of

Orbilia octosporoides, Pl. 793: 1a). A schematic representation of different SB types is given in Fig. 69. SBs develop very late in spore ontogeny, at a stage when the spores have attained their final size and shape. In comparison, LBs are usually formed much earlier, while at an early stage of development the spores are devoid of both LBs and SBs.

Those SBs which are apically narrowed to a point start as small dot-like initials. They either inflate to a broadly tear-shaped or globose drop (Fig. 69: b), or elongate more than they increase in width (Fig. 69: a), and such vermiform to subulate SBs sometimes exceed spore length by getting curled (helicoid or uncinate). Lens- and plug-shaped SBs start as similar initials, the former soon getting broader, the latter instead elongating (Fig. 69: c–d). SBs attain their maximum size and characteristic shape some time before the spores get dehydrated during ascus turgor increase.

In the course of SB development the refractivity of the matrix remains unchanged. Although SBs contain a liquid-like content surrounded by a delicate membrane, they have never been observed to show any migration during ontogeny when comparing different development stages, nor could any changes in their shape be seen whenever SBs in mature spores were monitored over a period of 5–10 min. When placing a water mount slide of an apothecial section in a moist chamber, SBs of immature spores inside living asci of *O. clavuliformis* were found to elongate for ~2–3 µm during about 1–2 days (e. g., from 1.5 × 0.8 µm to 4.5 × 1 µm).

As with LBs in spores of other groups of ascomycetes, SBs permit recognition of the development stage of living spores and consequently also that of living asci inside which they are found. When studying solely dead material, the question regarding spore maturity generally remains unanswered, i. e., it cannot be ascertained whether the observed spore characters (size, shape, septation, lipid contents) belong to immature, mature, or overmature stages (see p. 30, Recognition of maturity).

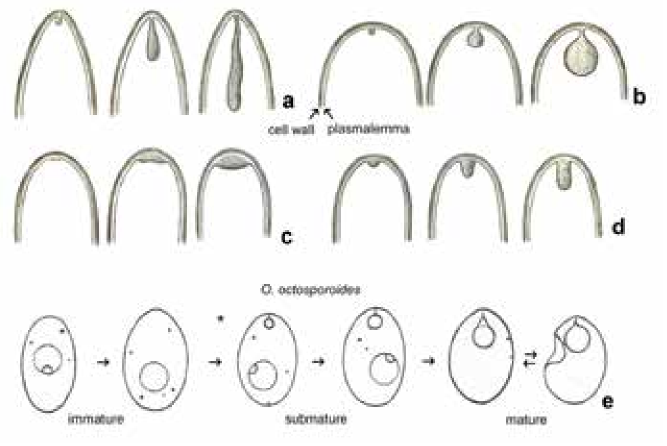

Figure 69: Schematic illustration of spore body ontogeny as seen with the LM in four different infrageneric groups of *Orbilia* (**a**. section *Habrostictis*, **b**. section *Ovoideae*, **c**. series *Lentiformes*, **d**. series *Microsomates*, **e**. *O. octosporoides* H.B. 5175b, section *Ovoideae*).

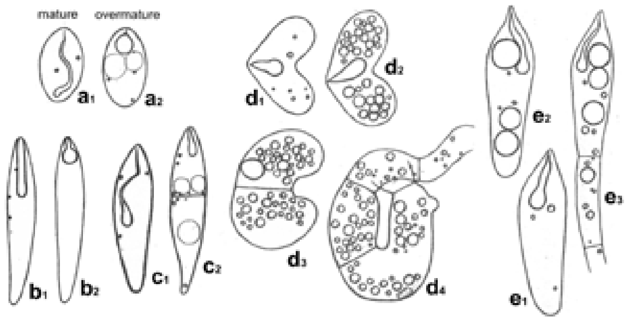

Figure 70: Mature (**1**) and overmature (**2**) ascospores observed in senescent apothecia (living state). SBs may change their size and shape before and during germination and LBs may increase in size. SBs often get shorter and wider (**a–d**), while lipid bodies sometimes strongly increase in size (**e**) and partly also in number (**d**). — **a–b**. from apothecia on the natural substrate, **c–e**. from apothecia kept at the lid of a Petri dish for some days. **a**. *Orbilia gambelii*: **b**. *O. vinosa*; **c**. *O. obtusispora*; **d**. *O. corculispora*; **e**. *O. carpoboloides*.

Spore bodies in overmature spores. At overmature stages a regression in the observed diversity of SB shapes is observed. Vermiform to subulate SBs, in particular, undergo severe changes during ageing. Often without noteworthy volume reduction, they become much shorter and thicker, i. e., broadly tear-shaped or even globose (Fig. 70: a–b). Only a short, more or less narrow apical part remains unaltered. These changes of elongate SBs are problematic because otherwise similar species may differ in showing consistently such short and thick SBs in mature spores. Examples are *O. vitalbae* – *O. caulicola* or *O. carpoboloides* – *O. pilifera*, the former of each pair with elongate SBs, the latter with globose SBs. Overmature spores often occur in collections, but can also be induced by incubation in a moist chamber. For instance, in *O. montigena* all short vermiform SBs changed to broadly tear-shaped in apothecia which were kept for a week inside a Petri dish. As a further complication, overmature spores with altered SB shape may exceptionally occur within the living asci. However, well-developed mature apothecia can be recognized by their abundant living mature asci that contain spores with SBs of a consistent size and shape. This conformity in SB shape allows to conclude that the spores are in a taxonomically reliable development stage.

When the spores germinate, SBs were observed to gradually decrease in volume until they completely disappeared (*O. corculispora* Fig. 70: d, *O. obtusispora* Fig. 70: c, *O. mesaverdiana* Pl. 673: 1a). Sometimes, however, SBs maintained their full size when germ tubes are formed (*O. carpoboloides* Fig. 70: e). LBs, on the contrary, may strikingly increase in number and size during germination in some taxa (Fig. 70: d–e, see also p. 89–90).

Cytological origin of spore bodies. Our light-microscopical and microchemical observations on spore bodies concentrate in the hypothesis that SBs are formed by invagination of the plasmalemma. Young SBs form a vesicle that increases in various, species-specific ways by genetic determination. From the beginning a substance of unknown composition is transported into the spore body, probably through the membrane of the young spore body. When inside the SB, the substance appears to change its chemical structure by becoming refractive.

As stated above, SBs behave very similar as vacuoles when treated with vital stains and lethal mountants. There is no doubt that both types of organelles are surrounded by a semipermeable unit membrane. Various TEM images have shown that vacuoles in general originate from small vesicles formed by invagination of the plasmalemma from which they finally separate. This process is related to endocytosis, by which cells absorb and engulf external substances (Weber 2002). In contrast to vacuoles, SBs remain attached to the plasmalemma, either broadly or by a more or less narrow point or filiform structure, for which spore bodies were considered to represent a special type of refractive vacuolar body (VB, Baral 1992: 363f., figs 34–37). The membrane that surrounds the large spore body of *O. vinosa* can be seen in Fig. 71: e as an electron-light line which at the spore apex clearly connects to the plasmalemma, suggesting an invagination process during SB ontogeny. TEM images of young stages of SB formation were not available, but our LM studies (Fig. 61) support this invagination process. Particularly when studying lens- to plug-shaped SBs in the dead state, the SB matrix is clearly seen as being located outside the detached sporoplasm Fig. 67: j–k, o, which is very obvious in the rare case when the matrix remains refractive (Fig. 67: h, l).

In SBs with a filiform upper part, the latter rarely enlarges like a funnel at the point of attachment (Fig. 59: a) which looks like an invagination. The filum is probably a very narrow tube composed of invaginated plasmalemma. Although lens-shaped SBs appear to be very different from those with a filiform part, the intermediate plug-shaped type (*Amphosoma*, Fig. 60: b; *O. cucumispora*, Pl. 179; *Orbilia series Microsomates*, Figs 63: b; 69: d) indicates that all types of SBs in the many groups of *Orbiliomycetes* represent a homologous structure that is formed by the same ontogenetic principle. SBs appear to be formed similarly as vacuoles, but the process of invagination never appears to result in a complete detachment from the plasmalemma. The more or less constant length of the filiform part suggests a connection of the SBs to the spore wall even in those species in which this connecting part is close to, or below the recognition limit of the light microscope.

SBs represent an extraplasmatic, sac-like organelle which contains a refractive hydrophilous substance. Whether SBs show a higher, equal, or lower osmotic pressure in relation to the surrounding sporoplasm is unclear. Probably the membrane around SBs is semipermeabile and elastic, because SBs shrink osmotically by water extraction (see p. 74, Shrinkage during osmosis). The ontogenetic similarity between SBs and vacuoles (including VBs) allows to speculate about a phylogenetic relationship between both organelles, and to consider SBs as a specialized type of vacuoles.

Literature reports of spore bodies based on LM observations. Despite their conspicuousness, reports of SBs, particularly those with a distinctly elongate shape, are extremely rare in the literature older than about 25 years. This is astonishing, because already 100–150 years ago light microscopes had a quality that permitted to resolve microstructures of < 0.5 µm diam. This quality is impressively demonstrated, e.g., by Patouillard's (1892b) microscopic drawing of subulate SBs in *Orbilia serpentina* (see Fig. 151: 1). That most workers of the 20th century failed to see SBs and consequently often also the inverse spore orientation, is a logical consequence of the prevailing method of herbarium taxonomy, besides the practice of applying too much pressure on the cover slip, or mounting fresh specimens in lethal solutions in order to obtain compatible results.

Although elongate SBs occur in a vast number of species, they have been reported in the older literature only in three desiccation-tolerant mediterranean species (*O. serpentina*, *O. hesperidea*, *Hyalinia ulicis*, see Fig. 151). Patouillard (1892a) described them as 'masses virgultiformes de protoplasma, réfringentes' (= rod-shaped refractive material of protoplasm). Rolland (1901) referred to them as 'gutta ovali', and Chenantais (1918) as 'guttula cylindrica nitenti sursum praedita' (= provided with an apical cylindrical shining guttule). Saccardo (1899: 802) even refrained from mentioning these bodies in his shortened diagnosis of *O. serpentina*, perhaps because he doubted their nature. He stated only 'sp[oris] intus granulosis' and the asci to be 8-spored, although the number of SBs drawn by Patouillard clearly indicates that the asci are 16-spored. Later, Saccardo & Sydow (1902: 767) and Saccardo et al. (1928: 1238) mentioned spore bodies when quoting the diagnoses of *O. hesperidea* and *H. ulicis*.

Ade (1924) described the polysporous species *O. paradoxa* with an apical 'spot-like' SB in each spore, but did not supply an illustration (the species is probably a synonym of *O. flavida* which has lens-shaped SBs). On his unpublished manuscript plates, Velenovský once (1925) illustrated subulate SBs in *O. sarraziniana* (as *O. luteorubella*, Fig. 156: b). The author possibly later doubted his observation, as he did not figure elongate SBs in any other specimen of *Orbilia*. SBs of a globose to ellipsoid shape have rarely been reported and figured in some species (usually as 'guttules'), e.g., in *O. comma* (Graddon 1977: fig. 17). The cytological difference between these and the associated, mostly smaller lipid bodies (LBs) was obviously unknown to all these authors.

TEM-studies of spore bodies. Obviously unaware of previous reports with the LM, Benny et al. (1978) found using transmission electron microscopy (TEM) in the mature ascospores of *Orbilia sarraziniana* (as *O. luteorubella*) an elongate, thick, electron-dense, membrane-bound structure of strong contrast and a length of up to three fourths of the entire spore, being attached to the inner wall at the acute, slightly acuminate spore end (Fig. 71: a). Since the function of this structure remained enigmatic, the authors applied the term 'spore body' as a neutral circumscription of the extraordinary organelle. In shape and contrast the organelle fully corresponds to the structure seen by us under the light microscope in living spores of that species.

The preparation procedure applied by Benny et al. (l.c.) comprised fixation in glutar-/paraformaldehyde and osmium tetroxide, and staining in uranyl acetate and sometimes also silver-methenamine. For examination under the LM, Benny et al. mounted their sections in CB_L, although they were dealing with a fresh collection. Obviously, the authors were unaware of the optical disappearance of SBs provoked by the freezing procedure in a cryostat and mounting in lactophenol Cotton blue, and believed that these structures can only be seen with the TEM. Whether the applied TEM fixation method maintains the exact ultrastructure of SBs is unclear. It appears possible that spore bodies as seen on TEM micrographs are comparable with non-refractive SBs in dead spores under the LM. SBs appear to receive high contrast under the TEM because their matrix, although having lost its refractivity, is selectively enhanced by the applied stains. Modern cryofixation methods are recommended here to avoid possible artifacts.

Benny et al. (l.c.) could not determine the function of spore bodies. On the basis of their TEM micrographs they came to the conclusion that SBs originate from mitochondria. The authors found SBs to become more and more opaque during spore maturation, being finally filled with a uniform, comparatively electron-dense material which showed a slight inhomogeneity (named 'cristae' by Benny et al., see their fig. 14). A membrane surrounds the spore body, but the authors did not state whether it was a double membrane typical of mitochondria. On their fig. 11 they reported rough endoplasmic reticulum in close contact

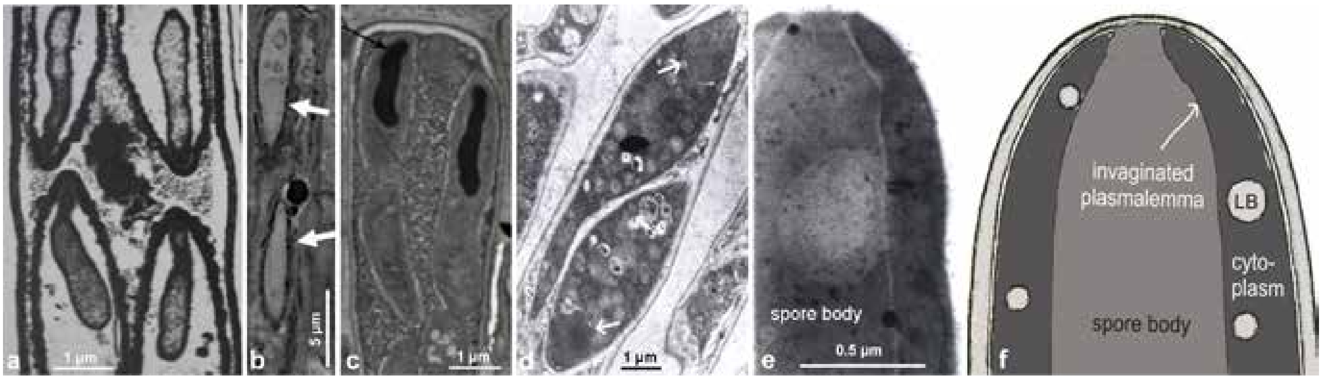

Figure 71: Ascospores with spore bodies as seen under the transmission electron microscope (TEM, arrows in **b** and **d** point to SBs). — **a**. *Orbilia sarraziniana* (Benny et al. 1978: fig. 17, as *O. luteorubella*); **b**. *O. sarraziniana* (Liu 2006: fig. 1D); **c**. *O. tenuispora* (Kumar et al. 2012: fig. 3, as *Orbilia* sp.); **d**. *O. aristata* (Müller 1998: fig. 21A); **e**. *O. vinosa* (Müller 1998: fig. 21B, spore apex); **f**. schematic representation of **e**. – Particularly **e** suggests that the SBs are formed by invagination of the plasmalemma as an extraplasmatic organelle remaining attached to the apical spore wall.

to the spore body. The spore wall was said to mature first at the spore apex by forming a distinctly thicker wall (as 'apiculus', see their figs 11–12), whereas the rest of the wall was said to attain this thickness at a later stage.

The connection between SB and spore apex is very clear on their fig. 17 (Fig. 71: a), but absent or only slightly perceptible in those micrographs at higher magnification. The reason for this is easily explained by the rather narrow connecting part which is difficult to hit in microtome sections. Since the spore inclusion is rather long in all of the micrographs presented by Benny et al. (l.c.), all these undoubtedly refer to more or less mature spores in which the SBs have attained their maximum length, contrary to the author's belief in different development stages. Benny et al. also stressed a close association between SB and nucleus. We consider this as a result of the length of the SBs and the narrow spore width. In species with wider spores and shorter SBs the nucleus is usually found a good distance away from the spore body (Fig. 93).

Liu (2006: 22, pl. 1 figs C–D) investigated asci and spores of *O. sarraziniana* with the TEM (see Fig. 71: b). The SBs are surrounded by a thin but distinct grey line, and their matrix appears almost as light as the sporoplasm. His TEM-procedure was very similar to that applied by Benny et al. (B. Liu pers. comm.).

Kumar et al. (2012) investigated another species of section *Helicoon* which, according to their molecular data, belongs to *O. tenuispora*. In their micrographs the SBs are shown as highly electron-dense (black) structures in the light grey sporoplasm (Fig. 71: c). Also Kumar et al. applied about the same fixation and staining procedure as Benny et al. (without silver-methenamine). The authors observed a mitochondrion at the apex of young spores which was later replaced by a spore body (A. Kumar pers. comm.). This was interpreted as a support for a mitochondrial origin of SBs (Kumar et al. 2012), a view followed by Pfister (2015).

Benny et al. (1978) and Kumar et al. (2012) did not study living spores under the LM, therefore, they overlooked that SB formation starts as a very small vesicle directly at the inner side of the apical wall of immature spores (Fig. 69). Such development of a gradually growing organelle is hardly concordant with the theory of a derivation from mitochondria, hence we are convinced that mitochondria do not directly develop into SBs. This was also the conclusion of Müller (1998) who applied a procedure similar as the above (without silver-methenamine) in his TEM-study on the ultrastructure of asci and ascospores of *Gyalectales* (*Ostropomycetidae*) and *Orbiliomycetes*.

Müller (l.c.) investigated three orbiliaceous species: *O. vinosa*, *O. aristata*, and *O. xanthostigma*. The two former taxa are representatives of section *Hemiorbilia*. Here the SBs are clearly visible as large, light grey areas within the more opaque sporoplasm (Fig. 71: d–e). They are surrounded by a thin transparent membrane and are broadly attached to the primary wall at the spore apex. The sporoplasm is completely absent at the place of attachment, where the spore body forms an aperture that is directly connected to the primary wall. At the place of attachment the lateral membrane of the spore body appears to merge with the plasmalemma, which would confirm the formation of SBs by invagination of the plasmalemma. However, Müller saw in *O. vinosa* at the place of attachment a thin membrane that seems to separate the SB matrix from the primary wall, and he could not exclude the possibility that this membrane is part of the plasmalemma.

Function of spore bodies. The chemical nature of the SB matrix is quite unknown, and about their function we can only speculate. The hypothesis that SBs are formed by invagination of the plasmalemma and their behaviour under staining indicate that they could have derived from vacuoles.

Benny et al. (1978) considered three possible functions of SBs: '(1) flotation and balance [of the spore] in a liquid environment before and during germination, (2) storage of waste products, and (3) storage of materials for use during germination'.

Possibility (1) implies a different, perhaps higher specific weight of the SBs. This seems to be confirmed when observing ascospores floating in a water mount. We have repeatedly seen that elongate spores of *Orbilia* tend to point with the spore apex downwards. However, this observation refers in part to spores with a slight or strong heteropolarity in shape, the widest part being nearer to the spore apex. Therefore, the observed effect might not only depend on the presence of a spore body. An interesting effect, though only rarely seen, was the adherence of the spores to large air bubbles (Fig. 72): the fusoid-clavate spores in the two species *O. mali* and *O. obtusispora*, in which the effect was so far observed, consistently adhered with their obtuse to subacute, SB-containing apical ends to the air bubble. The phenomenon might be explained by some difference in hydrophily between apical and residual spore wall. The rarity of the effect did not allow further experiments, e. g., whether it depends on the living state, or whether it vanishes when applying a detergent.

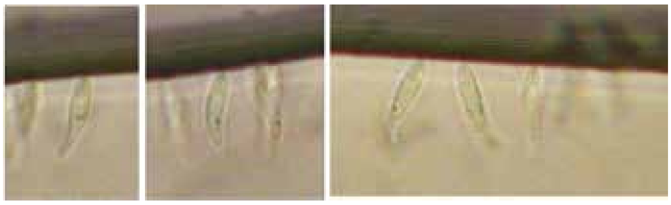

Figure 72: Living ascospores of *Orbilia mali* in water, adhering with their apex to a large air bubble.

Possibility (2) is not much convincing, since the body is so universal in the *Orbiliomycetes* and here completely restricted to the ascospores, that it is difficult to understand why other ascomycetes survive without such a structure. Concerning possibility (3) we must consider that storage products such as lipid and glycogen are not state-dependent, i. e., their presence can also be demonstrated in dead spores mounted in KOH (LBs), or by staining in MLZ (glycogen). In most of the species, SBs occur strictly at the spore apex, which is not that part of the spore where germination usually takes place (Fig. 70). With possibilities (2) and (3) the question remains open why the position of SBs is so fixed within a species, and why SBs remain connected to the plasmalemma.

The remarkably high refractivity of SBs during all stages of their development seems to suggest a metabolic substance that is accumulated within the organelle without undergoing further changes once it is transferred there. The fact that basic dyes accumulate within SBs does not necessarily indicate a more acidic pH inside the organelle. Unlike vacuoles, SBs seem to represent an open system connected to the environment by their attachment, although this connection might be closed by a membrane or plug. In any case, the sudden loss of refractivity when the spores die by mechanical influence strongly resembles refractive vacuolar bodies (VBs) in vegetative cells. The refractivity of VBs possibly originates from phenolic compounds which are known to lose their double bindings when the pH of the vacuoles increases (see p. 92).

Kumar et al. (l.c.) thought that the dense staining of SBs in basic dyes, such as Toluidine blue O, suggests that they might contain RNA, but it seems the authors did not take into account a vacuolar nature of the organelle.

The high morphological diversity of SBs that has evolved in the various taxa argues for a function important to the survival of the fungus. The predatory capabilities of some *Orbiliomycetes* tempted us to speculate that SBs might function as some kind of poison vial, whose contents paralyse small invertebrates when ingesting the ascospores. Another function might be in attracting animals in order to get swallowed from the apical spore end. A number of species of *Orbilia* with a peculiar ascospore shape support this idea, which implies that spores infect invertebrates via the ingestion tractus (see p. 144–145).

The long and filiform, flexuous and basally hooked SBs of many species of subgenus *Habrostictis* resemble somewhat the nematocysts of *Cnidaria* (medusas and polyps), or the injection (gun) cell of *Haptoglossa*, an endoparasitic oomycete that attacks rotifers (Barron 1980). However, the spore body of *Orbiliomycetes* is a soft and compressible structure surrounded merely by a cytoplasmic membrane, and there is no indication that SBs emerge as a whole through the spore apex.

The hypothesis that SBs might paralyse or poison motile organisms would shed some light on the high diversity in SB morphology among the taxa. The two main characteristics of SB shape are: (1) volume, and (2) ratio between surface and volume. There seems little doubt that these two parameters play some role in the life cycle of these fungi. The same two parameters are observed regarding the lipid content of living spores: number and size of globose LBs determine (1) the amount (total volume) of lipid and (2) their surface:volume ratio. The hypothesis is here that many small LBs are more rapidly degraded, whereas a few large LBs enable storage of higher amounts of lipid in a spore (Baral 2015: 284).

Undoubtedly, SB shape is genetically controlled. The simplest shape appears to be a sphere with a short apical connection, or a lens-like body. The stability of such a simple structure might be controlled by a slight difference in turgor, or by membrane properties. SBs with a more complex shape possibly need more elaborate membrane properties to stabilize their shape. Elongate SBs would then change to a globose shape in overmature spores by reducing the stabilizing properties of the membrane.

Vesicles found in trapping organs of *Orbiliomycetes* are thought to contain enzymes for the consumption of trapped invertebrates (see p. 116, 120). Although their size of ~0.1–0.3 µm should permit recognition under the LM, these organelles could not with certainty be seen in living traps. Possibly, their contents show only little refractivity though appearing electron-opaque in TEM micrographs.

Transient plasmatic inclusions in spores of non-orbiliaceous fungi. Despite a thorough search with the LM for spore bodies in numerous species of *Helotiales* and other ascomycetes, corresponding organelles that might be homologous have only very rarely been detected.

Globose refractive bodies of a similar behaviour upon treatment by KOH or CRB have been found in a few quite unrelated ascomycetes, for instance in the multiguttulate ascospores of a *Phaeohelotium* (as *Hymenoscyphus* cf. *sazavae*) and *Tubeufia paludosa* (Baral 1992: figs 34c, 35a), or in the multiguttulate conidia of *Symphyosirinia* (Baral 1994: figs 50–52, 63). The majority of droplets inside these propagules can be classified as vacuolar bodies (VBs). They disappear when KOH is added, and stain bright turquoise under vital staining with CRB, whereas adjacent, morphologically identical droplets (LBs) are KOH-resistant and not stained blue in CRB. In contrast to SBs of *Orbiliomycetes*, these VBs occur scattered inside the whole spore, with a variable distance to the spore wall.

The ascospores of '*Discinella*' *schimperi* possess two very large refractive VBs which touch the lateral wall but not the two spore ends (Fig. 73: a). This peculiar inclusion was also documented by Navashin (1888, tab. XV fig. 13, as 'biguttulate'). Similar as with SBs of orbiliaceous taxa, refractivity of these organelles is unstable in lethal agents such as IKI or KOH. Vital staining with CRB was not tested, but they might well be akin to SBs in their ultrastructure and chemistry. Although such big refractive spore vacuoles are very exceptional within the *Helotiales*, the presence of an amyloid ascus apical ring suggests a relation to this order, and in a phylogenetic

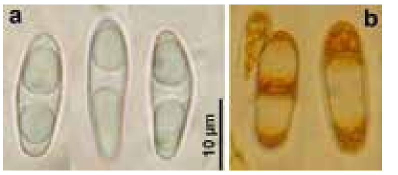

Figure 73: Ascospores of '*Discinella*' *schimperi* (H.B. 9386). — **a**. living state in water: two big refractive vacuoles (VBs) occur in each spore; **b**. dead state in IKI: the VBs instantly disappeared upon staining with IKI.

analysis of bryophilous ascomycetes (Stenroos et al. 2010) it clustered in a clade with, e. g., the genus *Pezoloma*.

Zhuang (1988: 93) reported for the globose ascospores of *Parencoelia myriostylidis* (*Helotiales*) a 'refractive equatorial plate' across the centre of the 'young' spore which disappeared upon treatment with KOH. This structure was observed in the nearly 100 years old type material and seems to be a feature of high consistency, as Zhuang depicted it in all 8 spores within an ascus. Vital studies should be performed to clarify the nature of this structure.

An interesting single, eccentric, refractive body (referred to as 'oil drop') reminiscent of SBs of *Orbiliomycetes* was described and figured by Barron (1985, 1991a) inside the conidia of several species of *Rotiferophthora* (in 1985 as *Diheterospora*). Since this genus of mitosporic fungi is predacious on rotifers and shows a diversity in conidial shape comparable to ascospore diversity in *Orbiliomycetes*, *Rotiferophthora* seems to be a candidate for a phylogenetic relationship to *Orbiliomycetes*. However, conidiogenesis is phialidic, and molecular data of two species demonstrates the group to belong to the *Clavicipitaceae* (*Hypocreales*, Sung et al. 2007), and particularly near another anamorph-typified genus, *Pochonia* (= *Diheterospora* s.str.), which preys on nematodes and has teleomorphs in *Cordyceps* (Zare et al. 2001). Regrettably, the bodies in *Rotiferophthora* conidia have not been tested with KOH or CRB (G.L. Barron in litt.), and cultures of two species kindly sent to us by S. Glockling did not produce conidia.

De Bary bubbles. When dealing with herbarium material, spores with thick rigid walls often contain eccentric, globose, refractive inclusions which represent a gaseous phase that originates from drying of the specimens. The bodies play a role in the desiccation tolerance of fungal cells, and are referred to as de Bary bubbles (DBBs, Ingold 1956, Dodge 1957). Due to the rather thin spores of *Orbiliomycetes* which collapse when drying out, DBBs do not occur in this class.

The presence of DBBs strongly depends on the method: DBBs are consistently absent in living specimens mounted in water. They are induced either when drying the specimen, or when adding dehydrating solutions (e. g., MLZ, lactophenol). When rehydrating dry living spores in water DBBs rapidly disappear, whereas when rehydrating dead spores they do not disappear (Baral 1992: 373). Uncritical reports of DBBs may, therefore, cause taxonomic confusion. For example, *Helotium zamurense* (≡ *Ascophanus zamurensis*) was described and illustrated as having ellipsoid ascospores with a single globose, eccentric guttule (Patouillard & Gaillard, 1889). Together with the reddish-orange apothecia the taxon resembles an *Orbilia* of section *Ovoideae*. However, the transfer to *Ascophanus* (*Pezizales*) by Svrček (1974), who saw this 'highly refractive large bubble' in some spores of the type, suggests that the bodies were DBBs.

Phylogeny of spore bodies. SBs are to be considered as a synapomorphy for the *Orbiliomycetes* in comparison with other classes of *Ascomycota* (Pfister 2015), because of their unique and almost consistent occurrence in all eight recognized genera with a known teleomorph. The high diversity in SB shape allows, in correlation with other characters, to speculate about phylogenetic lineages, along which SBs might have evolved. The phylogeny of SBs appears to follow two main parameters of storing the refractive substance under the premise of a constant volume occupied by this substance. (1) One parameter concerns the relation between surface and volume of the SBs: many taxa tend to increase the SB surface which results either in strongly elongated and curved SBs or in flattened SBs, whereas many other taxa minimize the SB surface which leads to tear-shaped or globose SBs. (2) The other parameter concerns SB attachment: taxa either tend to keep the width of the apical connecting part small, so that often only a very thin channel (the filum) remains, or they tend to have a wide connecting part, i. e., more or less broadly attached SBs.

Based on the hypothesis that vacuoles with a refractive content represent the evolutionary origin of SBs, the globose type with a short and narrow attachment should constitute the most primitive and ancient type of SB, as this would closely resemble a young vacuole which is yet attached to the plasmalemma. Two main evolutionary lineages would have evolved from the globose type of SB (Fig. 74). In one lineage the SBs tend to increase their width of attachment up to almost spore width, which leads to lens-shaped SBs; this SB type is typical of *Lilapila*, *Amphosoma*, *Pseudorbilia*, and *Orbilia* series *Lentiformes*. In the other main lineage the SBs tend to elongate, sometimes up to more than spore length, which leads to long, subulate to vermiform, often flexuous to curled SBs which are typical of sections *Habrostictis*, *Helicoon*, and *Aurantiorubrae* p.p. of the genus *Orbilia*. In both lineages the surface:volume ratio is strongly increased. Yet, only in the first lineage the entire SB surface borders on the cytoplasm. Judging from the consistent shape of SBs within a species, it can be concluded that these different parameters and also the absolute volume of SBs play a role in regard to SB function.

Another parameter concerns the number of SBs within a spore. The here presented phylogeny postulates that the multiguttulate spore with a bipolar arrangement of the up to about ten SBs per spore, which is typical of many species of *Hyalorbilia* and the monotypic *Bryorbilia*, represents the most ancient character state, i. e., a plesiomorphy within the *Orbiliomycetes*. This hypothesis presumes that the evolutionary direction was mainly characterized by a reduction in the number of SBs, which led at first to two SBs, one at each spore end, which is a characteristic pattern in the spores of *Amphosoma* and *Pseudorbilia*. In the large genus *Orbilia* the SB number was reduced to a unipolar arrangement with only one SB, which is usually situated at the spore apex, but the unipolar SB arrangement also occurs in a few species of *Hyalorbilia*. The direction of the evolutionary process from two SBs towards one can be assured by the rare observation in some species of *Orbilia* subgenus *Lentiformes* and section *Hemiorbilia*, in which a few (perhaps 1 %) aberrant spores with two SBs were sometimes seen, one at each end (Fig. 60: c–d). These aberrant spores appear to represent a regression to an earlier character state of SB arrangement, although the common ancestor of the

Figure 74. Hypothetical phylogeny of the spore body in *Orbiliomycetes*.

genus *Orbilia* is assumed to have already possessed spores with a unipolar SB arrangement.

An alternative hypothesis would consider the lens-shaped SBs as plesiomorphic, a view being supported by the fact that such SBs occur coupled with primitive ascus characters (hemispherical, often thick-walled apex), sometimes also with a bipolar arrangement of the SBs and with dark-coloured apothecia. Two presumably primitive features, lens-like shape and bipolar arrangement, are established in *Amphosoma* and *Pseudorbilia*, a small group of species growing predominantly on coniferous substrate, a phylogenetically old group of host plants.

Paraphyses

General remarks, **ontogeny**. In hymenia of mature apothecia the paraphyses generally occur with an equal abundance as the asci. When viewing under oil immersion in top view on the surface of the apothecial disc (water mount, living state, unsquashed), the distribution of asci and paraphyses is best seen. Especially in *Hyalorbilia* this is easy to observe due to the rather thin and translucent apothecia of that genus, and the wide, apically scarcely inflated paraphyses that contain pale chlorinaceous vacuoles (Fig. 75: a). Literature reports of sparse paraphyses usually refer to dead or overmature material in which the paraphyses are sometimes difficult to see, whereas reports of sparse asci refers to submature apothecia. The addition of IKI facilitates distinction between asci (which usually stain red-brown) and paraphyses (which remain unstained, Fig. 92).

As a common feature of most hymenium-forming ascomycetes, the paraphyses emerge from the vegetative hyphal system of the medullary excipulum separate from the ascogenous hyphal system. Due to the absence of a dikaryon in paraphysogenous hyphae, these never have croziers at their septa. As an exception, ascogenous cells in *Lophodermium* (*Rhytismatales*) are formed from anastomosing basal cells of paraphyses (Stephan 1971, Morgan-Jones & Hulton 1979).

The apices of paraphyses provide a valuable character at the species or higher level. However, their characteristic shape develops rather late in the ontogeny of an apothecium. Therefore, mature apothecia are required in order to properly estimate paraphysis characters. If only a few mature asci are found in a hymenium, the paraphyses have usually not yet developed their typical shape. Even in mature apothecia there are still some paraphyses to be found which are rather young; they are apically narrower and a bit shorter than the mature ones and should, therefore, be disregarded in descriptions.

The hymenium of young apothecia in the prohymenial phase merely consists of paraphyses, while the young asci are formed in the mesohymenial phase (see p. 37, Apothecial ontogeny). The hymenium is formed during the early prohymenial phase, thereby the paraphyses elongate and remain apically undifferentiated for a long time. They are early septate and often also branched at the base. Anastomoses between adjacent paraphyses are already present near the base. When the first asci are about to reach maturity, the paraphyses develop their typical characters: apices become swollen or beaked in some of the species, branching may extend to the upper part, also anastomoses sometimes occur more upwards, and cell contents (LBs, VBs, SCBs) appear or increase in size.

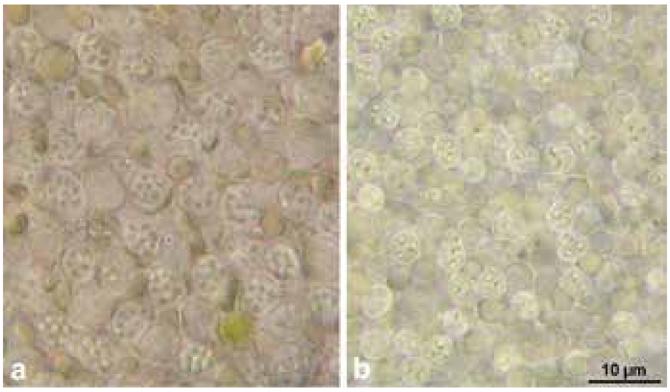

Figure 75: Hymenium of *Hyalorbilia* and *Orbilia* in top view (optical cross section, living state), showing mature asci (containing spores) intermingled with paraphyses (with pale chlorinaceous contents). — **a**. *H. juliae* (H.B. 7930, asci containing 8 spores in a parallel bundle); **b**. *O. luteorubella* (H.B. 9633a, spores in superimposed bundles, therefore only 3–4 spores visible).

Size and shape of apex. Although the lower parts of the mature paraphyses have a rather uniform thickness within the *Orbiliomycetes*, ranging at ca. *(1–)1.5–2.5(–3) µm, the width of the apex may vary considerably between taxa, ranging from *1.5–3 up to 3–5 or sometimes 6–8 µm.

Paraphysis apices have formerly been thought to provide a key character of the genus *Orbilia*. However, only about 40% of the species possess a more or less abruptly swollen, medium to strongly capitate (knob-like) or more gradually inflated (clavate or spathulate) apex which sometimes carries a beak on its top. The inflated knob-like apical part thereby has a diameter about two to four times of the lower part. The uninflated lower part shows in some groups a tendency to be narrowest directly below the inflated apex (often observed in section *Helicoon* and series *Orbilia*). In further ~30% species of *Orbilia*, medium to strongly capitate or clavate paraphyses occasionally occur besides the prevailing not or slightly inflated ones. Apically inflated paraphyses occur mainly in species with truncate thin-walled ascus apices, but even here they occur only in about 85% of the species.

Capitate to clavate paraphyses are more or less typical of sections *Habrostictis*, *Helicoon*, *Ovoideae*, and *Arthrobotrys*, and of series *Ovales*, *Aurantiorubrae*, and *Orbilia*, and also occur in some species of series *Lentiformes* and *Phanosomates*. Within each of these groups, paraphyses vary between slightly and strongly capitate, particularly when comparing different species (see Fig. 76, Tab. 62).

Eight small, more or less distant series within *Orbilia* (*Habrostictis*, *Regales*, *Abutilones*, *Albovinosae*, *Microsomates, Piliferae, Rubellae, Xanthoguttulatae* p.p.) are characterized by apices of a predominantly spathulate or even lageniform to mammiform (papillate to beaked) shape, and also some other series contain a few species with such paraphyses, e.g., *O. rhamni* and *O. fraxini* (series *Neodactylella*) or *O. anigozanthi* (series *Gamsylella*). However, paraphysis shape is rather variable within a species, e.g., apical beaks are not consistently present. Moniliform apices are taxonomically quite unreliable, as they occur only sporadically, mainly in species with capitate paraphyses with short terminal cells. In a few species of sections *Arthrobotrys* (*O. blumenaviensis*, *O. alba*) and *Orbilia* (*O. minutispora*, *O. guyanensis*, *O. umbilicata*, *O. spirospora*) the paraphyses are more or less lanceolate, showing gradually attenuated, obtuse to subacute apices. However, a sharp line between lanceolate and lageniform cannot be drawn.

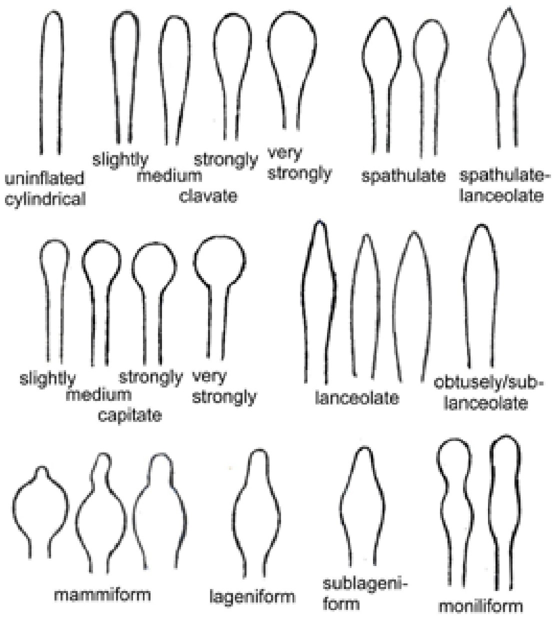

Figure 76: Different shapes of paraphysis apices in *Orbiliomycetes*.

The majority of species of *Orbilia* subgenus *Hemiorbilia* have paraphyses with more or less uninflated apices. Predominantly uninflated paraphyses are also typical of the genera *Hyalorbilia*, *Pseudorbilia*, *Lecophagus*, and *Lilapila*, whereas in *Liladisca* and sometimes also in *Amphosoma* (*A. macrosporum*) they are distinctly capitate.

Protrusion beyond asci. The tips of paraphyses are usually a few micrometres longer than the asci. However, when an ascus attains full turgescence, it usually protrudes above the paraphyses (Fig. 45). This is particularly the case in *Orbilia*, while in *Hyalorbilia* the asci at full turgescence are often more or less equal with paraphyses. Observations on protruding paraphyses or asci greatly depend on the living vs. dead state: upon adding lethal mountants, living asci shrink in length to a higher extent than paraphyses do. At moderate turgescence, asci of *Orbilia* are often slightly overtopped by the paraphyses, and even more strongly so in the dead state. However, in some cases the difference in protrusion between the living and dead state was not very clear, perhaps because the paraphyses shrink to a similar extent (e. g., in *O. pilifera*).

Remarkable protrusion beyond asci is mainly observed in paraphyses with a lanceolate or spathulate to lageniform or mammiform shape. Here the tapered or beaked apical parts protrude for 1–10 µm beyond the mature but not fully turgescent asci, resulting in a finely rough surface of the hymenium. Yet, a similarly strong protrusion occurs within series *Vibrioides* in which the paraphyses are rather undifferentiated.

Function of the apices of paraphyses. The capitate type of paraphysis apex may be mistaken as a glandular cell that excretes gelatinous or solid exudate. Yet, on the contrary, a rather strong trend can be observed in paraphyses with inflated apices showing diminished excretory activity, a correlation also observed by Velenovský (1934: 91). Thick clods of exudate are usually found over not or only slightly inflated apices, and are typical of, e. g., series *Microspermae* and section *Hemiorbilia* (Fig. 95: g), whereas capitate apices have generally low amounts of exudate, or even more or less completely lack exudates (e. g., various members of sections *Habrostictis*, *Helicoon*, and *Orbilia*, Fig. 95: h). Concerning excretion of gel, a similar negative correlation is exemplified by the genus *Hyalorbilia*, which is characterized by a continuous layer of thin granular exudate and a cohesive gelatinous matrix below, in which the usually more or less uninflated paraphyses are embedded (Fig. 95: d), whereas species of *Orbilia* with or without inflated apices have low amounts of gel around. The excretion of thick exudate from paraphyses with variable apical inflation (from uninflated to strongly capitate) is frequent in section *Ovoideae*.

Capitate apices of paraphyses occur fairly often in desiccation-sensitive species, but they are also typical of about 50 % of the desiccation-tolerant species. One of the functions of capitate apices might be to retain evaporation, i. e., to reduce water loss from the hydrated intercellular system of the apothecium. Undoubtedly, the tightly packed heads of paraphyses serve as some kind of protection of the young asci. They form a coherent layer, with more ore less small amounts of gel and exudate filling the minute gaps between the globose heads, thereby leaving only small openings for the ascus tips. These openings are widened when the asci attain full turgescence. However, cell walls are rather freely permeable for water, hence capitate apices cannot virtually prohibit dehydration. It can even be doubted that capitate apices of desiccation-tolerant species retard water loss at all. Among the desiccation-sensitive species, closely related taxa sometimes significantly differ in the strength of apical inflation. Thus, the function of capitate paraphyses remains unclear.

The ability to condense atmospheric humidity might be important, particularly for desiccation-tolerant taxa. We suppose that paraphyses with beaked or lanceolate apices and those with exudate caps (Fig. 91: i–l), as well as protruding cylindrical paraphyses in multispored taxa of series *Vibrioides*, favour condensation, and also the rough surface of exudate might assist condensation. Water that precipitates on a dry hymenium is rapidly soaked up by the hydrophilous exudate and rehydrates the cytoplasm of the collapsed cells beneath.

Septation. Paraphyses of probably all groups of sporocarp forming *Pezizomycotina* have septa, at least near the base, although drawings in publications often omit them. Septa are overlooked because they are difficult to discern in dead herbarium material unless cell wall stains are used (see p. 9). Some authors (e. g., Velenovský, see Fig. 154) have drawn septa of paraphyses quite arbitrarily. In most instances, septa become clearly visible in a squash mount of KOH to which Congo red (CR) is added, but in some cases even this method did not help. Cytoplasmic stains (IKI, CRB, CB_L, phloxine) added to a water mount of dead paraphyses occasionally yielded some good results. However, only the gap between the plasma portions of two adjacent cells can be seen while the septal wall remains invisible. Also adding cytoplasmic stains to KOH-mounts often did not allow us to see the septa.

In the living state, septa are mostly clearly visible, except for the quite rare case when the cytoplasm contains many small LBs which make septa difficult to discern. There is often a very slight constriction to be seen at each septum, which may help in detecting septa in difficult cases. However, this may be misleading since the individual cells have sometimes also slight constrictions in their middle part. Small portions of cytoplasm between vacuoles, but also rod-shaped SCBs, may be mistaken for septa when studying living paraphyses.

Although the length of the individual cells shows considerable variation within a species, a clear tendency within *Orbilia* concerning desiccation tolerance is obvious: in desiccation-sensitive species the terminal cell is generally (1–)2–4(–7) times longer than the lower cells, whereas in most of the desiccation-tolerant taxa the septa are more or less equally distributed from base to apex, the terminal cell being sometimes even shorter than the lower cells. Yet, much variation can be noted in the length of terminal cells. Because in desiccation-sensitive species the asci are generally comparatively short, each paraphysis possesses only a few lower cells, which are found near the level of the ascus base. In desiccation-tolerant species the asci are often rather long, and the long paraphyses with their short terminal cells multiseptate. However, in section *Aurantiorubrae* with only desiccation-tolerant species, the terminal cells are predominantly longer (often 1.5–3 ×) than the lower cells. In *Hyalorbilia* the terminal cells are always much longer (mainly 1.5–4 ×) than the few lower cells, irrespective of the rate of desiccation tolerance which is, however, never high in that genus.

Branching. Di- or sometimes trichotomous branching of the paraphyses occurs throughout the class. Paraphyses branch quite consistently only at the septa. Therefore, those paraphyses that have long terminal cells in combination with short asci show branching only near the ascus base. In taxa with short terminal cells and comparatively long asci, branching occurs not only near the ascus base but often also at the middle and sometimes upper level of the hymenium.

Due to the rather consistent occurrence within the *Orbiliomycetes*, branching of paraphyses in the lower part of the hymenium has little taxonomic value. In desiccation-tolerant species of *Orbilia*, branching at the uppermost septum appears to be of some taxonomic significance, being frequent in some species but rare in others. However, this feature was often found to vary strongly among collections, possibly depending on the age of the apothecia, therefore, its taxonomic value should not be overestimated.

The function of branching is apparently to fill gaps in the hymenium during apothecial growth. The general development of the apothecia from a concave to an eventually convex disc originates from both branching and apical inflation of paraphyses as well as from the formation of more and more asci.

Anastomoses. Anastomoses among adjacent paraphyses occur rather consistently throughout the *Orbiliomycetes* and have, therefore, hardly any taxonomic importance within the class. They are usually only found close to the level of the ascus stalk or slightly above, in taxa with large asci also at the middle level, and are usually provided with a vertical septum. Their function appears to be to increase mechanical stability of the hymenium.

Phylogeny of paraphyses. Phylogenetic considerations suggest that the equally septate, apically non-inflated type of paraphyses represents the plesiomorphic character state. This can be concluded from the fact that such simply constructed paraphyses are typical of various basal groups, particularly *Amphosoma*, *Lecophagus*, and *Lilapila*, but also *Orbilia* subgenus *Hemiorbilia*. Also in *Hyalorbilia* and *Pseudorbilia* the paraphysis apices are predominantly not or only slightly inflated, but here the terminal cells are generally much longer than the lower cells. Except for *Pseudorbilia*, all these genera are characterized by a hemispherical, often thick-walled ascus apex which is considered to be plesiomorphic in the present study (see p. 55). On the other hand, paraphyses with longer terminal cells and capitate or irregularly swollen apices occur in *Liladisca* and in *Bryorbilia*, two basal genera with unusual ascus apices of a conical shape.

When considering paraphysis septation, a comparison with the features of the marginal excipulum appear to be useful because the paraphyses (hamathecium) can be considered as ontogenetical descendants of the ectal excipulum. Mainly in desiccation-sensitive taxa the long terminal cells of paraphyses are in strong contrast to the short marginal cortical cells, whereas in many desiccation-tolerant taxa the length difference between the paraphysis terminal cells and the excipular marginal cortical cells is much lower. It seems conceivable that a low length/width ratio between paraphysal and excipular terminal cells is the plesiomorphic case, and it can be speculated that speciation within the *Orbiliomycetes* progressed towards paraphyses with strongly elongated terminal cells, particularly in desiccation-sensitive groups. This view is in concordance with the hypothesis that desiccation tolerance is a plesiomorphy within the *Orbiliomycetes*.

Ectal excipulum

The ectal excipulum constitutes from base to mid flanks the outer tissue of the ascocarp (Fig. 16) adjacent to the medullary excipulum and merges at the margin with the paraphysis palisade. Its development starts from the ‘conceptacle’ of the apothecial initial (see Fig. 18).

The cells of the ectal excipulum are usually larger and often also more tightly packed than those of the medullary excipulum. The two layers are frequently separated at the flanks by a more or less distinct, thin delimiting layer of textura porrecta, which consists of narrower cells and is, therefore, included in the medullary excipulum. In some species, especially of *Hyalorbilia*, *Liladisca*, and *Lecophagus*, but also in some taxa of *Orbilia* with large globose excipular cells, the border against the medullary excipulum is only very difficult to recognize. A layer of narrow hyphae covering the outer surface of the ectal excipulum may occur at the flanks or even up to the margin, e. g. in section *Habrostictis* (see, e. g., *O. trapeziformis* Pl. 592: 6f and *O. obtusispora* Pl. 595: 1f). At the base this layer intergrades with the anchoring hyphae and, therefore, it can be regarded as part of the latter. Living cells of the ectal excipulum frequently contain more or less distinct cytoplasmic inclusions (SCBs or LBs). The same inclusions usually also occur in the paraphyses, underlining the ontogenetic homology between paraphyses and ectal excipulum.

The individual cells are usually thin-walled and glued together by a thin refractive gel, but in various species of *Orbilia* and particularly *Hyalorbilia* the excipular cells tend to be slightly to distinctly thick-walled by a higher abundance of this gel (Figs 77: e–f). Also the genera *Liladisca* and *Amphosoma* p.p. are highly gelatinized in the ectal excipulum, and in *Lilapila* cap-like wall thickenings occur on the cortical cells (Pl. 29: 1h).

Layer thickness, **cell size**. The overall thickness of the ectal excipulum normally ranges at 20–50(–100) µm at the base, 20–30 µm at the flanks, and 10–20(–30) µm at the margin. Especially in large apothecia a basal thickness of 50–100 or sometimes up to 200–300 µm may be attained. Apothecial stalks of *Orbiliomycetes* are usually exclusively composed of cells of the ectal excipulum and are included in measurements of its basal height.

Excipular cell size provides some taxonomic value at the series level, but within a population it may considerably depend

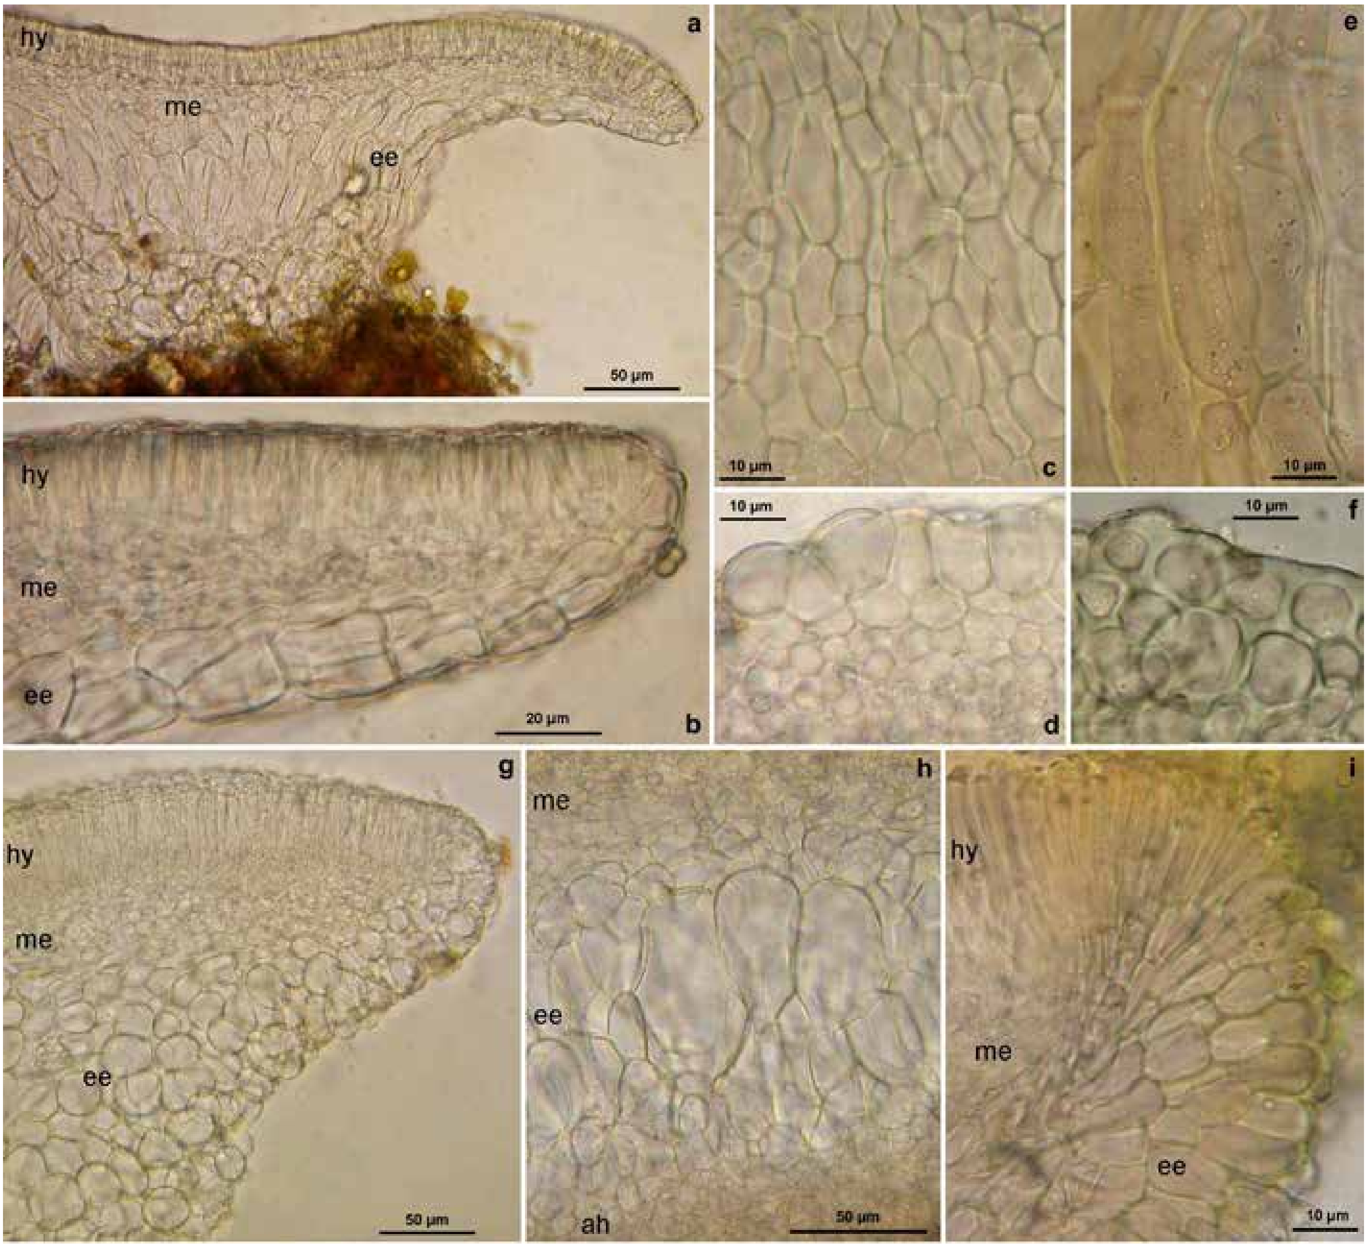

Figure 77: Ectal excipulum in median section (**a–b**, **g**. from base to margin, **h**. near base, **i**. at margin), external (surface) view at flanks (**c**, **e**), and top view on the margin (**d**, **f**). — **a**. vertically oriented, thin-walled textura prismatica in stipe (*Hyalorbilia inflatula*, H.B. 8882a); **b–c**. thin-walled textura prismatica oriented at a very low angle to the surface (*H. fagi*, **b**. on apothecial size and maturity. Generally, cells near the base are much smaller in immature apothecia, but even if the asci are mature, cell size in small apothecia is sometimes only about half of that of large apothecia. Typical cell size of the basal ectal excipulum in *Orbilia* ranges at 8–20 × 5–15 µm. In contrast, many desiccation-sensitive species with comparatively large apothecia show a clear tendency to much larger cells (around 20–50 × 10–40 µm, Fig. 77: g vs. h). Velenovský (1934) referred to such an excipulum as ‘parenchyma grandicellulare’. Interestingly, species with large excipular cells and large apothecia have usually small asci and spores. Large excipular cells might function as a water storage vessel to retard hymenial desiccation during dry weather. However, large apothecia and excipular cells are also found in a few highly desiccation-tolerant species, e. g., in *O. anigozanthi*.

Cell shape, **texture types**. The individual cells of the ectal excipulum are either globose to angular (cubical), or more or less rectangular (prismatic) with a varying length:width ratio. They form a tightly packed tissue, of which two main types can be distinguished according to cell shape: (1) textura globulosa to t. angularis (lichenologists currently use ‘paraplectenchymatous’ for the earlier term ‘parenchymatous’): cells ± isodiametric though sometimes elongated vertically to the surface of the apothecium (Fig. 77: g–i; 78: e); (2) t. prismatica or t. porrecta (lichenologists currently use ‘prosoplectenchymatous’ for the earlier term ‘prosenchymatous’): cells elongated, parallel to the surface of the apothecium (Figs 77: a–c; 78: a).

A prosoplectenchymatous tissue at the flanks oriented parallel to the surface is typical of *Hyalorbilia*, but rarely also occurs in *Orbilia* (some species of section *Habrostictis*, particularly series *Habrostictis*; *O. cupularis* of section *Ovoideae*), though only towards margin. A paraplectenchymatous tissue at the flanks is typical of most species of *Orbilia*, but also of *Pseudorbilia* and *Lilapila*. The texture of *Bryorbilia* and *Lecophagus*, also in *O. sarcobati* of section *Ovoideae*, is somewhat intermediate, with angular to short-prismatic cells oriented oblique or parallel to the surface, respectively. In some taxa (e.g., *Liladisca* and *Amphosoma*) a textura angularis-prismatica oriented at a high (90°) angle at the lower flanks gradually changes its orientation near the margin to an angle of ~10–50° (Fig. 78: b–d).

In the prosoplectenchymatous tissue of *Hyalorbilia* the length/width ratio of the cells may considerably differ between taxa, ranging from only slightly longer than wide (textura prismatica-angularis to almost t. globulosa, e.g. in *H. erythrostigma*, *H. orbiliicola*, *H. polypori*, *H. lunata*, *H. sibirica*, *H. tortuosa*) to about 2–3× longer than wide (t. prismatica) or 3–6× longer than wide (t. porrecta). In one collection of *H. subfusispora* (Pl. 117: 3f) a t. globulosa as in *Orbilia* occurred.

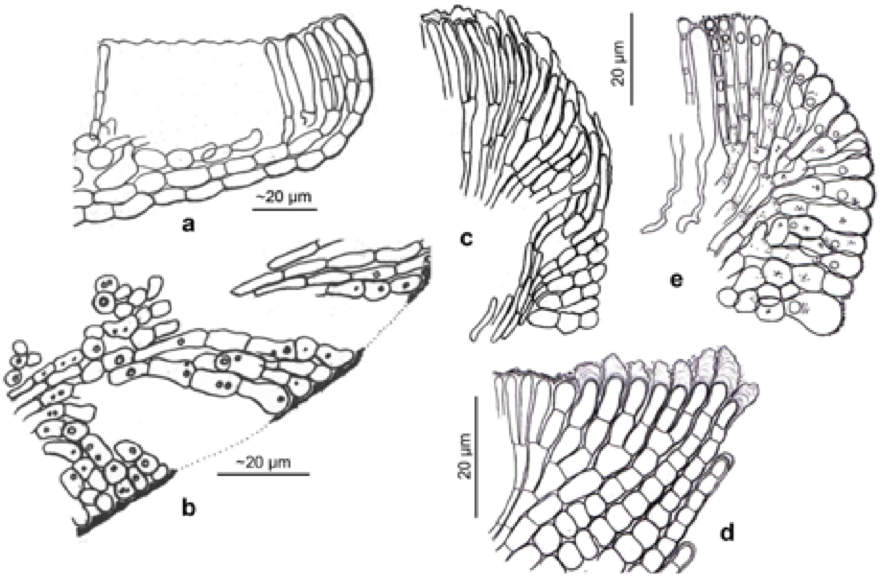

Figure 78: Different types of ectal excipulum at flanks and margin. — **a**. textura prismatica oriented parallel to the surface (*H. juliae*); **b**. lower flanks of t. angularis oriented perpendicular, mid flanks of t. prismatica oriented at ~40–50° (*Amphosoma atroolivaceum*); **c**. marginal excipular cells oriented at a rather high angle, but with the cortical hyphae curved upwards (*O. aristata*); **d**. margin of angular cells forming cell rows oriented at a low angle to the surface (*O. tenuissima*); **e**. ± clavate marginal cells oriented at a high angle to the surface (*O. sarraziniana*).

The cells of the paraplectenchymatous excipulum are either more or less angular (t. angularis) or tend to be globose (t. globulosa). The distinction between angular and globose cells is very gradual and, furthermore, state-dependent: the turgor of living cells provokes a more rounded shape whereas upon killing the cells become more angular.

Prismatic cells elongated vertically to the surface occur frequently in the paraplectenchymatous type, particularly in the more basal region of the apothecium (Fig. 77: h). Because of the prismatic shape, such a tissue is referred to as t. prismatica in the present study in spite of its vertical orientation. In *Hyalorbilia* a t. angularis of indistinct or sometimes vertical orientation is often present at the base, but this changes at the lower flanks to a t. prismatica oriented parallel to the surface. If there is a well-defined stipe, the cells form an upwards oriented t. prismatica parallel to the stipe surface (Fig. 77: a). Care must be taken, however, when doing median sections: if they do not run across the centre of the apothecium, a globular texture is simulated at the junction between receptacle and stipe, caused by tangentially cutting of a prismatic texture.

The hyphal origin of a paraplectenchyma is often not clearly discernible in an adult apothecium, in which it simulates a true parenchyma of higher plants. A vertical orientation, i.e., a connection of the excipular cells in a direction perpendicular to the surface, seems to be the general rule in *Orbilia*, even if the cells are isodiametric. Their growth at a high angle is obvious especially in the younger marginal region (Fig. 78: e). Here the thin t. porrecta of the medullary excipulum bends outwards into the ectal excipulum of angular to clavate cells oriented at a high angle to the surface.

Considerable variation in the structure of the ectal excipulum is usually observed within a species and even within a population. Therefore, the taxonomic value of the ectal excipulum should not be overestimated.

Marginal ectal excipulum. Whilst the structure of the ectal excipulum at the flanks (Fig. 78: a, b) is mainly useful for separating genera of *Orbiliomycetes*, that of the margin provides a number of different types which are characteristic of some sections or series of *Orbilia*. In many series the marginal cells are clavate to almost globose and oriented at a rather high angle to the marginal surface (see Figs 156, 78: e). However, a group within series *Neodactylella* deviates hereof in having rectangular, isodiametric to prismatic marginal cells that form characteristic cell rows at a low angle to the surface (Fig. 78: d). Some members of section *Habrostictis* show comparable marginal texture types, e.g., *O. carpoboloides* (see Pl. 568: 1f) (Spooner 1987: 192, fig. 28D, as *Habrostictis decipiens*), which Spooner believed to be diagnostic of *Habrostictis*. A similar margin is often found in section *Hemiorbilia*: the prismatic cells of the inner marginal excipulum are oriented at a high angle, whereas the hyphae of the cortical region bend upwards to run more parallel to the outside and often terminate in glassy processes (Fig. 78: c). In all species of *Hyalorbilia* the parallel layer of prismatic cells extends up to the margin (Fig. 78: a).

Phylogeny of ectal excipular textures. The two main types of tissues (proso- and paraplectenchymatous) at the excipular flanks, but also the variation at the margin require a hypothesis, which of the observed character states represents the old, plesiomorphic case. When considering a more complex texture as phylogenetically higher evolved, the parallel textura prismatica of *Hyalorbilia* would be more primitive than the vertical t. globulosa of *Orbilia*, based on two parameters, direction of growth and relation between cell length and width: (1) an ectal excipular texture parallel to the thin medullary layer of textura porrecta appears to be less evolved than a change in direction for 90°, and (2) isodiametric cells in a tissue appear to be higher evolved than prismatic cells which are typical of mycelial hyphae. On the other hand, the vertical cell elongation in the paraplectenchymatous ectal excipulum is a secondary phenomenon arising during the ontogeny of an apothecium.

The here presumed plesiomorphy in *Hyalorbilia* of a textura prismatica oriented parallel to the surface coincides with other presumably plesiomorphic features of that genus, such as homopolar ascospores with a homopolar spore body pattern, presence of croziers at the ascus base, and often uninflated paraphysis apices.

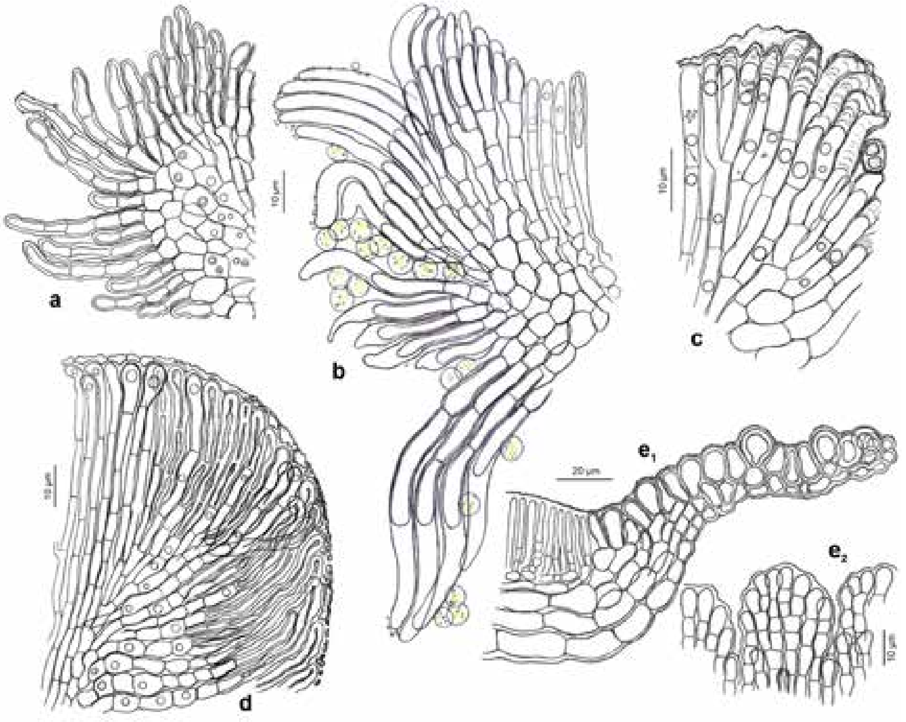

Figure 79: Structure of marginal excipulum (median section, **e**$_2$ in external view). — **a**. septate, thick-walled hairs (*O. phragmotricha*); **b**. septate firm-walled hair-like marginal hyphae terminated by glassy processes (*O. rubella*); **c**. similar as **b**, but cortical cells more compact instead of free (*O. flagellispora*); **d**. hair-like thick-walled hyphae forming a compact smooth margin (*O. ovoidea*); **e**. thick-walled ± isodiametric cells forming marginal teeth or lobes (*H. citrina*).

Hair- or tooth-like projections at the margin

Hair-, tooth- or lobe-like projections occur at the margin and often also the mid flanks in various groups of *Orbiliomycetes*. These projections may be of three very different kinds: (1) thin- or thick-walled hairs that are transversely septate when exceeding a certain length (Fig. 79: a); (2) solid (glassy), acellular processes of very different length, often with an internal stratification (Fig. 79: c); (3) a protruding compact texture of thick-walled, ± isodiametric cells (Fig. 79: e). Rarely types (1) and (2) occur in combination: the glassy processes emerge from the tips of septate hairs (e.g., *O. rubella*, Fig. 79: b, *O. octosporoides* (Pl. 793: 1g). All these types of marginal structures may easily confuse one into mistaking an orbiliaceous fungus as a hairy or toothed member of the *Helotiales*.

The two kinds of hair-like structures project either freely, or are more or less tightly agglutinated by some gel, and then either form more or less compact teeth or lobes, or sometimes a smooth margin. The latter is the case in *O. polyspora* and *O. ovoidea* (Fig. 79: d), and less developed in some other members of section *Ovoideae*, rarely in series *Phanosomates* (*O. myriosphaera*) and *Ovales* (*O. ovalis*): more or less elongated, thick-walled marginal hyphae are agglutinated to form a compact tissue that resembles a textura oblita. Contrary to those species with free hairs, the thickened wall in these conglutinate hyphae is composed of an inner wall layer that is able to swell, showing a distinct imbibition effect: only in the dead state the inner layer is thick and thereby of low refractivity, whereas the living cells have thinner and entirely strongly refractive walls. In *Hyalorbilia citrina* very thick-walled, ± isodiametric cells occur at the margin, which may form more or less prominent lobes or teeth (Fig. 79: e).

Septate hairs. More or less thick-walled septate hairs are typical of *Lilapila* and a few species of *Orbilia*, mainly of series *Rubellae* and *Drechslerella* (*O. pilosa*), whereas thin-walled hairs are typical of series *Habrostictis*, but also occur in series *Piliferae* (*O. pilifera*), *Abutilones* (*O. suberis*) and series *Hemiorbilia* (*O. fimbriata*). The latter species, in particular, is strongly reminiscent of a hairy member of *Helotiales*. The hairs in these species are usually free, but may also be somewhat conglutinate to form indistinct teeth. Hair size ranges from 20–30 up to 50–100(–200) µm in length and (2.5–)4–7.5(–10) µm in width. Very short (~7–20 × 2.5–5 µm) non-septate marginal hairs occur in a few species (e.g., *O. aethiopica*, *O. concoloris*, *O. pseudobrevistipitata*). The hairs are in most cases hyaline and smooth, or yellowish-ochraceous due to a thin exudate that covers the wall. Only in *Lilapila* are they densely punctate by a deep purplish-lilac pigment.

Glassy processes. In about 25% of the species of *Orbilia* a hyaline, solid wall substance is exuded from the tips of the cortical cells of the marginal excipulum. This wall material forms hair-like structures which vary in length from 1–10 up to 30–100 µm or more. In comparison, their width is rather consistent and ranges around 2–4(–5) µm, also the cell lumen below has a rather consistent size. The term 'glassy processes' is exclusively used here for the solid glassy matrix above the tip of the cell from which it is exuded. Earlier authors (e.g., Spooner 1987, Huhtinen 1987a) have classified this feature as hairs with a basal lumen and a solid, glassy, refractive apical part. In our opinion, the term 'glassy processes' facilitates description of septate hairs of varying length which are tipped by short to long solid parts. In some further species the solid parts attain only a length of 1–2 µm and are then easily overlooked. They are not included in the above 25%.

The processes are cylindrical, with a rounded or somewhat conical apex. They are more or less straight or somewhat flexuous, or they tend to be more or less strongly curved, especially when rather long, either under a wide arch, or sometimes only at their apices. Depending on the species, this curvature may consistently be oriented in one direction, either down-/outwards (Fig. 80: a–b) or up-/inwards (Fig. 80: c). The matrix of the processes somewhat differs in refractivity between the species, and often shows some kind of layering, referred to as 'stratified' in the descriptions (Fig. 80: d). Glassy processes are consistently without a central lumen.

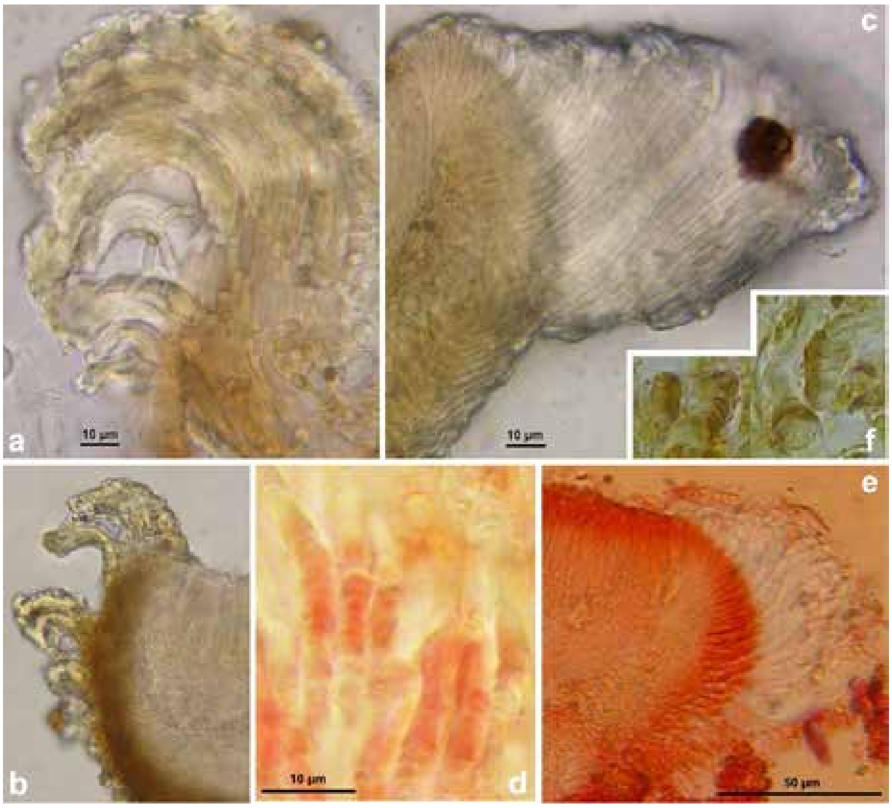

Figure 80: Glassy processes in *Orbilia* (median section of margin, except for **d** and **f**. squash mount). — **a–b**. curved outwards (*O. mirabilis*); **c**. straight or terminally curved upwards (*O. aviaristata*); **d–f**. chemical resistance and colourability (**d–e**. *O. aristata*, H.B. 9226a; **f**. *O.* cf. *puyae*): **d**. stained rose-red by CR_{SDS} after treatment with H_2SO_4 and then by KOH; **e**. glassy processes resist very strong H_2SO_4 treatment (heated); after adding KOH they were not stained by CR_{SDS}; **f**. stained in IKI after treatment with KOH.

In their microscopic appearance these processes resemble the glassy hairs of some *Hyaloscyphaceae*, particularly the genera *Olla* Velen. (= *Hyalopeziza* Fuckel p.p.) and *Urceolella* Boud. Indeed, a few species of *Orbilia* have been thought to be hyaloscyphaceous in the past (*Radotinea caudata*, Fig. 173, *O. albovinosa*, Pl. 520). Glassy processes are often agglutinated and, depending on their length, form either a minutely crenulate margin, or small to very large teeth-like structures. In a few species of series *Albovinosae* the very long glassy processes are less conglutinate and more or less free, therefore, the margin looks hairy or pubescent which strongly resembles apothecia of *Hyaloscyphaceae*.

The glassy matrix is insoluble in 10–20 % KOH, also in 30–60 % H_2SO_4, even when repeatedly heated. CRB, CB_L, or CR do not stain the matrix when applied to a water mount; only the surface is usually stained lilac or turquoise in CRB due to either a gelatinous sheath, or a covering exudate. Iodine reagents (IKI, MLZ) also yield negative results, even after pretreatment with KOH or H_2SO_4, though in one species (*O.* cf. *puyae*, Fig. 80: f) the glassy processes partly stained honey-brown by enhancing the stratification. CR_{SDS} stained the refractive matrix light pinkish-red to carmine if pretreated with KOH or H_2SO_4, but the results were somewhat inconsistent within the same collection (Fig. 80: d). Also a lilac-violet stain of the matrix in CRB was inconsistently obtained when adding SDS to an unpretreated CRB preparation. In contrast to *Orbilia*, the glassy hair matrix in *Olla* and similar genera often stains internally purplish-brown in IKI or MLZ (without KOH-pretreatment).

Glassy processes are sometimes difficult to recognize, especially when they are very short and covered by thick amounts of exudate. In this case strong squashing and subsequent staining with CR, IKI, CRB, or CB_L allows to differentiate between the unstained glassy matrix and the exudate that stains rose-red, red-brown, or blue, respectively. Alternatively, mounting in a drop of H_2SO_4 for a moment (and afterwards neutralizing the acid with KOH) more or less dissolves the exudate and allows to better see the resistant glassy matrix (Fig. 80: d–e).

In many members of series *Microsomates*, but also in some of sections *Aurantiorubrae* (*O. kingsiana*, *O. denticulata*, *O. xanthoguttulata*) and *Habrostictis* (*O. calyptrata*), small glassy caps occur not only on the excipular cells but also on the tips of the paraphyses. However, to clarify whether the interior of such refractive, firmly attached caps on the paraphyses are made up of a glassy matrix like those on the excipular cells, or entirely of exudate, proved difficult. In *O. xanthoguttulata* (Fig. 95: l) the caps obviously consist of an inner, thick, less refractive glassy wall matrix that does not stain in either CR or IKI, and a thin, strongly refractive covering layer of exudate that stains yellowish-brown in IKI and rose-red in CR. The exudate loosely covers the glassy matrix perhaps by a thin layer of gel between. The different nature of the two structures is best seen in IKI-mounts whereas in water or KOH the caps appear to consist of a single homogeneous layer. However, in *O. denticulata* treatment with heated 60 % H_2SO_4 dissolved the entire glassy cap on the paraphyses (Fig. 96: l).

Formation. The mode how glassy processes of *Orbilia* develop seems worth describing in detail. The more or less conspicuous hemispherical or subconical layering (stratification) of the glassy matrix is seen especially in mounts of KOH or acids (Fig. 80: d, f), even without applying stains. It consists of thin, low-refractive layers which occur ± scattered in the higher-refractive matrix. Upon strong pressure the processes may break at these layers. This layering could be interpreted as growth zones which indicate a discontinuous production of glassy substance. During formation, wall material is transported through the cell wall at the obtuse tip of the cortical cells and deposited externally on the wall, i. e., at the base of the growing glassy processes. Thus, the oldest wall material is found at the tip of each process. The cortical cells, from which the processes emerge, thereby retain their primal size during the whole growth period. The glassy processes, which thus grow in a basipetal manner, attain a length up to about ten times the length of the cortical cells.

Raschle (1977: 180) and Korf & Kohn (1980: 506) observed that the production of the glassy matrix in glassy-haired species of *Hyaloscyphaceae* 'proceeds from the apex backwards'. Such a process would likewise deserve the term 'basipetal', but it is fundamentally different: it means that the hairs at first attain their final length while they are still thin-walled, and later gradually deposit glassy substance to the inner surface of the cell wall by finally reducing their lumen to the cell base. The authors concluded that 'the glassiness thus appears to consist of secondary wall thickening'.

This is obviously true in species with hairs with a narrow central lumen (*Hyalopeziza*, *Urceolella*), but it might not be true in species without such a lumen (*Olla*, *Protounguicularia*). Here the glassy matrix appears to be deposited externally on the apical cell wall, resulting in a strong morphological similarity to glassy processes of *Orbilia* by showing an irregular outline of the glassy matrix and a cell wall bordering the base of the matrix. Like in *Orbilia*, the glassy matrix in *Olla* often shows an internal hemispherical or conical layering (see Baral & Marson 2005: *O. millepunctata*, *O. scrupulosa*), at which the processes may break. The chemical composition of the glassy matrix is obviously different between the two classes, because KOH-solubility and internal lumina (both typical of *Urceolella*), as well as amyloidity (typical of *Olla*) have never been observed in *Orbilia*. This seems to justify the assumption that the glassy matrices in *Orbilia* and the *Hyaloscyphaceae* are a result of convergent evolution rather than homologous structures.

Occurrence. Within the *Orbiliomycetes*, glassy processes are so far almost exclusively known in *Orbilia* (the single exception concerns *Hyalorbilia noduosa*), and here provide a valuable species marker. Very closely related species may differ in this respect (examples: *O. nemaspora* vs. *O. scolecospora*, *O. rectispora* vs. *O. cardui*, *O. sphaerospora* vs. *O. subsphaerospora*, the latter mentioned species always with glassy processes). Glassy processes are typical of many desiccation-tolerant species but also occur in a few more or less desiccation-sensitive taxa, e. g., *Orbilia crenatomarginata*, *O. cardui*, *O. polybrocha*, *O. desertorum*, *O. orientalis*. Formerly, glassy processes were used to define a separate genus *Hyalinia* Boud. (see p. 203), but the present work provides evidence that they occur scattered in various sections and series of *Orbilia*. Even within a species or species aggregate, populations with and without glassy processes were noted (e. g., *O. vinosa*, *O. aprilis*, *O. caudata*, *O. cardui*, *O. austrocylindrica*). Glassy processes are absent in section *Lentiformes* (with the exception of series *Ovales*) and section *Habrostictis* (with the exception of short glassy caps in *O. jurana*).

Function of marginal hairs, **teeth or lobes**. Like protruding paraphyses, an uneven margin might help in the condensation of atmospheric humidity. Thick-walled marginal cells or glassy processes could serve in protecting the apothecia from mycophagous invertebrates. The length of glassy processes might also be a response to a longer life span of the apothecia. In this concern they could serve as an UV-protection of the apothecia in the dry state, in which long processes may completely cover the disc. In some cases, closely related species differ in the length of the glassy processes. For instance, *O. subaristata* has longer processes and occurs in more thermophilous areas including the Mediterranean belt, in contrast to *O. aristata* which is absent in regions of such a high insolation. Similarly, *O. vinosa* is generally devoid of glassy processes, but a montane, mainly orosubmediterranean variant is characterized by such processes that form distinct teeth, perhaps as a result of cold temperature and short summers in the mountains and, therefore, a longer life span of single apothecia which are exposed to higher amounts of UV. On the other hand, many species of *Orbilia* that occur in subtropical desertic areas are devoid of glassy processes, although they are subjected to extremely high amounts of radiation in combination with a life span of single apothecia of probably several years.

Medullary excipulum

The medullary excipulum fills the space between hymenium and ectal excipulum of an apothecium. It develops from the 'carpocentre' of the apothecial initial (see p. 37 ff.). In *Orbiliomycetes* its thickness in mature apothecia varies from about 10 to 50, sometimes 100 µm. If the apothecia are stalked, the medullary excipulum may more or less extend down into the stalk. A separate subhymenial layer is rarely recognizable. In contrast to the ectal excipulum, the tissue of the medullary excipulum consists of a network of hyphae (textura intricata) among which inflated, more or less globose cells of varying abundance are interspersed in most species of *Orbilia*, being often aggregated in chains (Fig. 81: a–b). Hyphae and inflated cells form a texture varying in density between loosely interwoven with varying amounts of intercellular space and densely packed as in the ectal excipulum. The intercellular space is usually filled with water, but in a few species of *Hyalorbilia* and *Orbilia*, and in *Lilapila* and *Liladisca*, it is gelatinized (see p. 98).

The inflated cells vary in size among the species. Mostly they measure around *6–12 × 5–9 µm, but also sizes of *(3–)4–7 × 4–6 or up to (8–)11–20(–30) × 6–15(–20) µm occur. If the inflated cells are very abundant, the tissue takes the appearance of a t. globulosa (or t. angularis), and if the medullary excipulum is rather thick, the inflated cells may be crowded either below the subhymenium or close to the ectal excipulum. In both cases the medullary excipulum appears to be two-layered when viewed in median section. If the lower layer contains the inflated cells, the boundary against the ectal excipulum becomes rather indistinct.

A thin (~5–15 µm), more or less distinct layer of loose or dense, parallel hyphae (textura porrecta) is often found at the border between ectal and medullary excipulum at the flanks of various *Orbilia* species (Fig. 81: a). This layer ends up in the marginal growth zone of the apothecium from which the two adjacent tissues emerge by dichotomous branching of the hyphae: the ectal tissue on the outer (lower) side, and the medullary tissue on the inner (upper) side of the apothecium. This delimiting layer is considered to be a part of the medullary excipulum, because hyphal diameters and their sometimes loose texture correspond to the main part of the medullary excipulum.

The inflated, chain-like cells belong to the vegetative (haplontic) hyphal system and might serve in storing water. However, our tests on desiccation sensitivity indicate that these inflated cells exhibit almost the highest tolerance, which is only sometimes overtopped by ectal excipular cells or ascospores. In *Lilapila*, for instance, the ascogenous hyphae are quite easy to follow in the upper medullary excipulum, but did here not emerge from these cells. In *O. xanthostigma* they contain in the living state the same yellow VBs as the paraphyses (Fig. 81: b), while in most species they are without visible cytoplasmic inclusions. Bellemère (1968: 547) referred to these inflated cells as 'very voluminous cells 10 µm diam.', showing the cytoplasm strongly reduced (vacuolated), and the wall stained by Methyl green.

The hyphoid elements between the inflated cells seem to represent a mixture of vegetative and ascogenous hyphae. In *Orbilia* the ascogenous hyphae can hardly be recognized by morphology due to the absence of croziers, and also in *Hyalorbilia* with consistently present croziers they can usually be traced down only a short distance, while the paraphyses clearly emerge from inflated cells of the medullary excipulum.

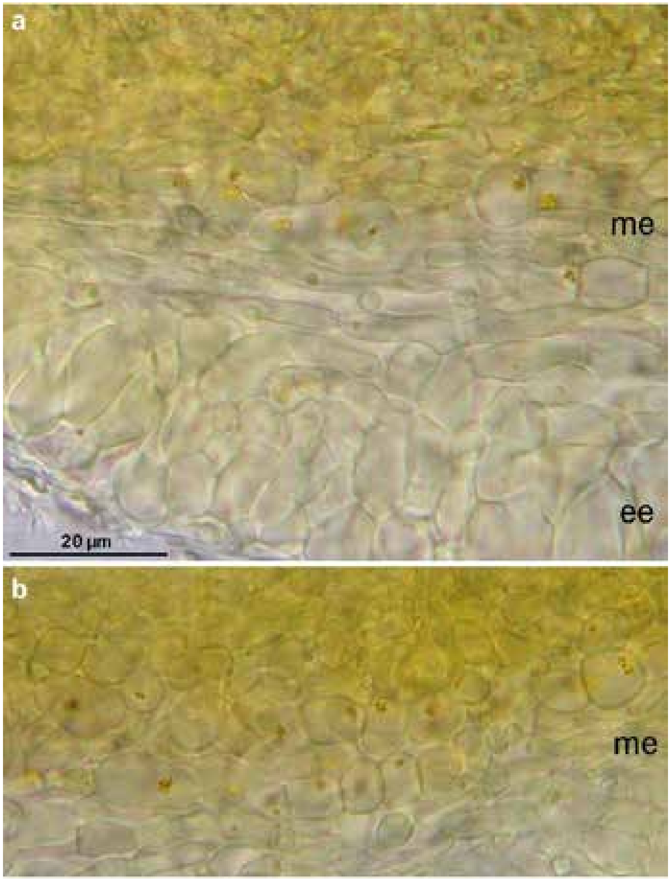

Figure 81: Medullary excipulum in *O. xanthostigma* (H.B. 7848), **a**. parallel hyphae near flanks; **b**. chains of inflated cells containing yellow LBs. ee = ectal excipulum, me = medullary excipulum.

There is some controversy in the terminology of the two excipular layers. In concordance with Durand (1901: 488, pl. 32 fig. 16, *Orbilia vinosa*) the complete tissue below the hymenium, except for a poorly developed subhymenium (as 'hypothecium') is named 'excipulum' in the present study. Durand distinguished between an outer layer of isodiametric cells, and a very sharply delimited inner layer of 'fine, closely interwoven hyphae', which corresponds to the medullary excipulum as here applied. Spooner (1987, *O. flexispora*) used the term 'medullary excipulum' only for the thin delimiting layer of t. porrecta, whereas the adjacent thicker layer above he termed 'subhymenium'. Nannfeldt (1932) used the term 'hypothecium' for the complete tissue between hymenium and 'excipulum' of globose or prismatic cells. We here use subhymenium only if there is a thin layer below the hymenium which clearly deviates in cell size or pigmentation from the main part of the medullary excipulum.

In those desiccation-sensitive *Orbilia* species with large isodiametric ectal excipular cells, these occupy the major part of the excipulum, and only a very thin layer of much smaller cells is to be found below the hymenium. The large-celled layer is sometimes assigned by authors to the medullary excipulum by restricting the ectal excipulum to the smaller cortical cells. This view was applied even to desiccation-tolerant species with rather small excipular cells, e. g., in *O. junci* by Kohlmeyer et al. (1998). We have usually not accepted this view, except for European species of section *Helicoon*, in which it seemed clear that the medullary excipulum attains a high central thickness by including many of the large globose cells. However, the boundary between ectal and medullary excipulum is often hard to see in the basal part of the apothecium.

Anchoring hyphae

The hyphae that emerge from the cortical excipular cells, mainly near the base of the apothecium (Fig. 82: e) but also at the flanks (here especially in *Hyalorbilia*, Fig. 82: a), attach the apothecium to the substrate and supply it with water and nutrients. Some of these hyphae might belong to the mycelium that gave rise to the initial stage of the apothecium, while the majority grew out of the excipulum at a later stage of apothecial development.

The anchoring hyphae have a diameter of about (1.5–)2–3(–4) µm in most groups of *Orbiliomycetes*. At the place where they emerge from the excipulum they may be thicker and sometimes tend to be moniliform or even form a paraplectenchymatous layer. A few species of *Orbilia* deviate in having wider anchoring hyphae (~3–6 µm), for instance, *O. auricolor*, *O. menageshae*, and *O. denticulata*. In contrast, in *Hyalorbilia* the hyphae are often ~3–6 µm wide (Fig. 82: a–c), sometimes up to 10 µm. Also *Lilapila* has comparatively wide anchoring hyphae [3.5–5.5(–6.5) µm], whilst the widest hyphae occur in *Lecophagus* [(5–)6–13(–17) µm].

Anchoring hyphae of *Orbiliomycetes* are generally hyaline and smooth. Only in *Lilapila* a rough thin layer of exudate was observed on the their walls. The cell wall is usually thin (†0.1–0.3 µm), but in some species it is sometimes or mostly thickened (†0.4–1 µm, in *Lilapila* up to †1–2 µm), particularly in those species with a gelatinized ectal excipulum.

The abundance of anchoring hyphae is sometimes typical of a species, but it usually varies considerably. Normally the hyphae are restricted to the base of the apothecium. Here they may occur rather sparsely, or they form a thin or thick (up to 100 µm) layer of loose or dense textura intricata (Fig. 82: e), which may laterally run out in more or less distinct hyphal strands. Sometimes, the intercellular space between the densely intermingled hyphae tends to be gelatinized. In quite a few desiccation-tolerant taxa the anchoring hyphae densely cover the flanks of the ectal excipulum by a thin layer of t. porrecta immersed in some gel. This layer may extend up to the margin, or even somewhat protrude beyond it, and then provokes a rough or finely crenulate, whitish appearance of the margin. In *Hyalorbilia* the anchoring hyphae are often rather long and straight and project more or less vertically from the excipulum by affixing the receptacle to the substrate.

If the anchoring hyphae occur abundantly, they can be recognized macroscopically around the apothecial base, especially in the dry state, as a white hyphal mat which may then be termed 'subiculum'. A conspicuous subiculum was ± inconsistently present in species with large, mainly desiccation-sensitive apothecia belonging to *Hyalorbilia* (e. g., *H. inflatula H. andina*, *H. japonica*, *H. arcuata*), *Orbilia* sections *Orbilia* (e. g., *O. dryadum*, *O. gaillardii*) and *Arthrobotrys* (e. g., *O. auricolor*, *O. neglecta*, *O. rectispora*), but also in some desiccation-tolerant species of sections *Aurantiorubrae* (*O. aethiopica*) and *Habrostictis* (*O. carpoboloides*). A certain macroscopic similarity between *H. inflatula* and *O. auricolor*, including their subiculum, led in the past to confusion of the two species.

Septation of anchoring hyphae is usually sparse, but in *Hyalorbilia* and *Lecophagus* a trend to more densely septate hyphae in relation to hyphal width can be noted. Living anchoring hyphae are usually without visible cytoplasmic

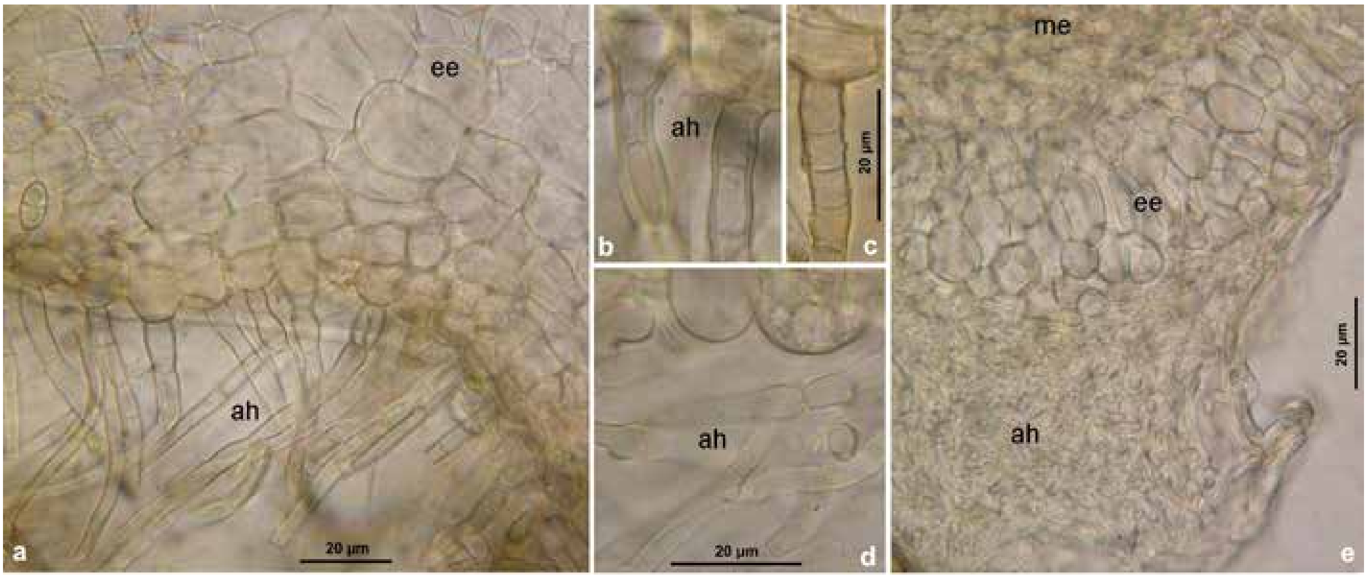

Figure 82: Anchoring hyphae emerging from cortical cells of the ectal excipulum. — **a**. *Hyalorbilia fagi* (H.B. 7934); **b**. *H.* cf. *japonica* (H.B. 8725b); **c**. *H. ulicicola* (H.B. 8357); **d**. *Orbilia anigozanthi* (H.B. 8831e); **e**. *O. eucalypti* (H.B. 7968). Living state except for **b** (in KOH); me = medullary excipulum, ee = ectal excipulum, ah = anchoring hyphae.

bodies. Remarkable inclusions (SCBs) occur only in a few cases (*Lecophagus*, *Hyalorbilia ulicicola*).

Cytoplasmic inclusions of the living cells

Within *Orbiliomycetes* a number of different cell contents can be seen under the LM in the living state in all types of cells and tissues of both anamorphs and teleomorphs. Although these cytological characters are usually transient, i.e., visible only in the living cytoplasm, they provide valuable and quite consistent features for the recognition of species or higher taxonomic entities. Because their visibility is confined to living cells, they have been overlooked by herbarium taxonomists and are, therefore, almost completely unreported in the literature. The most important organelle, the spore body (SB) inside the ascospores, is treated after the paragraph on ascospores, because its attachment to the spore wall is thematically interrelated to ascospore shape and polarity (see p. 69 ff.).

Lipid bodies (LBs). LBs are globose, strongly refractive, hyaline or pale to bright yellow-orange droplets with a diameter of about 0.1–4 µm or more. They are formed within the cytoplasm and are always to be found outside the vacuoles (Baral 1992: 357, for further literature see there). In the *Orbiliomycetes* they occur scattered and predominantly few in number and small in size in all types of cells, including ascospores and conidia. Examples of comparatively high lipid contents are shown in Figs 83–85.

LBs are very clearly visible when living cells are studied in a water mount. They are insoluble in 2–20 % KOH or 30–60 % H_2SO_4, even when heating the slide. Under vital staining with CRB, LBs remain unstained, in contrast to VBs which stain blue to greenish or purplish. Yet, LBs turn reddish when adding 0.5 % KOH to a CRB-mount (Baral l.c.), or when adding lactic acid or H_2SO_4 to either CRB or Réactif de Bailenger (Fig. 85: c). LBs are usually more or less invisible in dead herbarium material when mounted in media such as H_2O, MLZ, or CB_L, due to the masking effect of the dead cytoplasm around. They are, however, clearly visible when mounting dead elements in KOH. Although we recommend to mount dead herbarium material first in water in order to be able to search for living elements, or to see the natural colour of exudate, we later use to add KOH for swelling collapsed cells and for enhancing visibility of LBs.

Due to the prevailing study of herbarium material in all groups of fungi including lichens, the taxonomic value of LBs, particularly in ascospores and conidia, has very often been overlooked. The main reason for this lies in the fact that LBs tend to fuse in herbarium material, where they finally show a very irregular and variable pattern, but also because of the masking effect of the currently applied mounting media (MLZ, CB_L).

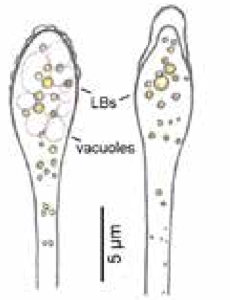

Figure 83: Yellow LBs in the living cytoplasm outside of inconspicuous hyaline vacuoles in paraphyses of *O. xanthoguttulata*.

LBs in asci and ascospores. Within the *Orbiliomycetes*, LBs in asci and ascospores are often very sparse and minute, or even absent. If present, they are formed at a rather late development stage when the asci or spores have almost attained their final size. Nevertheless, LBs in spores are present prior to the formation of spore bodies.

The absence of LBs in young ascospores is a frequent but not general feature of the *Ascomycota*. In certain groups of *Helotiales* and *Pezizales* the young asci are multiguttulate: they contain numerous small LBs around the fusion nucleus in the upper part of the ascus. After meiosis the usually eight spore nuclei are dispersed within this guttulate area. During spore wall formation, the double membrane between which the wall is later formed encloses besides the nucleus a certain amount of plasma that contains LBs. This peculiarity of a multiguttulate cytoplasm of young asci is only to be found in some of those species of *Helotiales* and *Pezizales*, in which the mature spores possess a high lipid content (example: *Pezicula*, Baral 1992: figs 42–43).

Multiguttulate asci have never been observed in *Orbiliomycetes*. Asci during and prior to meiosis are more or less devoid of LBs, also during spore formation the ascoplasm usually contains

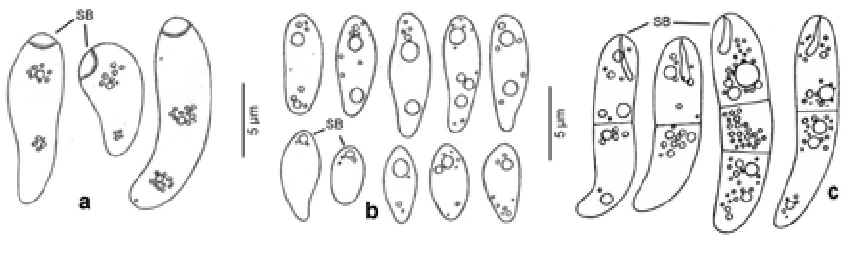

Figure 84: Ascospores containing globose, small to large LBs (living state, SB = spore body). — **a**. *Orbilia ocellata* (lipid content 1–2); **b**. *O. eucalypti* (lipid content 1–3); **c**. *O. septispora* (lipid content 2–4).

only some scattered small LBs. In some species of *Hyalorbilia*, however, a group of LBs 0.3–1.5 µm diam. occurs more or less regularly at the base of mature living asci (*H. berberidis*, Pl. 112: 5b, *H. fomentarii*, Pl. 110: 2b, also inconsistently seen in *H. juliae*, Pl. 106: 4b and *H. tortuosa*, Pl. 89: 1b).

Number, size, and arrangement of LBs within the living mature ascospores serve as a very important, albeit often neglected feature at the species or higher level in virtually all groups of fungi (Baral 1992: 359f.). Closely related species, or higher taxonomic entities may strongly differ in this regard. In order to have a measure for the relative lipid content of spores (in relation to spore volume), a scale ranging from 0 (no LBs visible) to 5 (maximum possible lipid content, excluding nuclear region) was introduced (Baral 1992: 363). This scale was adopted by various authors and was differently called. We here adopt the version OCI = oil content index introduced by Declercq in an unpublished key on *Hymenoscyphus* (2004).

Ascospores of *Orbiliomycetes* are characterized by a comparatively low lipid content that ranges from 0 to usually 0.5–1, rarely 2–4. Lipid body size is mostly ~0.1–0.5 µm, rarely 0.5–1.5 µm. Their colour is always hyaline. In contrast to SBs, LBs usually do not have a consistent arrangement within spores of this group of fungi. Therefore, and because of their rather uniform size and shape, the taxonomic value of LBs in ascospores of *Orbiliomycetes* is quite low. In those species with a higher lipid content, however, the LBs are usually arranged in two groups, or near the septa if spores are septate (Fig. 84). Examples of such higher lipid contents are known in series *Lentiformes* (*O. patellarioides*, *O. ocellata*, *O. cucumispora*), *Cercidicola*, *Orbilia* (*O. eucalypti*, *O. fissilis*, *O. guyanensis*), and *Serpentinae* (*O. septispora*), but such high lipid contents are not species-specific, instead, they occur sometimes only as an exception, possibly due to some external influence (e.g., in *O. eucalypti*, Fig. 84: b, see also p. 1357).

As a further complication, the lipid content in ascospores of *Orbiliomycetes* was found to increase either more or less strongly (Fig. 70: d–e) during ageing or not at all (Fig. 70a–c). This phenomenon, which was mainly observed when studying apothecia attached inside Petri dishes, is so far not understood. It is in contrast to the general situation in ascomycetes, in which LBs in ascospores are gradually disintegrated for the synthesis of cytoplasm and wall material during the process of germination. The increase in lipid happens simultaneously with the decrease of the spore body. Possibly, the absence of SBs means that such spores follow another strategy of substrate colonization than forcibly ejected spores containing SBs. Another surprising and not understood effect is that the number of small LBs in ascospores of *Orbilia* often increased rather strikingly if a preparation was kept moist for some hours, or rehydrated after being dried down.

In a few species (e.g., *O. quaestiformis*), it was repeatedly observed that submature spores contain 1–2 LBs of 0.3–1 µm diam. prior to spore body formation, which gradually disappear when SBs develop. Again, this is difficult to explain, because LBs in spores of other classes of *Ascomycota* generally increase in size until the spores attain full maturity prior to ejection.

LBs in vegetative cells. In the vegetative cells of paraphyses, ectal and medullary excipulum, and anchoring hyphae, LBs usually occur in low amounts near the lateral walls and especially near the septa. In many species LBs have a yellow to orange pigmentation due to the presence of carotenoids inside the droplets. In *O. xanthoguttulata* yellow LBs are found in a rather high abundance especially in the widened apical part of the paraphyses (Fig. 83).

LBs in the basal ectal excipulum may sometimes attain a size of 1–2(–4) µm (Fig. 85: a). However, such large LBs were repeatedly observed as being very inconsistent within a species or even a population of *Orbiliomycetes*. They were abundant in one apothecium, but in total absent in another (living state, full maturity). Therefore, the taxonomic value of LBs in the ectal excipulum is obviously very low.

In anchoring hyphae LBs have not been seen in remarkable quantities. Numerous small LBs have only been observed in the wide hyphae of *Lecophagus*, and especially in the assimilative hyphae also large LBs were among them (Pl. 45: 1i–j).

Refractive vacuolar bodies (VBs). Vacuoles are usually non-refractive and, therefore, more or less inconspicuous when studying living cells under the LM (oil immersion, bright field). They are perceptible as empty, transparent, small to large, globose or elongate areas within the likewise very slightly refractive cytoplasm (see, e.g., Figs 83, 86: e). A special type of vacuoles is characterized by a low to high refractivity and was termed 'refractive vacuolar bodies' (VBs) by Baral (1992: 363). Like non-refractive vacuoles, VBs usually occupy a major part of the internal lumen of a cell. The refractive substance occurs in two patterns inside vacuoles, either (1) homogeneously distributed (Fig. 86: a–c, g–h), or (2) as ± small, globose guttules (Fig. 86: d–f, i–j, l–m). In the homogeneous type the substance apparently occurs as a colloidal solution in the vacuolar water (similar as in spore bodies), whereas in the guttular type it forms individual droplets within the otherwise non-refractive vacuolar water. If

Living state (**h**: VBs stained blue-violet in CRB), except for **k** (in KOH) where VBs irreversibly disappeared. — **a**. *Orbilia sarraziniana*, **b**. *O. rubrovacuolata*, **c**. *Hyalorbilia ulicicola*, **d**. *Amphosoma atroolivaceum*, **e**. *Lilapila oculisporella,* **f**. *O. eucalypti* (H.B. 7825), **g**. *O. dryadum* (25.IX.2010), **h**. *O. sarraziniana* (H.B. 8225), **i**. *O. xanthostigma* (H.B. 7852), **j–k**. *O. xanthostigma* (H.B. 9723), **l–m**. *A. resinicola* (H.B. 9136d, 9162e).

these droplets do not completely fill the vacuole, they perform distinct Brownian motion by trembling or moving across the vacuole. The distinction between the two different types of VBs is not always clear, for instance, in Fig. 86: f each small droplet might represent a single vacuole because no Brownian motion was noted.

VBs occur mainly in the long terminal cell but also in the shorter lower cells of the paraphyses, and in the marginal cortical cells of the ectal excipulum. VBs are consistently absent in all species with a high desiccation tolerance (*Lilapila*, *Lecophagus*, *Orbilia* sections *Lentiformes*, *Habrostictis*, *Aurantiorubrae*, *Hemiorbilia*, *Ovoideae*, and *Orbilia* series *Microsomates*).

VBs of the homogeneous type are of low to medium, but sometimes also high refractivity, and were quite frequently observed in species which are sensitive or only slightly tolerant to desiccation, such as *Hyalorbilia*, *Pseudorbilia*, *Orbilia* sections *Helicoon* and *Arthrobotrys*, and series *Orbilia*, but in many species of these taxa they were only present in some of the studied populations. VBs of the guttular type are very diagnostic for the desiccation-tolerant genus *Amphosoma*. In the four recognized species the VBs occur as small (0.2–2 µm), consistently globose, strongly refractive droplets in low to high abundance, thereby often producing a multiguttulate pattern in paraphyses and cortical excipular cells (Fig. 86: d, l–m). These droplets occur inside vacuoles in which they sometimes perform vigorous (*A. macrosporum*) or only slight Brownian motion. Similar VBs were occasionally observed in *Lilapila* in the medullary excipulum, paraphyses (Fig. 86: e), and asci, where they occur scattered in the vacuoles by showing more or less distinct Brownian motion.

Only in a few species of *Orbiliomycetes* the VBs contain a conspicuous hydrophilous pigment. In this case, the pigment is usually homogeneously distributed in the vacuole. In *O. rubrovacuolata* the very low-refractive vacuoles have a rose-red colour (Fig. 86: b). VBs in *Hyalorbilia* are often very faintly or sometimes distinctly chlorinaceous-ochraceous (Fig. 86: c), and those in *O. atlantis* and *O. xanthostigma* have a yellow-chlorinaceous colour.

In a few cases, VBs of the guttular type develop from those of the homogeneous type. In populations of *Orbilia xanthostigma* the young paraphyses contain many small, globose, medium refractive, yellow-chlorinaceous vacuoles of the homogeneous type. With increasing maturity these fuse to form one or a few larger low-refractive, homogeneously yellow vacuoles. At maturity the pigmented substance in these vacuoles precipitates to form bright golden groups of droplets showing Brownian motion. These aggregations of yellow granules also occur in large vacuoles of the inflated ectal and medullary excipular cells (Figs 86: i–j; 98: e), at a time when the vacuoles of paraphyses may still be homogeneously pigmented. In *Hyalorbilia* spp., *O. rubrovacuolata*, and *O. atlantis*, however, such precipitation of vacuolar pigments was never observed.

The vacuolar nature of the golden yellow droplets in *O. xanthostigma* is easily demonstrated by their irregular movement inside large ectal excipular cells during about one minute across large vacuoles, which have a diameter of ca. 5–10 µm.

When adding KOH to the water mount, the granular droplets instantly disappear while the yellow pigment is stable and gets homogeneously dispersed (Fig. 86: j–k). However, very similar-looking yellow, minute, KOH-resistant LBs occur outside the vacuoles, particularly in the lower half of the paraphyses and in the subhymenium. In the lower paraphysis cells both yellow vacuoles and yellow LBs occur, the vacuoles in the centre and the LBs more laterally and at the septa. Interestingly, both types of pigments stain blue-green in IKI.

Besides *Orbiliomycetes*, VBs occur in many genera of *Helotiales* (here also in the hairs), and in some taxa of *Pezizales*. In the *Helotiales* the presence vs. absence of VBs in paraphyses and excipular cells, and also their shape and pigmentation provide a valuable vital character at the genus or species level (Baral 1992: figs 27–33). VBs with a yellow or rarely orange pigmentation occur, e.g., in some species of *Calycellina*, *Hymenoscyphus*, *Lachnum*, *Mollisia*, or *Trochila*. Exceptionally, VBs occur in ascospores of *Helotiales* (Fig. 73).

Recognition of vacuoles and VBs. Generally, vacuoles can be identified by staining with basic dyes. These are added to a water mount and require some patience, because entry of the dye into intact vacuoles may take some minutes, but can be accelerated by adding very diluted alkali (NH_4OH or KOH). Non-refractive vacuoles stain in CRB (or TB) either homogeneously violet (e.g., the large vacuole of mature asci), or dark blue-violet globose precipitations (MCs = metachromatic bodies) are mostly induced. Low- to medium refractive VBs yield a homogeneously blue-violet stain (Fig. 86: h), and high-refractive VBs stain bright blue to turquoise. Neutral red stains VBs light orange-red. The cytoplasm outside the vacuoles remains unstained as long as the cells are viable. Based on the different colours between non-refractive and refractive vacuoles, we assume that the blue to turquoise stain of VBs is induced by a metachromatic effect of the refractive substance rather than a deviating pH of the vacuole sap (see Baral 1992: 363f.).

When 1–5% KOH, NH_4OH, or other toxic mountants such as lactophenol, chloral hydrate, or acids (e.g., formic, acetic or lactic acid) are added to the water mount, the VBs disappear promptly and irreversibly (Figs 73, 86: j–k). The same happens if the cells die by mechanical influence or desiccation, or when heating the slide. Also the vacuolar pigment may promptly disappear thereby or become diffuse (see Huhtinen 1990a: 71, *Hamatocanthoscypha uncipila*). VBs of *Orbiliomycetes* do not give any colour reaction in KOH (in the *Helotiales* a transient yellow reaction is known for many species of *Mollisia*, Baral 1992: 373). Oxidative colour changes of VBs which are typical of many *Helotiales* have also been noted in section *Helicoon* (see p. 104, Colours of the dead cytoplasm).

The chemical origin of VB refractivity is unknown. Perhaps phenolic compounds play a role (Baral 1992: 364–5), which lose their double bindings when the pH of the vacuoles is raised. On the other hand, the two types of VBs lose their refractivity also when adding reagents which lower the pH (contrary to a statement by Baral l.c.), i.e., they optically disappear as soon as the tonoplast is damaged.

KOH-sensitive (‘soluble’) cytoplasmic bodies (SCBs). Among the cytoplasmic inclusions that can be seen under the light microscope, a further category of transient structures provides a character of rather high taxonomic importance in the *Orbiliomycetes*. These organelles occur in two different morphological types: (1) globose SCBs (Fig. 87: a–b, l–n), and (2) variously shaped, angular to rod- or ring-shaped SCBs (called ‘crystalloid’ in the present study, Figs 87: c–n; 88: a–i). For both the term ‘KOH-soluble cytoplasmic bodies’ (SCBs) was introduced by Baral (1992: 368). Yet, the first type of SCBs never shows any kind of pigmentation, and clear cases of transitional types have not been observed, which suggests a different nature of the two types of inclusions. The refractivity and contrast of both types of organelles may vary between low and high.

Like VBs, SCBs promptly and irreversibly lose their refractivity when treated by 1–5% KOH (Tab. 8). Other toxic agents such as strong acids, lactophenol, or chloral hydrate likewise make SCBs irreversibly disappear. SCBs are never stained by CRB, even if slightly alkalinized. SCBs disappear also when cells die in water mounts. Solubility is probably an incorrect term for the disappearance of SCBs. More probable is that strong deviations from the normal pH induce irreversible chemical changes that involve the loss of refractivity, whereby the organelle gets invisible although the altered chemical compounds are still there. Globose SCBs may be stained pale reddish in CR_{SDS} (Fig. 87: b). SCBs are only observable in living cells. Dead cells often contain irregular bodies when observed, e.g., in KOH. These bodies originate from distorted lipid bodies and unexperienced workers may easily confuse them with SCBs.

Crystalloid SCBs are sometimes seen attached to the tonoplast of vacuoles (Fig. 88: h–i). This peculiarity and the impossibility to stain SCBs with CRB indicate that SCBs are extravacuolar structures. It may well be that crystalloid SCBs are always tightly associated with vacuoles and, when ring-shaped, they might encompass a vacuole in their centre. Globose SCBs may also occur in the intervacuolar space of highly vacuolated cells.

SCBs may occur in all cell types of the apothecium except for asci and ascospores, but are particularly found in the ectal excipulum and paraphyses. Both globose and crystalloid SCBs often occur in a single cell, usually one globose and 1–2 crystalloid SCBs, either side by side (Fig. 87: n), or remote from each other, thereby globose SCBs occur preferably near the tip of the terminal or cortical cells at the apothecial periphery (Fig. 87: a–b, l–m). In ectal excipular cells SCBs occur particularly at the apothecial flanks and margin, where they are usually larger than in the paraphyses, but sometimes also near the base. If the paraphyses are strongly inflated at the apex, they usually contain here larger SCBs than in the lower cells. SCBs are exceptionally found in the medullary excipulum, e.g., in *Lilapila* Pls 30: 1h–i; 32: 4c–g), or in the anchoring hyphae (in *Hyalorbilia ulicicola*, Pl. 60: 2h, 3h).

Globose SCBs vary in diameter among the species from (0.3–)0.8–1.5 up to 2–3(–5) µm and are always hyaline. Large SCBs of this type inside uninflated parts of the paraphyses sometimes take on an ellipsoid shape because of the limited space between the lateral walls (Fig. 87: l). Slow migration of globose SCBs across the cytoplasm during a few minutes can sometimes be observed. This was mainly seen in excipular cells in which the SCBs migrated from one end of the cell to the other similar as the migration of VBs inside vacuoles. Globose SCBs are often of a rather low refractivity, and in some species difficult to discern in a water mount. Although our test with various dyes such as CRB and IKI failed to stain globose SCBs, their contrast can strongly be enhanced when stained with IKI.

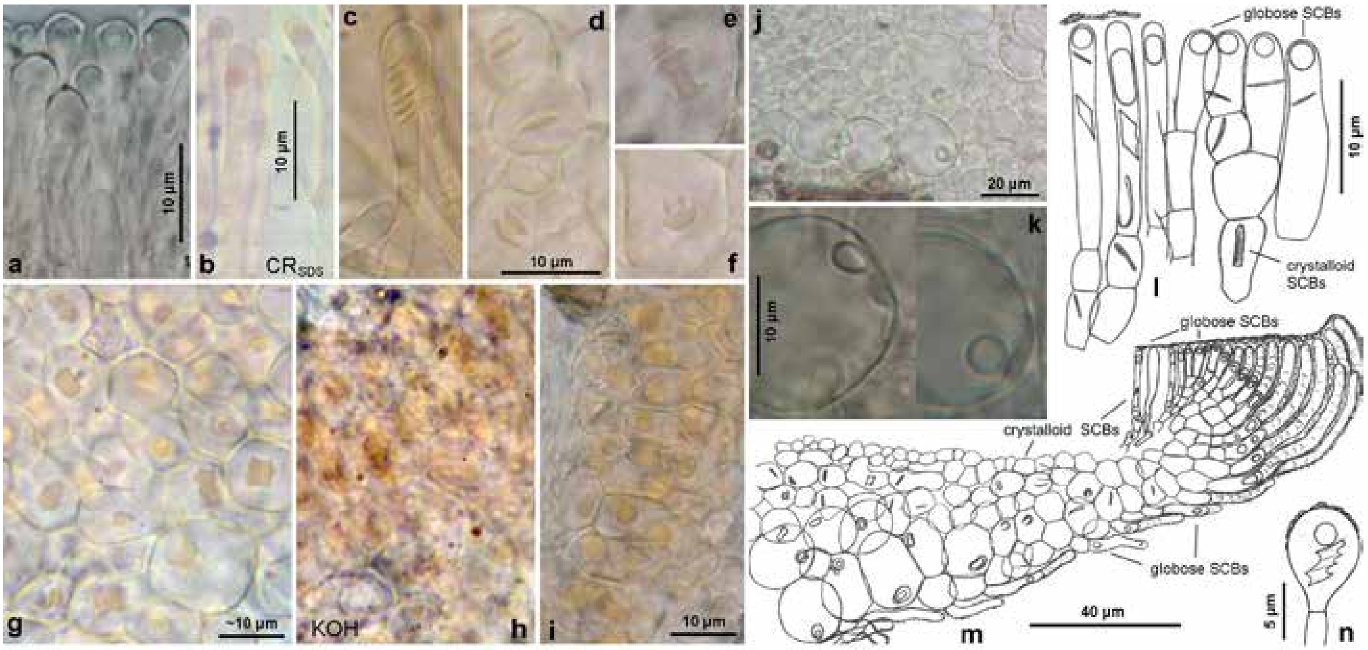

Figure 87: **a–b**. Globose SCBs in paraphyses (**a**. *O. vitalbae*, H.B. 9681, phot. R. Tena; **b**. *O. aprilis*, stained by CR_{SDS}, 15.XII.2011, phot. I. Wagner); **c**. crystalloid SCBs in paraphysis of *O.* aff. *myriella* (H.B. 8997c); **d–f**. crystalloid SCBs in excipular cells of *O. helicovinosa* (H.B. 9050b); **g–i**. crystalloid SCBs in cells of ectal excipulum at flanks (**g–h**: *O. corculispora* H.B. 7317a; **i**: *O. cercidicola*, H.B. 9151e; **h**: in KOH invisible); **j–k**: crystalloid (ring-shaped) SCBs in ectal excipulum (*O. crenatomarginata*, 27.VIII.2007, phot. P. Perz); **l–m**: crystalloid and globose SCBs in paraphyses and ectal excipulum (*O. crenatomarginata*); **n**: globose and crystalloid SCBs in terminal cell of paraphysis (*O. serpentina*).

SCBs of the globose type were observed in a majority of those species of *Orbilia* studied in the living state (84 %) and also sometimes in *Lilapila*, but could so far not be detected with certainty in *Lecophagus*, *Pseudorbilia*, and *Amphosoma*, and only exceptionally in *Hyalorbilia*. In the *Helotiales*, globose SCBs occur in several genera, being typical, e. g., of *Pyrenopeziza* (Baral 1992: 368, fig. 30).

SCBs of the crystalloid type often show a ring-, horseshoe- or keyhole-like shape, but they are also frequently rod-shaped or angular to spool-shaped, or only show an incomplete ring. Their size ranges from ~2–3 up to 5–10 µm in diam. In contrast to globose SCBs, migration of crystalloid SCBs has never been observed. Crystalloid SCBs are either hyaline or often pale to light yellowish-orange. Their pigment remains unaltered in alkali and acids.

The three-dimensional shape of crystalloid SCBs is not easy to resolve because it is impossible to turn single cells under the LM. The different aspects obviously depend on the direction of view. When viewing these bodies under an oblique angle, their spatial shape can best be resolved (Fig. 88: a, e). In top view they appear ring-like, and when viewed from the sides they look angular, reminiscent of a spool or reel with often jagged middle part (like a screw thread). The ring-like aspect varies from circular to irregularly keyhole-shaped (Fig. 88: b, g), but also incomplete rings occur or those with a strongly varying wall thickness, leading to sickle- or horseshoe-like shapes (Fig. 87: f; 88; a, b–c, f). In side view the bodies may form superimposed piles of rod-shaped structures (Fig. 87: c–e). Rings and keyholes or horseshoes on the one hand, and rod- to spool-shaped bodies on the other hand are thus mainly a matter of the viewing direction. Often one of the two types predominates in a section which suggests that the bodies tend to be oriented in one direction within an apothecium.

Like in globose SCBs, the chemical composition of crystalloid SCBs is unknown. Understanding the function of these bodies would be essential, particularly regarding the question why very closely related taxa differ in such a way that one of them has abolished formation of crystalloid SCBs. The reddish pigment suggests carotenoids, but this seems quite unlikely since IKI does not give any colour reaction to SCBs (see also p. 101–105). An osmotic test with a high-concentrated sugar solution in *Orbilia cercidicola* caused strong shrinkage of the living excipular cells but no perceptible size reduction of the crystalloid SCBs. The ontogeny of crystalloid SCBs in *Orbilia* appears to start from thin needle- or plate-like structures which are in close contact to the outer surface of the tonoplast of vacuoles.

Crystalloid SCBs occur in about 32 % of the species of *Orbilia*, and almost exclusively in desiccation-tolerant taxa. Among the desiccation-sensitive members of *Orbilia* only some species of series *Hyalinia* (*O. crenatomarginata*, *O. laevimarginata*, *O. crenatofalcata*, *O. scolecospora*) and *Xanthoguttulatae* (*O. nemaspora*, *O. crenatonemaspora*) are known to have crystalloid but always unpigmented SCBs. Very often the presence of these bodies helps in separating very closely related or otherwise similar taxa (Tab. 7). Further morphological or ecological characters are usually correlated with this feature and support the taxonomic value of crystalloid SCBs.

Although crystalloid SCBs are somewhat variable within a species regarding size, shape, and colour intensity, they must be attributed a high taxonomic value. Their remarkably consistent presence (or absence) was recorded in a lot of species, although the exceptional absence (or presence) was also sometimes noted. In only one species of *Hyalorbilia* (*H. ulicicola*) crystalloid SCBs could so far be observed, and in *Lilapila* similar ring-shaped SCBs were occasionally seen. *Lecophagus* is characterized by a special type of cubical bodies (see p. 94), whereas in *Pseudorbilia* and *Amphosoma* crystalloid SCBs never occurred. Also in *Orbilia* section *Lentiformes* they have never been observed, except for *O. cercidicola*, which has large, orange crystalloid SCBs, and which our phylogenetic analysis clearly assigns in

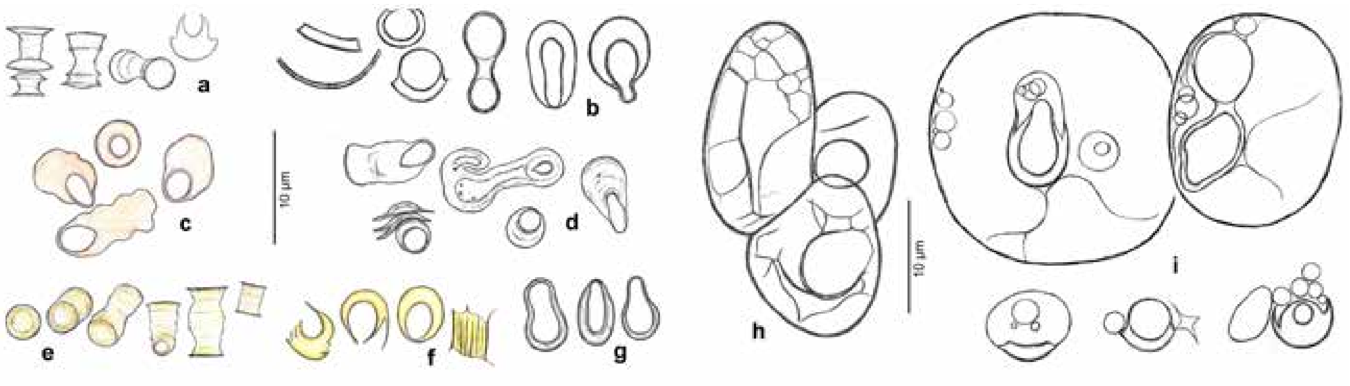

Figure 88: Different shapes of crystalloid SCBs in ectal excipular cells (cell wall only shown in **h–i**), partly seen from different viewing directions. — **a**. *O. helicovinosa*, **b**. *O. crenatomarginata*, **c**. *O. cercidicola*, **d**. *O. pleiohesperidea*, **e**. *O. pleiocoronohesperidea*, **f–g**. *O. carpoboloides*, **h**. *O. aurantiorubra*, **i**. *O. crenatomarginata*.

section *Lentiformes*. Because of this unexpected occurrence of crystalloid SCBs we place *O. cercidicola* in a series of its own.

Crystalloid SCBs resemble paracrystalline pyrenoids of algae, which likewise disappear optically in KOH and do not stain in CRB, according to our observation on an unidentified species of *Chlorophyta* associated, e.g., with *Orbilia aradi* (IVV: 25.VIII.2004, H.B. 7995). The oil bodies of liverworts (*Jungermanniidae*) are sometimes angular (e.g., in *Porella* or *Metzgeria*) and then resemble crystalloid SCBs. Contrary to SCBs of *Orbilia*, they generally do not disappear in unheated KOH, though they disappear when heating a water or KOH mount, apparently because they contain terpenoids.

Crystalloid SCBs have not been observed in any other order of *Ascomycota*. However, a similar type of SCBs usually occurs in the lanceolate paraphyses of species of *Brunnipila* and *Trichopeziza* (*Lachnaceae*, *Helotiales*): the centre of the long terminal cells typically contains unpigmented, rod-shaped or crystalloid SCBs of rather low refractivity (Baral 1992: 368, fig. 31, as 'crystalline SCBs'). Within the *Oomycota* an 'ooplast' occurs in the oospores of various genera. In *Wilsoniana bliti* (*Albuginaceae*, *Peronosporales*, Frey 2012: fig. 8–2) these ooplasts are ring-shaped with a strongly eccentric perforation, highly reminiscent of ring-shaped SCBs of *Orbilia*, apart from their larger size of ~17 µm.

Table 7. Examples of similar species differing in the SCBs.

Crystalloid SCBs present	Crystalloid SCBs absent
O. cercidicola	*O. cucumispora*
O. hesperidea	*O. montigena*
O. bicknellensis	*O. jacaensis*
O. serpentina	*O. maeandrina*
O. subvitalbae	*O. vitalbae*
O. subdelphinus	*O. delphinus*
O. nothoaprilis	*O. aprilis*

Cubical bodies. Strongly refractive bodies of a crystalloid, rectangular-isodiametric or sometimes almost globose shape are referred to as 'cubical bodies' here, which characterize the genus *Lecophagus* (Fig. 89: a–e). They might be related to Woronin bodies, but unlike those they occur more in the centre of the cell. Our tests showed that they do not take up basic dyes, although small vacuoles close to the SCBs stain deep blue (observed in *Lecophagus muscicola*). Like SCBs and WBs, also cubical bodies instantly disappear when KOH enters the cell. Abro & Dick (1990: fig. 1; Fig. 89: d) and Powell et al. (1990: figs 16, 21; Fig. 89: e) observed cubical bodies in their TEM micrographs. Obviously in error, Powell et al. identified them as large vacuoles that contain electron-dense material.

The cubical bodies in *Lecophagus* permit recognition of the genus even if only mycelial hyphae are available. These bodies also occur in the trapping organs, conidiophores, conidia,

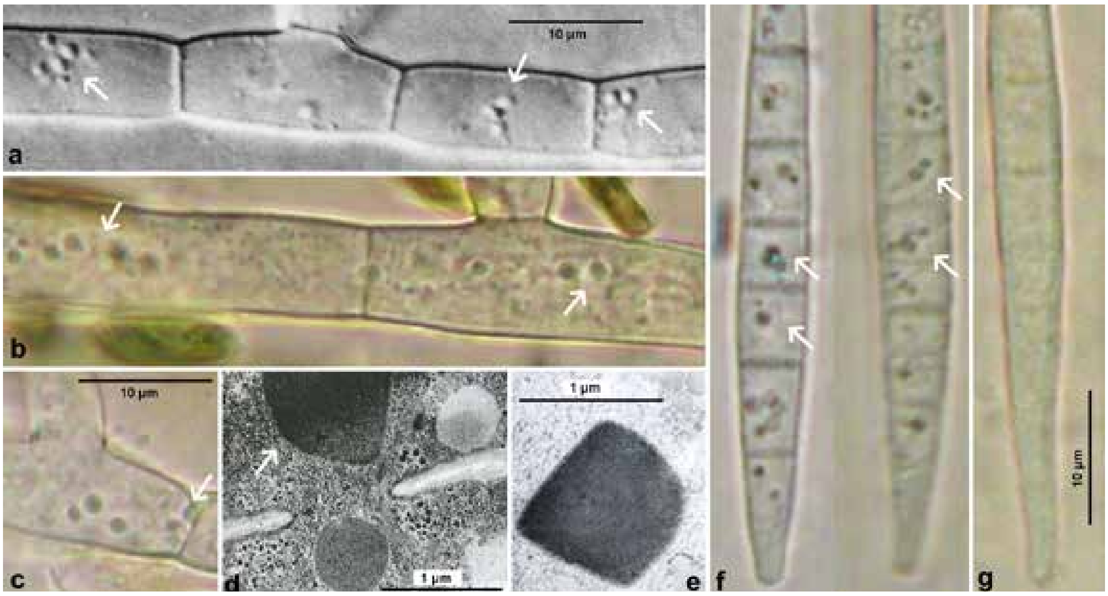

Figure 89: **a–e**. Cubical bodies in living mycelial hyphae of *Lecophagus* and conidia of *Hyalorbilia* as seen with the LM or TEM. — **a**. *L. navicularis* (from Tzean & Barron 1983: fig. 1); **b–c**. *L. muscicola* (H.B. 7771); **d–e**. *L. muscicola*, **d**. septum with WB (below) and cubical body (arrow; from Abro & Dick 1990: fig. 1, as *L. fasciculatus*), **e**. cubical body (from Powell et al. 1990: fig. 21, as *Zoophagus insidians*); **f**. conidia of *H. inflatula* (H.B. 9041a, 8173); **g**. id., in KOH, bodies disappeared (H.B. 8173).

and excipular cells. Similar bodies were observed in conidia of *Brachyphoris*, the anamorph of *Hyalorbilia* (Figs 9: a–b; 89: f–g), and also here the presence of these bodies aids identification of conidia as belonging to this genus. The bodies in *Hyalorbilia* are perhaps more globose than angular, and they were never seen in the anchoring hyphae or excipular cells, with a single exception of small ring-shaped SCBs in the centre of excipular cells in *H. fagi* (Pl. 92: 1d).

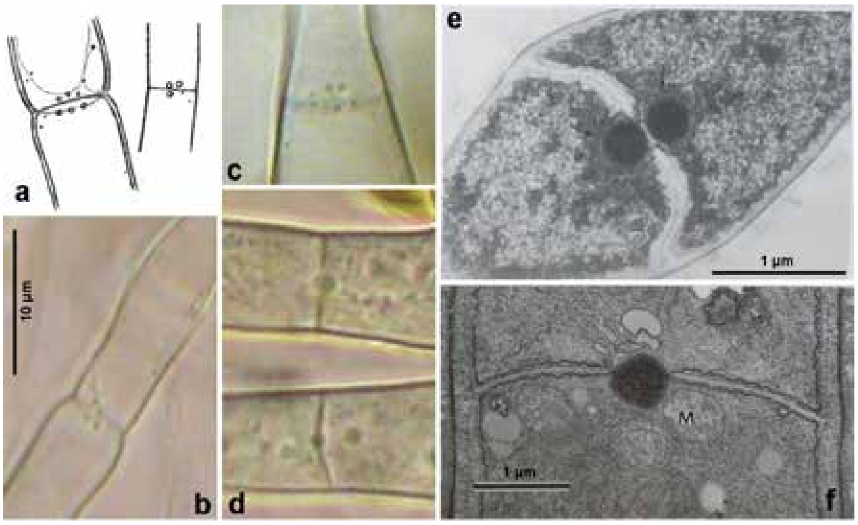

Figure 90: Woronin bodies at septa (**d–f**. while plugging the pore). — **a–c**. *O. alba* (H.B. 9051a), **a–b**. anchoring hyphae, **c**. stalk of adhesive knob; **d**. *Lecophagus muscicola* (H.B. 7771), mycelial hyphae; **e**. *Drechslerella brochopaga* (from Dowsett et al. 1977: fig. 18), mycelial hypha; f. *Lecophagus longisporus* (from Morikawa et al. 1993: fig. 10), adhesive peg.

Woronin bodies (WBs). WBs are minute, globose or crystalloid, membrane-bound structures in the cytoplasm close to the septa, and function in plugging the pore if one of the adjacent cells loses turgor (see Baral 1992: 368, also for further literature). WBs have mainly been reported in *Pezizales* and *Sordariales* (*Pezizomycotina*), but also *Neolectales* (*Taphrinomycotina*, see Landvik et al. 2003).

Under the LM, WBs are only seen in the living state, therefore, their presence usually escaped notice of those working with herbarium material. As with other sensitive organelles (SBs, VBs, SCBs), the substance which constitute WBs irreversibly loses its refractivity in KOH. This optical disappearance of WBs in alkali permits distinction from very similar looking LBs. Like LBs, WBs are found in the cytoplasm outside the vacuoles, and are not stained by vital stains.

WBs in *Orbiliomycetes* are often perceptible as very small (~0.1–0.2 µm), refractive, globose bodies that are situated very close to the septa, 1–2 on each side. They can be discerned especially in the paraphyses. In some taxa they are a bit larger, for example, in *Lecophagus* they attain ~0.3 µm diam. at the septa of anchoring hyphae. Exceptionally large WBs of 0.4–0.5(–0.8) µm diam. were observed in anchoring hyphae and adhesive knobs of *Orbilia alba* (Fig. 90: a–c). Drechsler (1937a, 1943b, 1947, 1952, 1954) frequently illustrated minute WBs at the septa of mycelial hyphae and often also conidiophores, usually two on each side, mainly in those predacious hyphomycetes that are today assigned to the *Orbiliomycetes*. However, he apparently never mentioned these bodies.

With the TEM, globose WBs were repeatedly observed at the septa of mycelial hyphae and trapping organs in *Orbilia* section *Arthrobotrys*: e. g., in *Drechslerella brochopaga* (Dowsett et al. 1977, Fig. 90: e), *D. dactyloides* (Heintz & Pramer 1972), *D. bembicodes* (Glockling & Dick 1994), *Dactylellina lysipaga* (Wimble & Young 1983), and '*D.*' *entomopaga* (Saikawa et al. 2010). Their size can be evaluated as (0.2–)0.3–0.4(–0.5) µm diam., in the latter species as 0.45–0.65 µm. WBs in *Lecophagus* show a size of 0.3–0.6 µm (*L. fasciculatus*, Abro & Dick 1990; *L. longisporus*, Morikawa et al. 1993, Fig. 90: f). Kumar et al. (2012: figs 14–17) figured WBs of 0.2–0.25(–0.35) µm diam. in cells of excipulum, paraphyses, and ascogenous hyphae in *O. tenuispora* (section *Helicoon*).

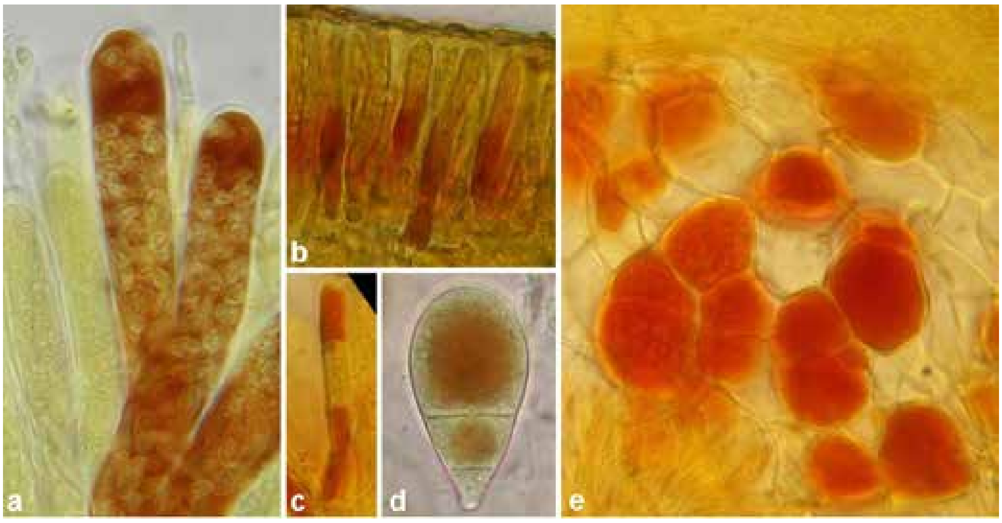

Figure 91: Glycogen in *Orbiliomycetes* stained red-brown in IKI (**e**. KOH+IKI). — **a**. mature dead asci of *Orbilia myriophanosoma* (H.B. 8865; immature asci on the left are unstained); **b–c**. mature dead asci of *Hyalorbilia polypori* (**b**. H.B. 6939a, **c**. H.B. 7965b), pars sporifera remaining unstained; **d**. living conidium of *O. elegans* (H.B. 6972a); **e**. ectal excipulum of *O. blumenaviensis*, some of the cells showing a strongly dextrinoid cytoplasm (H.B. 8029b).

Glycogen. Dextrinoid, more or less globose areas in the cytoplasm indicate the presence of glycogen depots. In many genera of the *Helotiales* they occur in ascospores with a low to medium lipid content (Baral 1992: figs 12–13), where they are usually surrounded by small LBs which form a hollow sphere around them. The reaction is light to deep red-brown and can be obtained in IKI as well as MLZ (with or without KOH-pretreatment). The dextrinoid reaction is generally attributed to the presence of glycogen as a storage carbohydrate, and

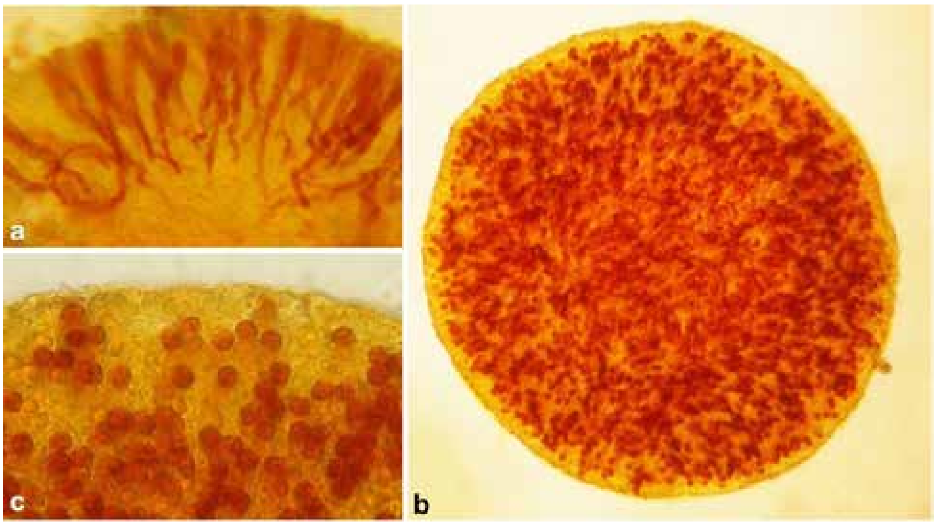

Figure 92: Asci in apothecia of *Orbilia* stained deep red-brown in IKI (KOH-pretrated) due to the presence of glycogen. — **a**. median section (*O. pleistoeuonymi*, H.B. 6494a); **b–c**. top view on apothecium (*O. sarraziniana*, H.B. 8721a).

can be observed in many classes of ascomycetes, particularly in the ascoplasm.

In the *Orbiliomycetes* such dextrinoid areas were observed in asci, ascospores, conidia, and excipular cells (Figs 91–92). Glycogen depots in ascospores were only seen in rather broad spores, e. g., in *O. lentiformis* they showed a diameter of 1–2 µm (Pl. 158: 1a). Similar dextrinoid areas occur occasionally in conidia, particularly in those species of section *Arthrobotrys* with swollen conidial cells. Such conidia contain quite large glycogen depots which attain a size of up to 5–15 µm, depending on conidial width (Fig. 91: d). Conidia without swollen cells may also sometimes contain such depots (*H. polypori*), whereas different types of branched conidia have so far never been seen to contain glycogen (see Tab. 9).

In virtually all species of *Orbiliomycetes* the whole ascoplasm stains pale to deep red-brown, while the sporoplasm remains unstained (Fig. 91: a–c). The reaction is usually strongest in mature asci, whereas young asci are non-reactive and those containing immature spores show often only a faint reaction. In living asci the reaction is less intense. Some mature, dead, unemptied asci may lack the reaction, and it seems quite obvious that these had full turgescence when still alive. Very probably, a short period of time prior to spore discharge the glycogen is degraded into osmotically active monomers which are the cause of turgor increase (see also p. 46–47, Four different states of asci).

In some species the reaction may be rather faint irrespective of ascus maturity. A pale yellowish-reddish reaction was noted in *Lilapila* and some species of sections *Aurantiorubrae* (*Orbilia kingsiana*, *O.* aff. *puyae*), *Ovoideae* (*O. cupularis*, *O. multimexicana*, *O. octosporoides*), and *Orbilia* (*O. liliputiana*).

Nuclei (N). Nuclei are sometimes discernible in young asci and in large spores when studied in the living state in water mounts under bright field optics or phase contrast (oil immersion), either unstained, or in vital stains like IKI or CRB. Nuclei form globose, non-refractive regions more or less in the centre of the cells. They always contain a nucleolus, a small, distinctly refractive, eccentric, (semi)globose body being broadly attached to the inner side of the nuclear membrane (Fig. 93: c). Nucleoli appear round in outline when seen in front or oblique view but half-moon-like in profile view (Fig. 93: a–b, see also Baral 1992: 372).

Nucleoli are selectively stained blue in CRB, whereas the remaining part of nuclei is unstained. IKI provokes a higher contrast to both nucleoli and nuclear membrane. Phase contrast may improve the visibility of nuclei in unstained preparations of living spores or young asci. In dead cells nuclei are completely invisible unless special staining techniques are applied.

The largest and most easily visible nuclei are the fusion nuclei which are found in or some distance above the centre of immature asci (Fig. 93a, see also Pls 163: 1c; 175: 2d; 375: 8b; 610: 1d). Fusion nuclei represent the short-lasting diplontic phase of an ascomycete, and can be seen with the LM in most species of ascomycetes without applying staining agents. Their diameter in *Orbilia* and *Lecophagus* was found to vary from 3.5–4.5 to 6–8 µm, and the nucleoli from 1.3 to 3 µm. Sometimes fine

chromatine fibres can be seen in the non-refractive nucleoplasm of fusion nuclei.

Haplontic nuclei formed during meiotic division of the fusion nucleus are much smaller and much less conspicuous. Binucleate stages were sometimes observed, those with 4 or 8 nuclei only exceptionally, and higher stages in multispored species could never be seen.

Nuclei in the living ascospores were observed in a few desiccation-tolerant, more or less large-spored species of *Amphosoma* (*A. macrosporum*, Fig. 93: b), *Orbilia* sections *Lentiformes* (*O. patellarioides*, *O. cercidicola*, *O. cucumispora*, *O. lanternae*), *Hemiorbilia* (*O. megahesperidea*), *Habrostictis* (*O. multihamulata*, *O. barrowensis*), and *Ovoidea* (*O. octosporoides*, Fig. 93: c). In all these species the spores were uninucleate, and the size of the nuclei ranges from 1.7 to 2.8 µm, that of nucleoli from 0.7 to 1.3 µm. Uninucleate ascospores were also reported by Benny et al. (1978) in *O. sarraziniana* and by Müller (1998, Fig. 93: d) in *O. aristata*.

Weber (1992: 124) observed by means of cytofluorometry (DAPI) that the ascospores of *O. eucalypti* (as *O. coccinella*), *O. comma*, *O. ?xanthostigma* (as *O. delicatula*), *O. sarraziniana*, and *O. vinosa* are uninucleate. With this method also the cells of paraphyses were found to be uninucleate. Cultures of *Orbiliomycetes* were not available during this research, therefore, nuclear numbers in mycelia could not be observed. Berthet (1964a: 126, 1964b: 23) reported the mycelium of *O. tremulae* (as *O. xanthostigma*) to be uninucleate (stained by haematoxylin or Giemsa). Multinucleate cells were reported with the TEM for mycelia of *Lecophagus* by Dick (1990) and Morikawa et al. (1993), and in constricting rings of *Drechslerella brochopaga* by Zachariah & Insell (1979) and Nordbring-Hertz et al. (1995). Rubner (1996: 30) found mycelia, conidia, and trapping organs in most of her nematophagous species to contain more than one nucleus (stained with DAPI): depending on the species, the mycelial cells were either 1- or 2–5-nucleate, the conidial cells either (1–)2(–4)-, 6–12-, or up to 20-nucleate or more if conidial cells strongly swollen, and the cells of adhesive hyphal branches 2–4-nucleate. Nakagiri & Ito (1996) observed in *Orbilia multiformis* (as *Dactylella iridis*) (1–)2–3(–5) nuclei in each hyphal cell, and 3–14 nuclei in each conidial cell stained with Hoechst 33258. In the present study, the cells of mycelium and conidiophores in *O. menageshae* were about 4-nucleate (LM-observation, living state, in IKI).

Weber (l.c.) evaluated the relative DNA-content in various groups of ascomycetes. With eleven strains of seven species investigated, the *Orbiliomycetes* turned out to have a somewhat intermediate ploidy level in comparison with the *Helotiales*. With the assumption that the basic ploidy level is somewhat higher than in the *Helotiales*, then *O. crenatomarginata* (as *Hyalinia rosella*) has a ploidy level of 1 ×, *O. sarraziniana* and *O. vinosa* 2 ×, and *Hyalorbilia inflatula* 4 ×. *O. leucostigma*/*xanthostigma* varied in ploidy levels: some apothecia of one sample (REG 143) deviated in having 1 ×, whereas others had 2 ×; the other two samples (REG 134, 138) had consistently 2 ×. Two species were intermediate compared to these ploidy levels (*O. comma* 1.5 ×, *O. eucalypti* [as *O. coccinella*] 2.5 ×) and would thus better concur with the 2 × and 3 × ploidy levels of the *Helotiales*.

Excretions on the cell wall

Gelatinous sheaths. Gel layers that show a ± strong metachromatic reaction were observed in all groups of *Orbiliomycetes*. The gelatinous matrix is exuded from almost all types of cells of both anamorphs and teleomorph, including the asci, conidia trapping organs (Figs 94, 107: d–i), but excluding the ascospores. The gel covers the cell wall as a thin, rarely thick, usually hyaline sheath. It is either non-refractive and then invisible without staining, or more or less visible in water or KOH by a varying strength of refractivity. In those *Orbilia* species with a dark olivaceous exudate, the gel is more apparent by a somewhat olivaceous colouration.

Gelatinous excretions that are non-refractive can usually be visualized by their property to get stained in basic dyes. For example, aqueous Cresyl blue (CRB) or

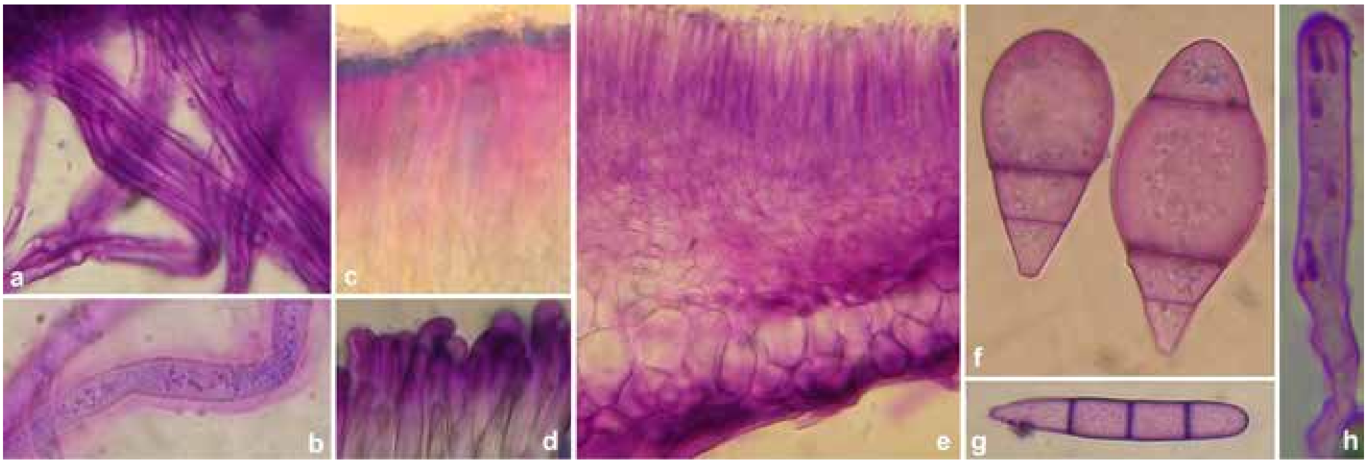

Figure 94: Gel that stains lilac in Cresyl blue (CRB) is excreted from the cell wall of most organs of *Orbilia*. — **a**. anchoring hyphae (*O. pilifera*, H.B. 8076a), **b**. hyphae in pure culture (*O. menageshae*, H.B. 9275a), **c**. hymenium (*Orbilia aristata*, H.B. 9226a, exudate over the paraphyses stained turquoise-blue), **d**. tips of glassy processes (*O. albidorosea*, H.B. 9031), **e**. hymenium, medullary and ectal excipulum (*O. alba*, H.B. 9051a), **f–g**. conidia (**f**. *O. elegans*, H.B. 6972a; **g**. *O.* cf. *cotoneastri*, H.B. 9051b), **h**. ascus (*O. vinosa*, 15.V.2010, phot. I. Wagner).

Toluidine blue (TB) provoke a metachromatic stain to the gel, i.e, the blue colour of the dye is changed to a pale or bright purplish lilac. Such metachromatic effects in the outer cell walls might be due to a more alkaline pH of the gel; yet, they are generally referred to a denser storing of the molecules (see Grube 1993). In any case, the different colour that CRB adopts in contact with exudate (Fig. 94: c) should result from a different chemistry of the stained structure. Methyl blue (CB_a) stains gel in a blue colour, and Neutral red (NR) orange-red. When ingredients such as lactophenol are added to these basic dyes (e.g., in CB_L), the staining of gel as well as the metachromatic colour change are completely suppressed. Congo red (CR) hardly gives any stain to the gel. Only when the gel is thick enough it can be visualized by adding India ink to a water mount, or by dehydrating it with alcohol (Fig. 107: d). Refractive gel is apparently more dense and contains less water, and its ability to take up stains is perhaps therefore reduced.

Gel on excipular cells and anchoring hyphae. Gel between excipular cells and on the anchoring hyphae stains generally deep lilac in CRB in the *Orbiliomycetes* (*Lecophagus*, *Hyalorbilia*, *Amphosoma*, *Orbilia*) as well as the *Helotiales* (Fig. 94: a–b, e). The cells of the ectal excipulum firmly cohere by a lower or higher amount of gel. However, even within a species the abundance of gel is rather variable. For instance, in *Hyalorbilia citrina* (Fig. 77: e–f) the gel thickness varies from 0.5–1 to 1–3(–5) µm, depending on the collection. The cells of the medullary excipulum are normally covered only by a thin gel layer and are, therefore, not firmly agglutinated. Yet, in about a third of the species of *Hyalorbilia* (*H. brevistipitata*, *H. lunata*, *H. polypori*, *H. puertoricensis*, *H. inflatula*, *H. japonica*, *H. citrina*, *H. tortuosa*, *H. fagi*, *H. arcuata*) and in a few species of *Orbilia* (e.g., *O. suberis*, *O. blumenaviensis*, *O. pilosa*), the gel was often found to be rather abundant and refractive. In *Lilapila* the gel is very abundant and provokes a rather strong gelatinous consistency of the apothecia, but it stained only faintly lilac in CRB.

As with the solid matrix of glassy processes, gelatinous sheaths can probably be interpreted as an outer layer of the cell wall. Actually, in those species of *Orbiliomycetes* with a more or less gelatinized ectal or medullary excipulum, gelatinized anchoring hyphae, or thick-walled hairs, the distinction between a thickened cell wall and refractive gel on the wall or between the cells was often quite impossible. Within the excipular texture no sharp limit is usually visible between the gel produced from two adjacent cells (Fig. 77: e), therefore, only the total thickness of both gel layers (referred to as 'common wall' in the descriptions) can be measured. At the surface of gelatinized cortical cells a sharp external limit of the gel is usually seen, which causes a thick-walled appearance of these cells (Fig. 77: f). Anchoring hyphae in *Hyalorbilia* are often thick-walled, and it seems possible that the matrix of this wall corresponds to the gel found between the excipular cells. The same could be true for the thick-walled anchoring hyphae in *O. denticulata* and the hairs in *O. pilosa* and *O. phragmotricha*.

Gel on asci and paraphyses. Agglutination of the hymenial elements is often reported as typical of the genus *Orbilia* (s.l.). However, such strong agglutination of paraphyses and asci is more or less restricted to the genus *Hyalorbilia*. Here the hymenial gel is generally abundant and more dense and tough, and stains pale to bright lilac in CRB. It holds the paraphyses and asci together by forming a coherent gelatinous matrix which often completely prohibits separation of the elements. Completely isolated, sometimes still turgescent single asci could only be seen in a few species with sparse gelatinization.

In the other genera of *Orbiliomycetes* the gel does not fill the entire intercellular space of the hymenium but forms an individual thin sheath over each paraphysis or ascus. Particularly the ascus apex is covered by a distinctly stainable gel layer which is mainly seen in species of *Orbilia* (Fig. 94: h) and *Amphosoma*, but less so in *Hyalorbilia*. The ascus gel increases in thickness towards the tips, where it seems to correspond to the 'periascus' in the sense applied by Chadefaud (1973) and Bellemère (1975, 1977). In contrast to *Hyalorbilia*, only the tips of paraphyses are more or less held together by gel, particularly in desiccation-tolerant species. If little of such material is present, the paraphyses are easily separable even by slight mechanical pressure, at least in living specimens. This feature of non-coherent hymenial elements was also stressed by Haines & Egger (1982: 112) for *O. piloboloides* (= *O. carpoboloides*) and by Spooner (1987) for those species of *Orbiliomycetes* without abundant exudate. Although the gel is quite invisible in water mounts, its presence over the tips of paraphyses and asci is evident when there is some distance between refractive exudate and cell wall (Fig. 95: b, f).

Random tests in the *Helotiales* showed that the ascus wall

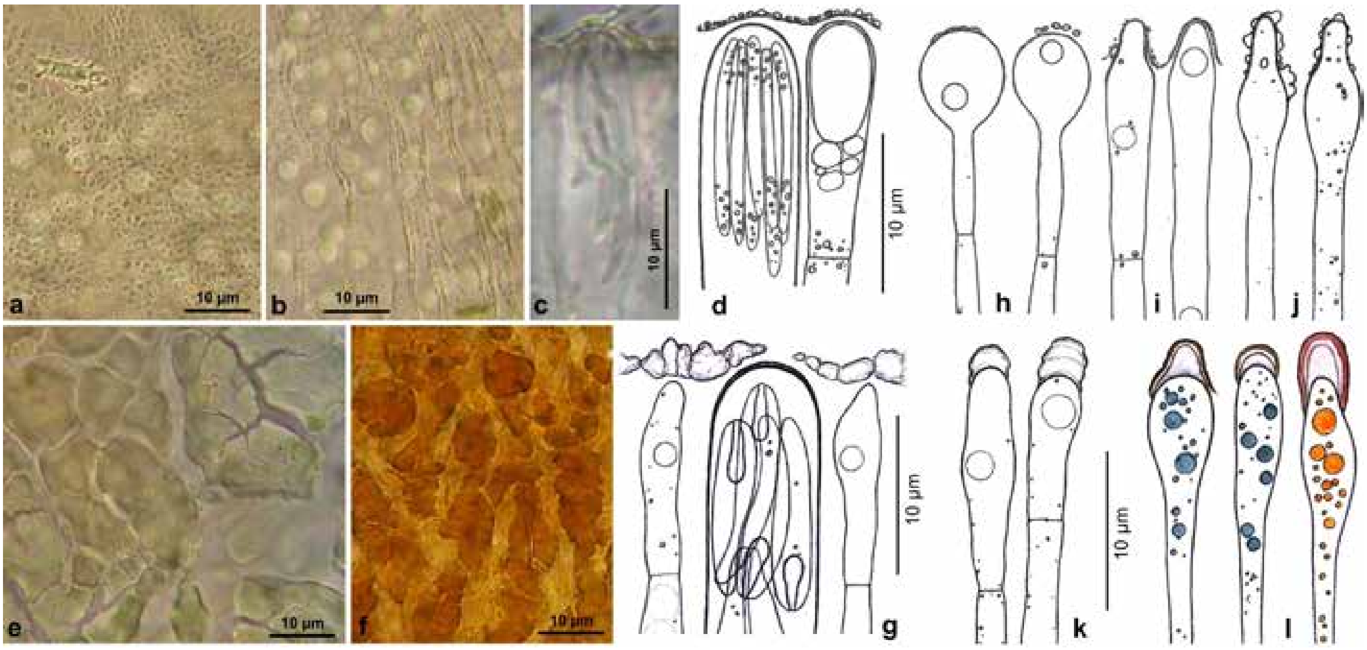

Figure 95: Exudate over paraphyses and asci in *Hyalorbilia* (**a–d**) and *Orbilia* (**e–l**). — **a–b**, **e**. top view on hymenial surface; **f**. external view on marginal excipulum; **a–d**. small angular clods on a thin, continuous, inelastic layer firmly attached to a gel matrix; **b**. after squashing, the rigid layer gets folded whereby the clods do not join; **c–d**. paraphysis and turgescent asci lifting the overlying gel and exudate; **e–g**. large irregular clods ± loosely attached to gel over paraphyses or marginal excipular cells (*Orbilia* section *Hemiorbilia*); **h–l**. exudate ± firmly attached to each paraphysis tip (but in **i** forming a thin coherent layer). Living state (in H_2O, **l** left in IKI) except for **a** (in KOH), **b**, **e** (in H_2O), **f** (in KOH+CR), **l** right (in KOH+CR). — **a**. *Hyalorbilia inflatula* (VII.1881); **b**. *H. fagi* (H.B. 7812); **c**. *H. berberidis* (H.B. 7648b); **d**. *H. juliae* (H.B. 7029); **e**. *Orbilia pleionavajoana* (H.B. 8049a); **f**. *O.* aff. *aprilis* (H.B. 9132a); **g**. *O. montigena* (H.B. 7152a); **h**. *O. cylindrosoma* (H.B. 6393); **i**. *O. rubella* (H.B. 7442); **j**. *O. euphorbiae* (S-F 41427); **k**. *O. aradi* (H.B. 7628c); **l**. *O. xanthoguttulata* (H.B. 7464).

surface does not stain in CRB, except for the periascus which gets pale lilac (e.g., in *Hymenoscyphus*). Metachromatic reactions of ascus walls (including the endotunica) and gel sheaths were reported for members of *Arthopyrenia* by Grube (1993) using mainly Toluidine blue. Also in *Deltopyxis* the ascus wall surface stains faintly to deeply lilac in CRB (Baral & Marson 2012).

Gel on ascospores and conidia. The ascospores of some helotialean genera are covered by an often invisible gel that stains pale to bright purplish-lilac in CRB (see Baral 1992: 356). No such gel layer on the walls of ascospores could be found in any of the many species of *Orbiliomycetes* tested. However, when dead spores inside dead asci are examined, the spores look seemingly ensheathed because both the asco- and sporoplasm may be detached from the spore wall, which provokes the impression of a spore sheath (see Fig. 10: d–e).

The gel layer over conidial walls is usually very thin and also here only seen when applying a stain (Fig. 94: f–g). A survey on the examined species with a CRB-lilac conidial gel is found in Tab. 9. Rubner (1996: figs 14, 46) found the large cell of the 1-septate conidium of *Drechslerella polybrocha* (as *Monacrosporium*) to be often enveloped in a layer of mucus. A ~1–2 µm thick gel layer was seen in our isolate of *O. polybrocha*.

Function. The function of gel is not clear in every case. In the ectal excipulum it undoubtedly provides mechanical stability of the tissue. In the hymenium the gel might serve as a lubricant for the growth of young asci. This is supported by the fact that the thickness of the gel layers in the hymenium decreases with maturity. In contrast to exudate, gel swells upon water uptake. In addition to serving as a gluing substance to affix the exudate clods to the wall of the paraphysis apices, gel in desiccation-tolerant apothecia of *Orbilia* should play a role in the de- and rehydration process: shrinkage and swelling of the gel might assist in closing and opening of the crevices between the exudate clods in *Orbilia*, and in folding of the continuous, inelastic exudate layer in *Hyalorbilia*.

An ecological function of gel in apothecial tissue was frequently believed to lie in retarding evaporation, but we doubt this view. When observing specimens during drying at normal room conditions, small-sized apothecia dry down within a few minutes when they adhere to rather small portions of substrate, irrespective of being gelatinized or not.

Gel also facilitates attachment of conidia to invertebrates which serve as vectors or victims (see Fig. 118).

Amorphous exudate. In many desiccation-tolerant taxa of *Orbiliomycetes* a usually strongly refractive, solid, amorphous, mostly cloddy or granular exudate covers the exterior of the apothecia (tips of paraphyses, cortical cells of ectal excipulum on margin and flanks), whereas in most desiccation-sensitive taxa the exudate is quite poorly developed or more or less absent. The exudate forms ~0.3–2 µm, rarely ~3–5(–8) µm thick granules or clods which are attached to the gel exuded by the paraphysis tips and cortical cells (Fig. 95). The outer surface of exudate is often strongly uneven by protuberances and clefts. In section *Aurantiorubrae* and series *Microsomates* (section *Orbilia*) the exudate often individually covers each paraphysis tip as ± firmly attached, thin granules or thick glassy caps (Figs 95: k–l; 96: h–k).

Usually the exudate is hyaline or shows a faint to distinct yellowish colour. In *Hyalorbilia* it is generally faintly chlorinaceous-amber. In a few species of *Orbilia* and *Amphosoma* the exudate is deeply olivaceous, and in *Lilapila* and *Liladisca* it has a deep purplish-lilac colour (see p. 102). In *Lilapila* the exudate occurs as granules between the cells of the whole excipulum, also between the paraphyses but not above their tips, and the anchoring hyphae are covered by a thin, rough, hyaline exudate; all this is quite unusual within the *Orbiliomycetes*.

The exudate neither swells by imbibition during water uptake, nor does it shrink during drying. Nevertheless, it is hydrophilous, which is obvious when spraying water on dry desiccation-tolerant apothecia: the water is immediately absorbed, and there is rarely any trapped air to be seen around the exudate in a water mount. In contrast to this, the hymenia of *Propolis* or *Mellitiosporiella* (*Rhytismatales*) are very difficult to rehydrate, and trapped air is often found among the exudate which is rather hydrophobous.

There is a noticeable difference between exudate in *Orbilia* and *Hyalorbilia*, particularly when comparing desiccation-tolerant species. In *Orbilia* the exudate is usually broken by a web of cracks into irregularly-shaped pieces of clods of varying size (about 1–10 or even 20 µm diam., best seen in surface view, Fig. 95: e–f). When the apothecia shrink during drying, the clods close their crevices by forming a continuous shield over the complete surface of the apothecium, also the underlying gel matrix contracts thereby. Upon rehydration the gel matrix and cell lumina swell by water uptake and the clefts reappear.

In *Hyalorbilia* the compact gel matrix is terminated by a ~0.2–0.3 µm thick refractive, inelastic, continuous layer of exudate which is densely covered by small roundish warts or angular clods ~0.2–1.5 µm diam. (Fig. 95: a). Although the borders of these warts seem to match together as in *Orbilia*, the thin inelastic, continuous layer beneath gets folded in squash mounts (Fig. 95: b), a phenomenon never seen in *Orbilia*. This folding of the exudate certainly happens also upon drying. Both gel and exudate cover the asci even when they attain full turgescence. Thereby the asci sometimes lift the covering layer a few micrometers above the paraphyses (Fig. 95: c). The continuous outer layer appears to burst only when the asci explode. In *Orbilia* the gel is more isolated around each paraphysis and, therefore, much less coherent, and the clods of exudate easily separate from each other, when the asci elongate at full turgescence.

Terminology. Höhnel (1907a: 132, *Hyalinia crenatomarginata*) and Boudier (1904–10: 269, pl. 465, 466, *H. rosella* and *H. crystallina*) were apparently the first to mention the exudate in *Orbilia* (= *O. crenatomarginata*), the former as a ‘cuticle-like waxy layer’, the latter as ‘epithecium’. Spooner (1987) called the exudate ‘amorphous matter forming an (encrusting) epithecium’ in which the apices of paraphyses are ‘embedded’. We have avoided the term epithecium which means ‘above the hymenium’ or ‘above the asci’, since its application in the literature is not very consistent, and since the very same exudate is also found on the surface of the excipulum. In the literature, the apices of paraphyses in various groups of ascomycetes are frequently reported to form a coherent epithecium above the asci due to the presence of some intercellular, hyaline or pigmented amorphous matrix. However, such application of the term epithecium is more or less connected to the dead state of asci: living, fully turgescent asci frequently penetrate and overtop the ‘epithecium’ prior to spore discharge. The creators of the term epithecium were obviously unaware of the much greater length of living asci, and refer to the artificial situation in dead herbarium material in which the shrunken asci are usually overtopped by the apices and the exudate of the paraphyses. A different definition of the term ‘epithecium’ is found in Cannon et al. (1995, see also Korf 1973: 250): ‘tissue at the surface of an apothecium formed by the branching of the ends of the paraphyses above the asci’. In this literature another term (‘pseudoepithecium’) appears better to apply to the exudate of the *Orbiliomycetes*: ‘an amorphous or granular layer overlying paraphyses in an apothecium and in which their tips are immersed, but not forming a separate tissue’. We feel, however, that it is very difficult to decide whether apically branched paraphyses do actually form a tissue or not, especially considering the fact that, within a species, the amount of branching varies and increases with the age of the apothecium. In *Orbilia* frequent branching near the paraphysis apices is typical of desiccation-tolerant species, but is not coupled with a higher amount of exudate over them.

Formation. The exudate is formed at an early stage of ascoma development, long before the ascogenous hyphae reach the hymenium. It is excreted from the tips of the vegetative cortical cells by passing both cell wall and gel. During growth of the young apothecium the clods increase in size and number. In *Orbilia* the exudate often detaches from the tips of the paraphyses when squashing a water mount. This is particularly the case when the apothecia are still rather young. During maturation, however, the exudate becomes more and more firmly attached, apparently because of the underlying gel becoming significantly more able

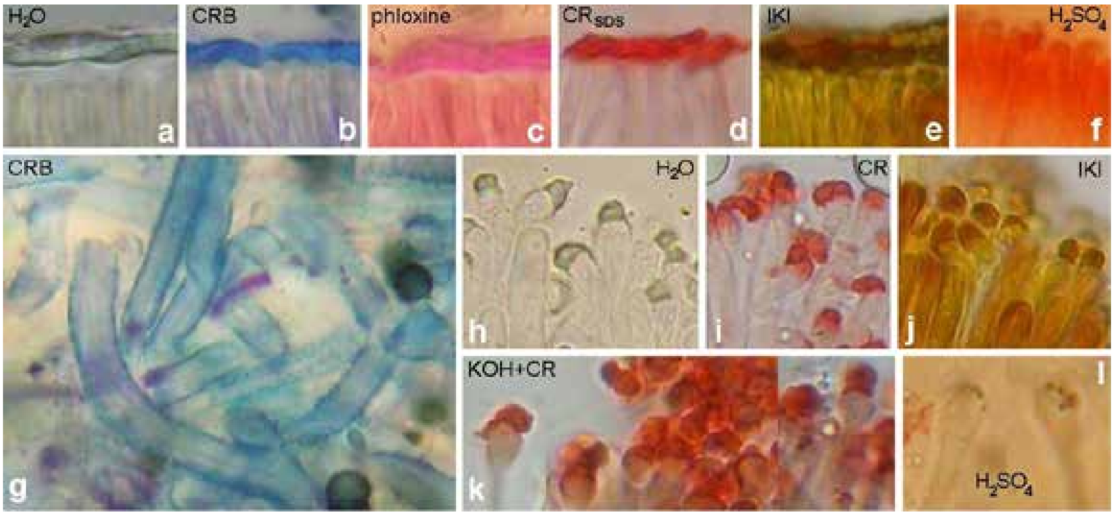

Figure 96: Hyaline exudate stained by different dyes and reagents, and dissolved by acids. — **a–f**. *Orbilia aristata* (H.B. 9226a): **a** in H_2O, **b** in CRB, **c** in phloxine, **d** in CR_{SDS}, **e** in IKI, **f**. exudate dissolved when heated in 60% H_2SO_4, neutralized with KOH, stained by CR_{SDS}; **g**. exudate on anchoring hyphae of *Lilapila oculispora* (H.B. 9162h) in CRB; **h–j**. caps of exudate over paraphyses in *O. kingsiana* (H.B. 8303b) in H_2O, CR, and IKI; **k**. caps of exudate in *O. denticulata* (H.B. 5430) in KOH+CR, **l**: id., dissolved in heated 60% H_2SO_4, neutralized with KOH.

to swell. In submature apothecia of section *Hemiorbilia* the exudate may completely detach from the whole hymenium and float in the medium as an entity or broken in several parts.

Chemistry. The chemical nature of the exudate is unknown. Höhnel (1907a) concluded from its insolubility in high-concentrated ethanol that the thin covering layer in *O. crenatomarginata* is of a waxy rather than resinous nature. Further properties were found in the present study: the exudate is insoluble in high-concentrated alkali (KOH) and in not too strong acids, and is usually strongly stained in CRB, phloxine, CR, and IKI (Tab. 8, Fig. 96, also in Vert lumière = Fast Green fide Bellemère 1968: 548). In 60 % sulphuric acid (H_2SO_4) the exudate of *Orbilia* dissolves, at least when briefly heated (Fig. 96: f, l), whereas it resists in hydrochloric acid (HCl). In *Hyalorbilia*, however, the warts and the underlying continuous exudate were not found to dissolve when briefly heated on the slide in a drop of 60 % H_2SO_4 or 10 % KOH.

A high affinity to all these above-mentioned dyes is observed in *Orbilia*: the exudate takes up the dye already at rather low concentrations (about 0.1 %) at which other parts of the apothecia are not stained. Hyaline exudate stains in a clear turquoise to blue colour in CRB (Fig. 96: b), but the stain turns more deep blue or (violet-)blue at high concentration. The exudate of *Hyalorbilia* often shows a lower affinity to these dyes, staining only light blue(-turquoise) in CRB or hardly at all, but also sometimes deep blue(-violet). Also in CR the reaction was often less intense. This might indicate a chemical composition different from *Orbilia*.

Neutral red (NR) stains the exudate of *Orbilia* bright orange-red, Methyl blue (CB_a) uniformly blue, and phloxine in a bright pink colour (Fig. 96: c); these colours correspond to the colour of the dye because they do not show a metachromatic effect.

CR stains the exudate of *Orbilia* generally light to deep rose-red (Fig. 96: d, i, k), also the thin exudate of *Hyalorbilia*. IKI stains the exudate of *Orbilia* often pale to bright dirty red-brown (dextrinoid, Fig. 96: e, j, KOH-pretreated or not), though this was mainly observed in taxa of section *Hemiorbilia* with thick exudate. In MLZ the reaction is less distinct.

In its behaviour with staining reagents, the exudate of *Orbiliomycetes* resembles hyaline to yellowish 'resinous' exudates of the *Helotiales*, e. g., in *Hyaloscypha aureliella* (see Huhtinen 1990a: 62, 110) and *Dasyscyphella*. These exudates likewise stain turquoise in CRB, but they differ in disappearing instantly in KOH (including their often yellow colour), perhaps also in being less solid.

Function. Exudate might function as a mechanical protection of the hymenial and excipular elements during periods of drought: the compact casing by exudate would serve as a barrier against mycophagous invertebrates. The rough surface of exudate could also support condensation of atmospheric humidity. Both this would explain the scantiness of exudate in desiccation-sensitive apothecia with a much shorter life span.

Autofluorescence. The yellow exudate on the exterior of the apothecia often shows a more or less striking autofluorescence under UV-illumination (365 nm). This was particularly observed in multispored members of series *Vibrioides* of the genus *Orbilia*.

Under UV in a dark room the apothecia then appear yellow to orange (Fig. 97: f). Taxa with unpigmented exudate do not show this effect. In case the surrounding substrate does not show a similar autofluorescence, the effect permits rather easy detection of scattered growing apothecia even in the dry state. The yellow colour of the exudate is best seen on macro- and microphotographs when using LEDs with a high proportion of blue (e. g., Luxeon) under reflected or transmitted illumination, while under halogen lamps the exudate may appear rather uncoloured.

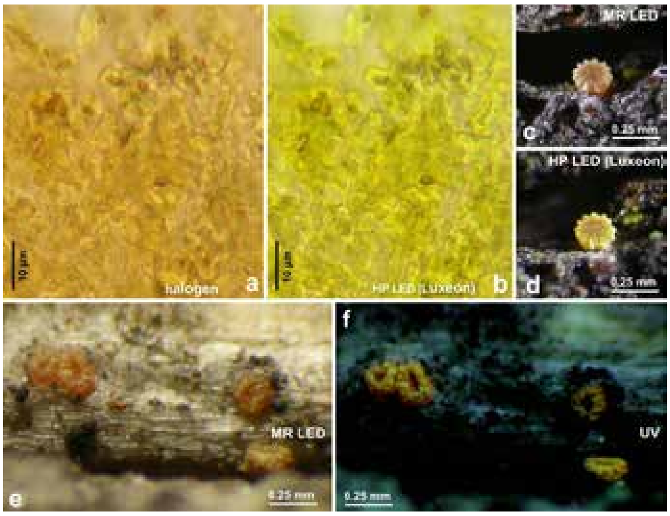

Figure 97: Autofluorescence of yellow exudate in *Orbilia myrioobliqua* and *O. angustoobliqua*. — **a**. illuminated by a halogen bulb; **b**, **d**. by HP LED (Luxeon); **c**, **e**. by MR (mid range) LED; **f**. by UV (365 nm). **a–b**. *O. angustoobliqua* H.B. 9050; **c–d**. *O. myrioobliqua* H.B. 8391a; **e–f**. *O. myrioobliqua* H.B. 7087b.

Extracellular crystals. Crystalline excretions of any kind are normally absent in the *Orbiliomycetes*. Particularly octahedral crystals, usually identified as calcium oxalate, excreted from hairs, excipular cells, or paraphyses in many genera of *Helotiales*, have never been encountered in the *Orbiliomycetes*, neither in apothecia, nor in pure culture. Rarely, small crystals were seen on the surface of gel which covers the tips of cortical excipular cells and paraphyses in *O. cucumispora* (Pl. 179: 1f, 2b–c). Crystals were infrequently observed below apothecia on the natural substrate. However, they were not formed by the fungus but originate from inside host cells.

Pigments

The apothecial colour of a species of *Orbiliomycetes* (see also p. 34, Apothecia) has generally a genetical basis, but it depends also on rather complex interactions of various parameters. What we can see under a handlens or dissecting microscope, or on a photography depends on influences such as exposition to sunlight during growth, development stage, rate of hydration, and long-term storage in herbaria, but also the spectral properties of the light source, and (in photography) white balance effects. The colour of the living apothecia results from a superposition of apparently four different types of pigments (Tab. 10). These are located in four different microstructures in- and outside the vegetative cells (paraphyses and ectal excipulum, see also Baral 1992: 370). Most of them may occur simultaneously within an apothecium. Secondary pigments which arise in some species through apparently oxidative chemical processes during senescence or when preserved as herbarium material need to be sharply separated from the original pigmentation (see p. 104, Colour of the dead cytoplasm).

Extracellular pigments are those of the exudate which is mainly found on the exterior of the apothecium, sometimes also in the intercellular space of the tissue. Intracellular pigments comprise lipophilous compounds (carotenoids deposited in LBs), hydrophilous pigments in vacuoles, and pigmentation of crystalloid SCBs.

Typical of section *Hemiorbilia* are thick yellowish exudates (Fig. 98: a). Yellowish-orange LBs characterize quite a number of species of *Orbilia* (e.g., *O. euphorbiae*, Fig. 98: b; *O. xanthoguttulata*, Figs 83, 98: c, 99) but are rarely seen in *Hyalorbilia*. Rose-red vacuoles (VBs) are so far unique to *O. rubrovacuolata* (Fig. 98: e), and a yellow vacuolar pigment is typical of *O. flavovacuolata* and *O. xanthostigma* (Fig. 98: f). Pale yellow-orange crystalloid SCBs occur in many desiccation-tolerant species (e.g., *O. cercidicola*, *O. hesperidea*, Fig. 98: d, see also Figs 87–88). A little understood diffuse pale rose-orange pigment of the whole apothecial texture is typical of many desiccation-tolerant species and could not clearly be allocated. Olive-brown and purplish-lilac pigments were so far exclusively found in the exudate. In all these types of pigments the intensity of colour may vary considerably within a species (living hydrated state, see p. 34, Pigmentation of apothecia).

The colour of apothecia in external view is usually the result of a superposition of pigments from two or three of these microstructures, though often one of them strongly prevails. For instance, bright golden-yellow to yellow-orange apothecia may originate from a combination of yellow-orange LBs and VBs (*O. xanthostigma*), or of yellow exudate and yellowish-orange SCBs (e.g., *O. hesperidea*). Likewise, the chlorinaceous colour of *Hyalorbilia* apothecia derives from chlorinaceous exudate and vacuoles. The colour of yellow-orange apothecia of *O. xanthoguttulata* is exclusively provoked by abundant yellow-orange LBs (Fig. 98: c). In multispored taxa of series *Vibrioides* the yellow dots of exudate on the surface and the diffuse pale rose-orange pigment of the excipular and hymenial texture are even macroscopically separately recognizable, provoking the appearance of a crumble cake.

1. **Extracellular pigments (exudate)**. Apothecial colours in *Orbiliomycetes* often originate from pigmentation of the **exudate** on the surface of the apothecium. Under transmitted light the exudate in bright yellow to orange apothecia appears pale yellowish, chlorinaceous, or even colourless, depending on the thickness of the sections. Only in thick sections a bright yellow exudate can be seen (Fig. 98: a).

The dark pigmented exudate of black-olivaceous apothecia in some species of *Amphosoma* and *Orbilia* (Fig. 98: j) might be due to a chemical change from yellowish to dark olivaceous, judging from the fact that very closely related taxa mainly differ herein. Moreover, in the dark-coloured *O. patellarioides* the hyaline medullary excipulum was found to be pale rose in some collections, but this pigmentation is completely masked in external view by the dark cortical pigment. The bright lilac exudate of the purplish-black apothecia of *Lilapila* occurs inside granules among the paraphyses and excipular cells, and also as a covering layer over the hairs (Fig. 98: g). Light grey-brown-olivaceous granules and clods of exudate are more or less typical of *O. polybrocha* and may not only occur on the apothecial surface but also in the marginal ectal and perihymenial medullary excipulum (Pl. 1003: 1e–f). Similarly, a yellowish-ochraceous exudate occurs in *O. pilifera* in the medulla and on the ectal excipulum (see Pl. 496: 5c).

The chemical nature of the pigments in exudate is unknown. Dissolution in strong alkali (10% KOH) has never been observed in all of these pigments, even when briefly heating the slide, while they are more or less dissolved only in very strong

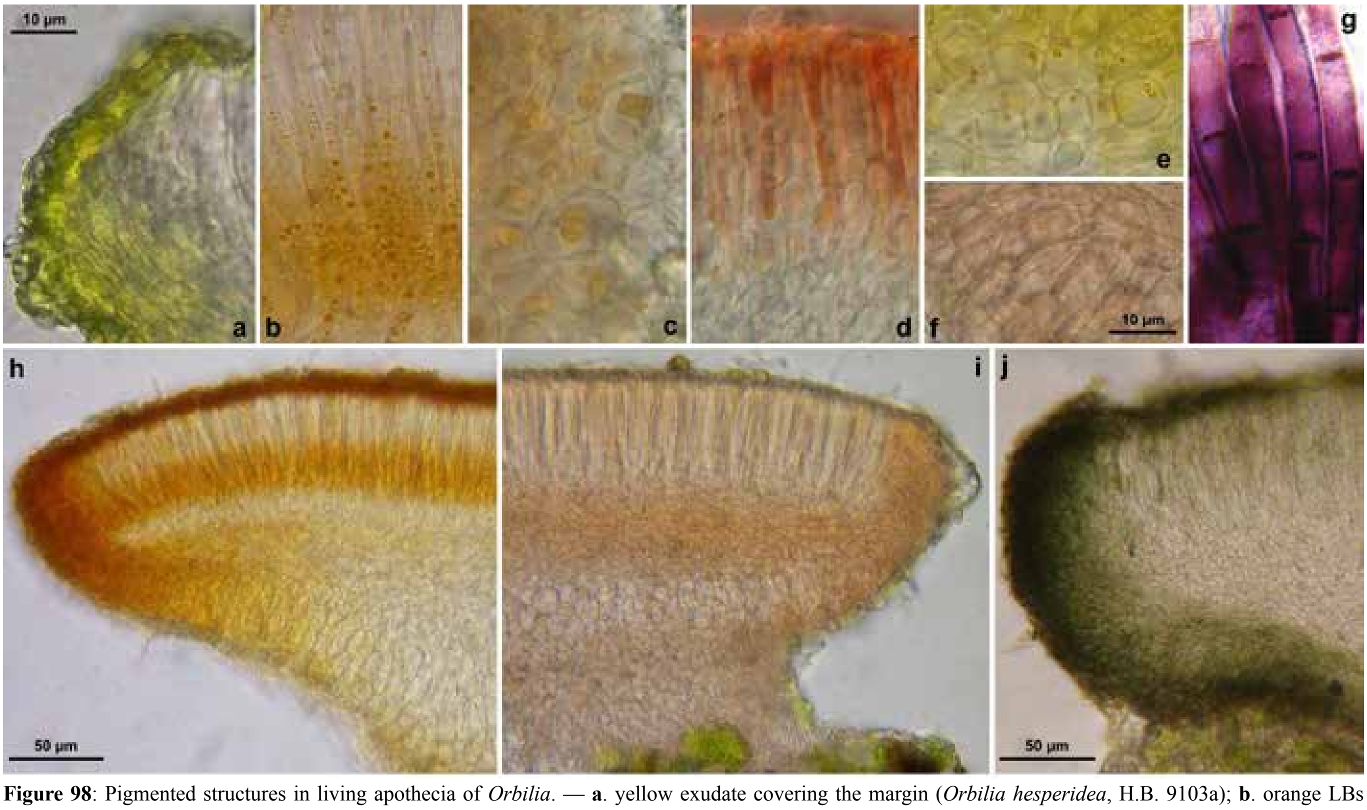

Figure 98: Pigmented structures in living apothecia of *Orbilia*. — **a**. yellow exudate covering the margin (*Orbilia hesperidea*, H.B. 9103a); **b**. orange LBs (carotenoids) in paraphyses (*O. euphorbiae*, 8777c); **c**. orange SCBs in ectal excipular cells (*O. hesperidea*, H.B. 8883b); **d**. red vacuoles (VBs) in paraphyses (*O. rubrovacuolata*, H.B. 7719a); **e**. yellow trembling VBs in inflated cells of medullary excipulum (*O. xanthostigma*, H.B. 7848a); **f**, **i**. diffuse rose pigment in *O. clavuliformis* (H.B. 8218); **g**. dark lilac hairs in *Lilapila oculisporella* (7.IX.2010); **h**. distribution of orange carotenoids in apothecium of *O. xanthoguttulata* (H.B. 8208); **j**. dark olivaceous exudate in *O. patellarioides* (H.B. 9173a).

Table 10. Four different types of pigments observed within the *Orbiliomycetes*.

Pigments		Colour	Microstructure	Organ	Affinity
Extracellular pigments		chlorinaceous, yellowish, purplish-lilac, olive	exudate	covering apothecial surface, rarely between cells	?
Intra-cellular pigments	Vacuolar pigments	chlorinaceous, yellow, rose-red	vacuoles and VBs	paraphyses, marginal cortical cells	hydrophilous
	Carotenoids	yellowish-orange	lipid bodies (LBs)	paraphyses, medullary excipulum	lipophilous
	Pigments in SCBs	yellowish-orange	crystalloid SCBs	paraphyses, excipulum	?

acids (H_2SO_4). Colour changes of the pigments may occur: hyaline and yellowish exudates remain unchanged in KOH, whereas olivaceous (blue-green) exudates turn ochraceous-olive or yellowish- to reddish-brown; yet, also purplish-lilac exudates turn yellowish- to olive- or violaceous-brown. The original colour of these dark pigments is restored in full strength when enough acid is added, or when transferring the apothecial fragment into PVA, hence the colour depends on the pH. The absence of a bluish or greenish IKI-reaction of yellowish exudate appears to exclude carotenoids.

2. **Pigments in lipid bodies (carotenoids)**. Golden-yellow to orange LBs occur in the paraphyses and marginal region of the excipulum in various groups of *Orbilia*, particularly in section *Aurantiorubrae* (e.g., *O. xanthoguttulata* Fig. 99: a, *O. aradi*, *O. euphorbiae* Fig. 98: b, *O. denticulata*), more exceptionally in sections *Hemiorbilia* (e.g., *O. arachnovinosa*, Pl. 269: 4e) and *Orbilia* (*O. xanthostigma*, *O. xanthoflexa*), and in *Hyalorbilia* (e.g., *H. erythrostigma*, Pl. 126: 1b, 6b, 7b, h). LBs with a high amount of carotenoids considerably contribute to the colour of the apothecia. Within a species the abundance of carotenoids is often rather variable, however.

That these lipophilous pigments should fall in the category of carotenoids can be concluded from the fact that they typically show a faint to distinct dirty blue-green iodine reaction (Fig. 99), in contrast to yellowish vacuolar pigments which do not react in this way. The reaction of carotenoids is obtained in both IKI and MLZ, with or without KOH-pretreatment (Baral 1987b: 428, see also Arpin 1968: 429). In *O. xanthoguttulata* and *O. xanthostigma* a change of colour from blue-green to brownish at a high IKI concentration was sometimes observed, similar as reported for *Scutellinia* by Baral (l.c.).

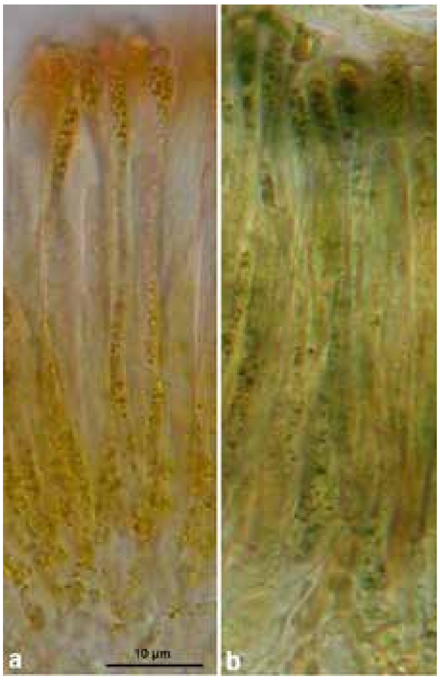

Figure 99: IKI reaction of carotenoids in paraphyses. — **a**. in water, **b**. stained blue-green in IKI (*O. xanthoguttulata*, H.B. 8698).

A faint rose pigmentation is often perceptible throughout the tissue (ectal and medullary excipulum, hymenium) in sections of living xerobiotic apothecia with a reddish external colour. The location of this pigment is unclear. It could be located in the extracellular space, perhaps in the gel, or in the cytoplasm in which a very faint homogeneous pigmentation, or a location in minute LBs, cannot be excluded with certainty.

In dead herbarium material of such reddish-coloured desiccation-tolerant apothecia, the faint rose pigmentation is enhanced and may turn more orange, but it is then clearly located in the dead granular cytoplasm. Again it is unclear whether this effect originates from a secondary pigmentation of the previously hyaline cytoplasm, or is due to carotenoids in LBs which were, in the living state, located at the periphery of the cytoplasm, but scattered throughout the cytoplasm in the dead state. IKI never gave a perceptible reaction to this faint rose pigmentation, however.

Mycelia in pure culture of xerobiotic taxa also frequently exhibit orange to pink colours (Fig. 102). Also Olivier (1978) noted pink to orange mycelia in pure culture of the two treated anamorphic species, *Retiarius superficiaris* and *R. bovicornutus*, that grew on exposed living leaves. She mentioned that this type of pigmentation was characteristic of many phyllosphere inhabitants, but also of some aquatic hyphomycetes and predacious fungi in culture. It is uncertain if these colours are due to the deposition of carotenoid-containing lipid droplets in the ageing mycelium.

3. **Pigments in VBs**. A very pale chlorinaceous colour in low-refractive VBs is typical of *Hyalorbilia*. In *Orbilia* refractive vacuoles occur only in more or less desiccation-sensitive species of sections *Helicoon*, *Orbilia*, and *Arthrobotrys*. Pigments inside these vacuoles were only found in a few species (*O. rubrovacuolata*, *O. flavovacuolata*, *O. atlantis*, *O. xanthostigma*) where they have a faint to light rose-red or yellowish-chlorinaceous colour. In *O. xanthostigma* the pale yellow vacuolar content precipitates at a later stage of development by forming groups of adhering yellow granules that tremble within the large non-refractive vacuoles (see Fig. 86: i–j).

The chemical nature of these hydrophilous pigments is unknown. The refractivity of VBs instantly disappears in both KOH and acids, while the pigment may remain recognizable. The granular VBs can easily be mistaken for yellow LBs, which also occur in apothecia of *O. xanthostigma* but which resist treatment with KOH.

4. **Pigments in crystalloid SCBs**. Pale to light yellowish-orange crystalloid SCBs occur in quite a few desiccation-tolerant species of various subgroups of *Orbilia*, but exclusively in sections *Hemiorbilia* and *Habrostictis*, and in the single species of series *Cercidicola* of section *Lentiformes* (Fig. 87). The chemical nature of this pigment is unknown. Even large, bright orange SCBs did not show a blue-green IKI reaction typical of carotenoids. Moreover, SCBs disappear in alkali or acids, whereas those types of carotenoids that form needle-shaped crystals in paraphyses of *Scutellinia* (Baral 1992: fig. 38) are KOH-resistant, i.e., they remain visible in full strength. Although SCBs op-

tically disappear concerning their shape, their pigment is still present and unchanged in these media (Fig. 87: h).

Loss of pigmentation in the dead state. In the dry state, the external colour of recently collected apothecia is generally much more intense due to concentration of the pigments. On the other hand, apothecia may completely lose their original colour in the herbarium over some 3–10 years concerning most types of pigments (Fig. 15: a–h). Only the dark pigments located in the exudate persist unaltered during longtime storage in the dry state, and also the yellowish pigment in the exudate of *Hyalorbilia* generally persists. For instance, *H. citrina* was still bright yellow ca. 100 years after it was collected.

Fading of pigmentation is also a frequent feature of, e. g., helotialean and pezizalean discomycetes which completely lose their bright original, particularly yellow and red colours. Carotenoids are known to strongly fade in colour within some decades in the herbarium (see Baral 1992: 372). For instance, Döbbeler (2004) reported a vivid orange-red colour of *Octosporella erythrostigma*, provoked by oil drops inside excipular and paraphysis cells, which gradually disappears in herbarium material. The yellowish pigmentation of the exudate in *Orbilia* appears to fade more slowly but fast enough in order to alter bright orange apothecia towards pale orange-ochraceous or whitish-cream within ~10–20 years. Different species or even different groups of apothecia of the same population may behave very different: e. g., *O. breviaristata* (H.B. 7171a) completely lost its colour after about 4 years, although *O. vitalbae* and *O. clavuliformis* which grew in the same collection were still bright orange. *O. occulta* (H.B. 7402a) lost its pigment already after 3.5 years in the herbarium. In *O. pleionavajoana* (H.B. 8049a) and *O. aviceps* (H.B. 7322a), groups of apothecia completely faded within 8 years, while others in the same population had fully retained their original orange-red colour. *O. obtusispora* (IVV: H.B. 6294) was still bright orange after 9 years, but rather strongly discoloured after 12 years, and *O. multiurosperma* (IVV: H.B. 9573c) was still bright orange after 16 years.

A phenomenon difficult to understand concerns the pigments in VBs and SCBs. These are often not further recognizable inside the dead cells in a water or KOH mount, although the apothecia still show the reddish colour several years after placing them in the herbarium. For example, the red vacuoles in the desiccation-sensitive *O. rubrovacuolata* disappear very soon in the herbarium concerning both refractivity and pigment, but the dried apothecia remain bright salmon- to blood-red over many years. The red colour was still perceptible even in material collected about 150 years ago by H.M. & P.L. Crouan (J.P. Priou pers. comm.). Instantaneous loss of colour and refractivity of VBs that contain yellowish or reddish hydrophilous pigments occurs when pressing on the slide or when adding KOH to a water mount.

Colour of the dead cytoplasm (secondary pigmentation). In addition to pigment loss, hyaline apothecia may turn yellow or reddish-brown by some oxidation process of the dead cytoplasm, either with senescence or bruising, or during drying of fresh, desiccation-sensitive apothecia. This is especially observed in taxa with refractive vacuoles (VBs) in the vegetative cells, which are actually responsible for these colour changes (see Baral 1992: 364). In *Orbiliomycetes*, changes towards a faint to distinct, mostly golden- to ochraceous-yellow pigmentation of previously hyaline VBs were recognized in water mounts, particularly in subtropical collections of *Orbilia* section *Helicoon*. Also the exudate in these species frequently turns more yellow with the age of the population. Likewise, hyaline VBs of the guttular type in *Amphosoma* turn copper-amber in dead cells. A change to reddish-brownish, typical of various *Helotiales*, has never been observed in the *Orbiliomycetes*, however.

Both colour loss and secondary pigmentation can be observed within the same taxon. When a fully viable apothecium of a *Hyalorbilia* is very gently squashed in a water mount, the numerous asci may remain intact although most of the paraphyses die and the VBs then completely disappear, including their chlorinaceous colour. However, if the paraphyses die during ageing of the apothecium in the field, the VBs do not disappear but become distorted and gain a more intense yellow-amber colour.

Huhtinen (1990a: 71) restricted the term ‘pigment’ to coloured substances inside the cells and used the word ‘resin’ for (yellowish) excretory substances. Since Huhtinen often had only herbarium material at his disposal, he could not notice that some of the treated species were white when fresh and formed a ‘yellow pigment’ only in the herbarium. For this reason, he often could not distinguish between coloured substances inside living cells and those inside dead cells. Due to his predominant herbarium studies, he considered pigments to be ‘typically persistent in most reagents’, a feature characteristic of secondary pigmentation of the dead cytoplasm. Yet, he emphasized the observation that a faint yellowish pigment is seen in fresh material of *Hamatocanthoscypha uncipila* which becomes invisible in water-mounted herbarium material.

A striking brown secondary pigment in old herbarium material was noted in a few cases. For example, the type of *Hyalinia rectispora* var. *majuscula* (= *Hyalorbilia inflatula*) showed varying degrees of a deep ochre-brown pigment in the cytoplasm of the asci, but also the excipular cells (Fig. 100: a–b). This pigmentation was not observed in other material of the same species, whether old or recent, and is thus an inconsistent feature of herbarium material with enigmatic origin.

Pigmented dead cytoplasm is a common feature of fungal genera that have a strikingly pigmented exudate or gel (e. g., *Chlorociboria*, with a blue-green dead cytoplasm). In the

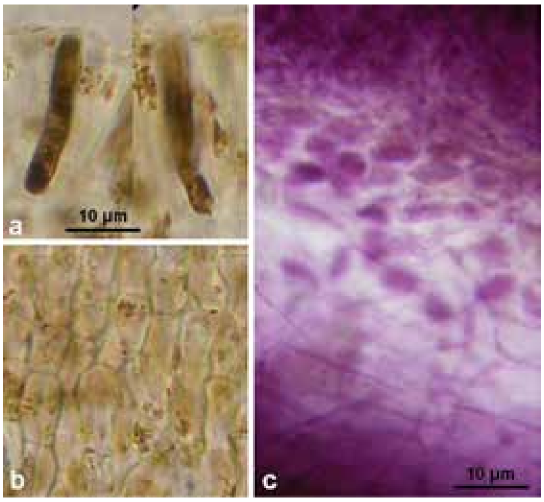

Figure 100: Secondary pigment in cytoplasm of asci (**a**), ectal (**b**) and medullary excipulum (**c**). — **a–b**. type of *Hyalinia rectispora* var. *majuscula* (= *H. inflatula*), examined ~90 years after collecting (in KOH); **c**. *Lilapila oculisporella* (in PVA, H.B. 7063a).

Orbiliomycetes, those species with a dark olivaceous exudate show a pale olivaceous pigmentation of the dead cytoplasm (ochre-brown in KOH), and in *Lilapila* dead cells may contain a bright lilaceous cytoplasm (Fig. 100: c). The effect might be explained as follows: under physiological conditions, a hyaline precursor molecule in the living hyaline cytoplasm is exuded through the cell wall and gets coloured outside. When the cells die, this precursor molecule becomes coloured also in the cytoplasm. According to Baral (1992: 372), the cytoplasm of fungal cells outside the vacuoles is generally colourless in the living state, except for lipophilous pigments and carotenoid crystals. The pigment in crystalloid SCBs of *Orbilia* represents a further exception of this rule.

Function of pigments. The function of exudate that carries a dark pigment could be seen in the longevity of dark-coloured apothecia, which usually grow at sun-exposed habitats and might need a strong protection against ultraviolet light. However, dark pigments are quite a rare feature in *Orbilia*, whereas reddish pigments are the most typical colours of desiccation-tolerant species of that genus. Dark pigments are more frequent in other genera of inoperculate discomycetes that belong to different orders and classes (e.g., *Claussenomyces* s.auct., *Durella*, *Patellaria*, *Sclerococcum*). Although all these genera form their apothecia under xeric conditions, the exposure to light varies strongly and includes also rather shaded situations. Differences in the desiccation tolerance between light- and dark-coloured species of *Orbiliomycetes* could not be found. Dark pigments are thus no prerequisite for either longevity, desiccation tolerance, or exposure to a high strength of illumination. Like the dark pigments, yellowish-reddish pigments in *Orbilia* are also often located in the exudate. Due to their frequency in desiccation-tolerant species of *Orbilia*, we assume a filter function against ultraviolet light for both dark- and light-coloured exudate, considering the fact that the life span of apothecia in semiarid areas undoubtedly lasts several years (see p. 158).

Intracellular pigments (carotenoids and pigmented SCBs), however, can hardly serve as a protection against UV, because they generally occur in the lower part of paraphyses and in the region of the marginal ectal excipulum. Their function could be to attract invertebrates which might play a role in ascospore dispersal. Particularly species with bright orange disc and white hairs might well have a function similar as showy flowers of higher plants.

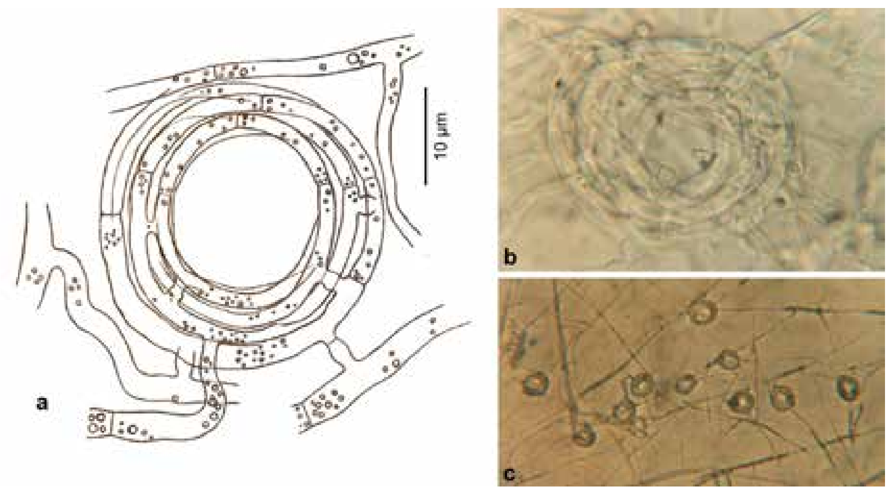

Figure 101: Coiled aerial hyphae formed in pure culture (MEA). — **a**. *O. aurantiorubra* (H.B. 5041); **b–c**. *Orbilia eucalypti* (H.B. 5023a).

CULTURAL AND ANAMORPH CHARACTERISTICS

Observations in pure culture

Isolation from ascospores. Spore discharge from fresh, desiccation-intolerant apothecia of *Orbiliomycetes* generally starts within a few minutes or hours, whereas discharge from rehydrated, desiccation-tolerant apothecia was observed within (0.5–)1–4 days. When subjected to vibration and slight heating, discharge often occurred within about 15–30 min (P. Perz pers. comm., see p. 11). Ascospores of *Orbiliomycetes* are ejected as a cluster, i.e., all spores of an ascus stick together and remain so on the agar surface (see p. 60–61). Germination takes place one or a few days later. Yet, for reasons unknown to us, the ascospores often germinated only tardily or not at all on the used media (mainly CMA:2 and CMA:4), e.g., in most of the tested species of *Hyalorbilia*, or in *Orbilia xanthostigma*, in which the spores germinated only after several trials. Also Pfister (2015) noted for *Hyalorbilia* ‘only a few reports of successful cultivation’, whereas in *Orbilia* he observed that ‘spores germinate quickly, and growth is often luxuriant on substrates containing glucose’.

Mycelial characters. Under the light microscope, mycelial hyphae are hyaline, ± sparingly septate, thin-walled, smooth, ca. *2–6(–8) µm wide, branched and anastomosing. Those hyphae being immersed in agar are often flexuous. The cells usually contain some minute guttules (LBs), sometimes also larger ones in greater abundance. Aerial mycelium was abundant in series *Arthrobotrys* but usually sparse or absent in all the other series and sections of *Orbilia* (Tab. 11; see also, e.g., Chen et al. 2007b, c), including all desiccation-tolerant taxa, and also in *Hyalorbilia*. A thin or sometimes 0.5–2.5 µm thick mucilaginous sheath that stains lilac in CRB covers the aerial or immersed hyphae (see p. 97–98).

Coiled aerial hyphae were rather frequently observed in our pure cultures of *Orbilia*, e.g., in *O. aurantiorubra*, *O. eucalypti*, or *O. menageshae*, often in great abundance (Fig. 101). The hyphae form ring-like structures lying on the agar surface, and superficially resemble ring traps. Their outer diameter lies in the range of ~(20–)25–50(–65) µm and their inner diameter ~15–30(–40) µm. The hyphae are *1.5–3(–4) µm wide and perform about 3–8 turns, being finally connected by a few to many anastomoses. Tarjan (1961: fig. 1ah, as ‘spiral mycelial ramifications’) observed them in several nematophagous fungi, such as *Dactylellina drechsleri*, and considered them as ‘purely vegetative and wholly without nematode-trapping ability’. Rubner (pers. comm.) obtained them in virtually every culture of nematophagous and also non-nematophagous orbiliaceous anamorphs.

Observations by one of us (G.M.) suggest that coiled aerial hyphae originate from long, erect hyphae growing vertically from the agar. These hyphae instantaneously coil down to the agar surface when touched or otherwise disturbed. A still air with high humidity

Table 11. Cultural characteristics in 48 investigated strains of 41 species from different series and sections of *Orbilia*, isolated mainly from ascospores [MEA 2 %, under artificial light-dark and temperature change (20/12 °C), each lasting 12 hours].

appears to be a precondition for their growth. Possibly, on the natural substrate they detach when touched by animals and adhere to them, thereby contributing to the dispersal of the species. Our observations showed that such coiled hyphae may also occur in cultures of other, quite unrelated fungi. A figure of coiled hyphae in a helotialean species is found in Görke (1998: 302, fig. 125, *Phialocephala fortinii*).

Growth rates. Colonies of desiccation-tolerant species of *Orbilia* (anamorphs trinacrium-, dwayaangam-, dicranidion-, tridentaria-, descalsia-, vermispora-like) were generally slow-growing. A radial growth rate of ~0.2–0.9(–1.3) mm/day was noted on MEA 2%. Colonies of the desiccation-tolerant *Lilapila oculispora* and *L. oculisporella* showed a comparably low growth rate of ~0.37–0.43 mm/day (10–12 mm diam. after 2 weeks, 20–25 mm diam. after 4 weeks, on CMA:5). When grown on CMA:3 in a single Petri dish, the growth rate was much lower, but striking differences were observed between both species: after 2.5 months *L. oculisporella* formed a colony of 17–20 mm in diam., whereas *L. oculispora* only 8–10 mm. Possibly *L. oculispora* was inhibited by the mycelium of *L. oculisporella*.

Generally higher growth rates of ~0.6–2 mm/day on CMA, PDA, or MEA 2% at 20–25 °C were found in predominantly desiccation-sensitive species: in those of section *Orbilia* with dicranidion-like anamorphs, including the desiccation-tolerant *O. eucalypti* (see Tab. 11), in desiccation-sensitive species of *Hyalorbilia* (including *Vermispora*; Chen et al. 2007c, Harris 1985, Liu et al. 2005b, *H. polypori* in this study); in semiaquatic species of series *Helicoon* (*O. rosea* and *O. sarraziniana*, this study Tab. 11, Liu 2006, *O. yuanensis* in Qiao et al. 2015), and in series *Pseudotripoconidium* (Su et al. 2011c, Yu et al. 2011). In *Orbilia* spp. with arthrobotrys-, dactylella-, dactylellina-, drechslerella-, and gamsylella-like anamorphs, growth rates may attain the highest values observed: ~(0.7–)1.2–4(–6) mm/day, though sometimes only ~1 mm (Chen et al. 2007b, Liu 2006, Rubner 1996, this study Tab. 11). The highest growth rate was observed by us in *O. menageshae* (series *Arthrobotrys*) with 4–5.5 mm/day on MEA.

Rubner (1996: 26) found in her study on predacious hyphomycetes of the '*Dactylella-Monacrosporium* complex' that species forming adhesive networks (now placed in *Arthrobotrys*) grew faster than species with other trapping organs (at room temperature of 20–23 °C, but also at 15 or 30 °C). They showed the highest radial growth rates (up to 6.5 mm/day on CMA:2 at ~23 °C, though rarely only 2.2 mm/day (*A. eudermatus*). Those with unstalked or stalked adhesive knobs and/or adhesive hyphal branches (*Dactylellina*, *Gamsylella*) grew more slowly (1.7–3.3 mm), and those with constricting rings (*Drechslerella*) were the slowest (1.7–2 mm). At 15 °C a growth rate of only (0.8–)1.6–2.8 mm was noted in *Arthrobotrys* (*A. thaumasius*, '*A. rutgeriensis*', *A. eudermatus*), 0.7–1.4 mm in *Dactylellina* (*D. ellipsospora*, *D. lysipaga*, *D. mammillata*, *D. phymatopaga*) and *Drechslerella* (*D. effusa*). In conclusion, *Arthrobotrys* species grew distinctly faster at 30 °C compared to 15 °C, except for one strain of *A. eudermatus* which grew faster at 15 °C. *Dactylellina* species (except for *D. phymatopaga*) and *Drechslerella effusa* hardly grew at all at 30 °C but were slow-growing at 15 °C. Instead, *Dactylellina phymatopaga* grew fast at 30 °C but very slowly at 15 °C.

Colony colours. In desiccation-tolerant species of *Orbilia* with trinacrium-, dwayaangam-, dicranidion-, tridentaria-, descalsia-, or vermispora-like anamorphs and frequently reddish apothecia, colonies usually had a pale to bright cream to orange or salmon to pink colour (on MEA 2%, under artificial light, Tab. 11, Fig. 102). However, in several subgroups of *Orbilia*, the colony colour of a few species of sections *Lentiformes*, *Hemiorbilia*, *Habrostictis*, and *Orbilia* deviated in showing a pale salmon- to orange-brownish tinge. On the other hand, *O. patellarioides* with dark olivaceous apothecia produced a bright pink mycelium.

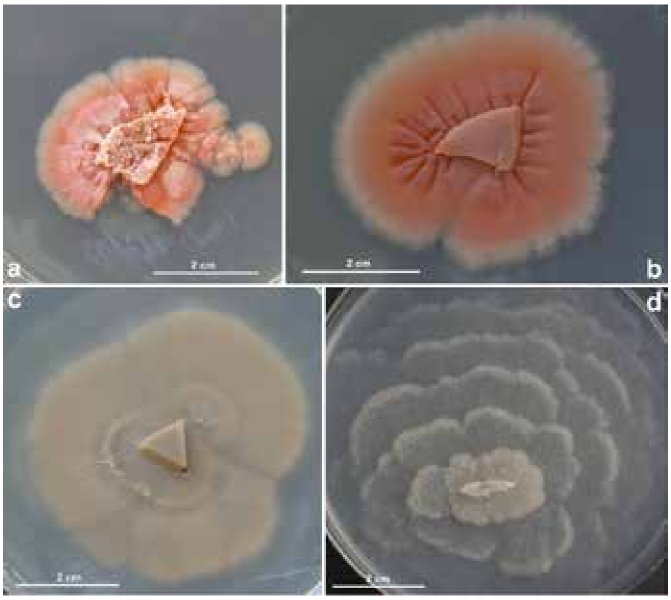

Figure 102: Colonies of desiccation-tolerant (**a–c**) and -sensitive (**d**) species of *Orbilia* in pure culture. — **a**. *O. pleistoeuonymi* (H.B. 6494a); **b**. *O.* cf. *vinosa* (H.B. 6748g); **c**. *O. carpoboloides* (H.B. 6639c); **d**. *O. sarraziniana* (18.X.2012). **a–c** on MEA, **d** on CMA:2.

The colony colour of desiccation-sensitive species of *Orbilia* was ± hyaline, (very) pale cream (series *Orbilia* with dicranidion-like anamorph), but also pale rose to salmon(-orange), or reddish-brownish. In desiccation-sensitive species of *Hyalorbilia* the colony colour was white, sometimes becoming slightly yellowish or brownish with age (MEA 2%, OA, CMA, CMA:2, PDA).

Colonies with distinct concentric zones were observed by us only in *O. sarraziniana* on CMA:2 (Fig. 102: d), but also X.Z. Jiang (pers. comm., IVV: 25.VII.2008) obtained them in the closely related *O. luteorubella* on PDA.

Chlamydospores have never been observed by us in our cultures, although they were frequently described in the literature in many desiccation-sensitive *Orbilia* species (e.g., Drechsler 1937a, 1943b, 1950a, 1952; Rubner 1996: 13; Yu et al. 2011; Chen et al. 2007b; see also Jarowaja 1970: 342).

Chlamydospores were reported as occurring either singly or in long moniliform chains, terminally or intercalarily, with individual cells more or less isodiametric or elongated (~*7–30 × 7–20 µm), multiguttulate, with hyaline, ± thickened, smooth or warted walls. They serve as resting spores which are able to survive unfavourable conditions like drought or heat (Rubner l.c.).

No chlamydospores were so far seen by us in pure culture of any desiccation-tolerant *Orbilia*. However, in one such species (*O. occulta*) Y.Y. Shao observed small, subglobose, cells with ochraceous wall formed on short side branches. Despite its unusual colour it appeared that these structures do not represent a contaminant (Shao et al. 2018).

Formation of conidial state. Conidia developed rather frequently in our ascospore cultures. CMA:2 and CMA:4 were found to be the best among the used agar media for inducing the formation of conidial states. On WA conidia formation was moderate, and rare on MEA 2 %. Conidia usually appeared within one or some weeks. Yet, in species of section *Arthrobotrys* and sometimes also in series *Orbilia* (*O. dryadum*) they appeared already within a few days. Those species which failed to produce conidia on the agar media tested, also failed on water agar with sterilized fragments of decayed branches. Yet, conidia formation was stimulated when pieces of inoculated agar were flooded with distilled water (see p. 12). This method was successful in many desiccation-tolerant species of *Orbilia*, but also in the anguillospora-like anamorph of the semiaquatic *O. rosea*.

Out of a total of ca. 160 cultured species of *Orbiliomycetes* with known teleomorph which came to our notice, connections to an anamorph have been established in ca. 140 species (sometimes by molecular methods), ca. 45 of which have already been published (see Appendix 4 & Tab. 41). Most of them were gained from ascospore isolates in pure culture, but some from hyphae growing out of apothecia on the lid of a Petri dish (Tab. 12, for literature reports see also Tab. 41). In further 90 species connections could only tentatively be suggested based on conidia observed on the natural substrate.

Since the anamorph and teleomorph of a given species may, in our experience, occur both successively as well as simultaneously on the natural substrate, conidia can be found regardless of the presence of apothecia, and very often no conidia at all could be detected around the apothecia. Indeed we have several times found quite characteristic conidia which we were able to connect to a teleomorph (species or species aggregate) by its peculiar conidial morphology, although the apothecia growing there in association belonged to very different sections of *Orbilia*. Therefore, rarely observed associations of anamorphs and teleomorphs need confirmation by pure culture studies.

Formation of apothecia in pure culture. During our study on ~ 160 cultured strains of *Orbiliomycetes*, apothecia developed in pure culture only in two strains (*Orbilia flavida*, mature apothecia on WA in the presence of sterilized wood fragments; *O. alba*, immature apothecia on CMA:4 with or without sterilized wood fragments). No anamorph was formed in the *O. flavida* strain, whereas another strain of *O. flavida* produced conidia but no teleomorph.

Literature reports of apothecial production in *Orbiliomycetes* concern *Hyalorbilia erythrostigma* (Matsushima 1995, as *O. trinacriifera*), *Orbilia* sp. (Drechsler 1937a: 458, in a culture of *Arthrobotrys superbus*, see under *O. auricolor*), *Orbilia* sp. [Zachariah 1983, in a culture of *Drechslerella* (‘*Arthrobotrys*’) *dactyloides*], *Orbilia* sp. (as *O. coccinella*, anamorph *Arthrobotrys* sp., Guo et al. 2009b), *O. auricolor* (Guo et al. 2009a/b), *O. ?cardui* (Thakur & Zachariah 1989, as *Orbilia* sp.), *O. crenatomarginata* (Guo et al. 2009b), *O. dorsalis* (Yu et al. 2007b, Guo et al. 2009a/b), *O. elegans* (Rubner 1996, as *O. auricolor*), *O. oligospora* (Guo et al. 2009a/b, Zhang et al. 2011b), *O. rosea* (Descals et al. 1999), and *O. sarraziniana* (Guo et al. 2009a/b). Guo et al. (2009a) found that certain nitrogen (L-proline, L-tyrosine) and carbon sources (D-mannose, D-cellobiose) strongly stimulate the formation of apothecia. Zachariah (1983) discussed the possibility that auxotroph strains of predatory anamorphs, which need several amino acids for growth, especially histidine and methionine, are essential for the initiation of teleomorphogenesis. (see also p. 40, Sexual reproduction).

Table 12. Number of anamorph-teleomorph connections within *Orbiliomycetes* known at present (*in pure culture or from unsterile formation on lid of Petri dish, or by DNA comparison, literature reports included; **conidia observed on natural substrate). Numbers include undescribed (aff./cf.) taxa listed in Tab. S3, see also List of anamorph-teleomorph connections.

Tests with nematodes, rotifers and pollen

Formation of trapping organs. Living **nematodes** were added to 30 of our cultures (Tab. 13). In nine strains belonging to eight species the formation of trapping devices could be induced. Those 21 tested strains of *Orbiliomycetes* with brachyphoris-, dactylella-, dicranidion-, trinacrium-, vermispora-, and anguillospora-like conidia did not form any trapping devices when treated with nematodes.

In one species (*O. menageshae,* H.B. 9309b) with an arthrobotrys-like anamorph, sparse adhesive networks developed without the presence of nematodes. Also in *O. alba* (H.B. 9645a) adhesive knobs were spontaneously formed.

Our tests with **rotifers** (*Macrotrachela quadricornifera* and unidentified bdelloid rotifer) failed to induce trapping organs. The rotifers often increased in size by forming eggs, but we never observed a connection between fungal hyphae and eggs or adult rotifers. One reason of this negative result might be the low number of rotifer individuals. The tests were soon stopped because of considerable difficulties to maintain the rotifer culture.

In order to find out whether parasitism on **pollen** is a common feature of *Orbiliomycetes*, we started a study with living pollen grains of *Sambucus nigra* and *Corylus avellana*, which we added to 20 strains of 19 different species of *Orbilia.* In 13 of these species we found hyphae that formed haustoria in some of the pollen grains within 1–2 weeks (Tab. 14, see also Fig. 110).

However, not only orbiliaceous fungi are capable of parasitizing pollen (see also Magyar et al. 2017a). We tested cultures of four species of *Helotiales* (*Durella atrocyanea*, H.B. 7074; ‘*Hymenoscyphus*’ *salmanovicensis*, H.B. 6977; *Ombrophila janthina*, H.B. 7044; *Gemmina gemmarum*, H.B. 6883) and one of *Dothideomycetes* (*Rhizodiscina lignyota*, 20.V.2001). In those of *R. lignyota* (Fig. 110: k–m) and ‘*H.*’ *salmanovicensis* many infected pollen grains (*Corylus avellana*) were observed, whereas the other three species were negative. Obviously, the ability to infect pollen grains is not restricted to the genus *Orbilia*, but it appears to vary between species of a given genus or family.

Table 13. Strains of *Hyalorbilia* and *Orbilia* treated with nematodes in the present study (*Acrobeloides maximus* and unidentified spp.).

Taxonomic group	Species	Anamorph	Nematode	Desiccation tolerance	Formation of trapping devices

series *Drechslerella*	*O. orientalis* (H.B. 8146a)	drechslerella-like	unidentified	–	constricting rings
	O. bembicodes (H.B. 7165b)	drechslerella-like	unidentified	–	constricting rings
	O. polybrocha (H.B. 8317a)	drechslerella-like	unidentified	–	constricting rings

Morphology of the anamorph

Conidiophores. Conidiophores in pure culture develop scattered to abundantly as hyphal outgrowths from mycelial hyphae. They are thin-walled, smooth, hyaline, one-celled or sparsely septate, morphologically similar to the mycelial hyphae, and occur solitary or in loose fascicles. On the natural substrate, conidiophores emerging from mycelial or anchoring hyphae, or from the apothecial tissue were only occasionally seen, although detached conidia were frequently encountered. Conidiomata have never been observed in pure culture by us. Exceptional records on the natural substrate include synnemata in *Dicranidion fragile* (Seifert et al. 2011, pl. 300A, see under *O. eucalypti*, p. 1364) and a few species of *Arthrobotrys* (*A. stilbaceus*, Meyer 1958, Matsushima 1995; *Roigiella lignicola*, Castañeda Ruíz 1984; *A. dendroides*, Kuthubutheen et al. 1985, Yu et al. 2014), and sporodochia in association with *O. purshiae* (H.B. 7462a, see p. 467).

Table 14. Strains of *Orbilia* species treated in pure culture with pollen grains of *Sambucus nigra* and/or *Corylus avellana*. + = pollen invaded by mycelium, – = no invasion of pollen.

Depending on the group, conidiophore length encompasses a wide range of 1.5–20 up to 40–400(–600) µm. Long conidiophores (predominantly over ~50 µm) occur mainly in section *Arthrobotrys* (series *Arthrobotrys*, *Neodactylella*, *Dactylellina*, *Drechslerella*, *Gamsylella*), in series *Hyalinia* and *Xanthoguttulatae* p.p. of section *Aurantiorubrae*, and in series *Pseudotripoconidium* of section *Helicoon*, rarely in *Hyalorbilia*. Anamorphs with long conidiophores and their teleomorphs are desiccation-sensitive, i. e., they require a protected environment of still air and continually high humidity. Short conidiophores (up to ~50 µm) were observed in sections *Lentiformis*, *Hemiorbilia*, *Aurantiorubrae*, *Habrostictis*, *Orbilia*, and *Helicoon* (p.p.), exceptionally in series *Neodactylella* of section *Arthrobotrys*, also in most species of *Hyalorbilia* and all of *Lecophagus*. They are typical of desiccation-tolerant species. Anguillospora-, vermispora-, and helicoon-like anamorphs reported in series *Helicoon* vary in conidiophore length between short and medium long, although these taxa are adapted to hygric, semiaquatic habitats. Also some ± desiccation-sensitive taxa of section *Orbilia* with dactylella- and dicranidion-like anamorphs (*O. dryadum*, *O. battenii*, *O. cejpii*, *O. fissilis*, *O. tremulae*, *O. leucostigma*/*xanthostigma*) were found to have a conidiophore length of only (1.5–)7–50(–105) µm.

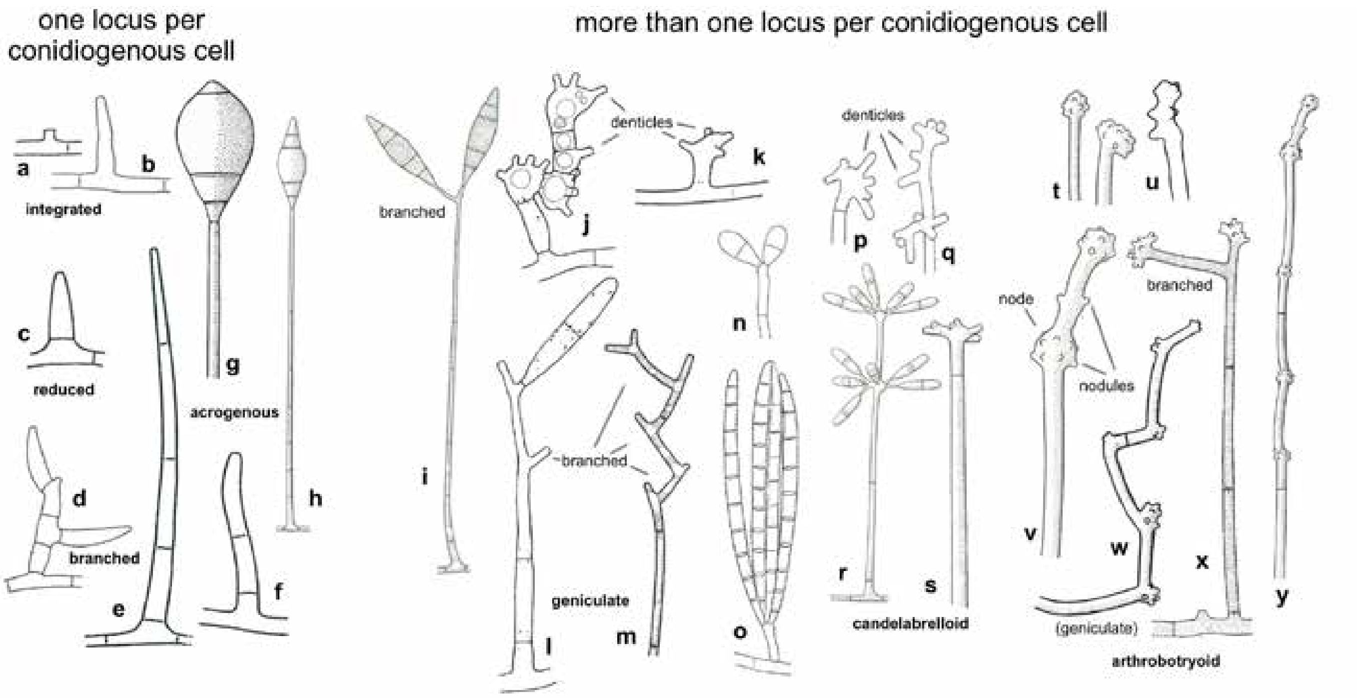

Figure 103: Conidiophore morphology: different types of conidiophore tips in regard to branching and conidiogenous loci (mainly according to Jarowaja 1970, Rubner 1996, and Seifert et al. 2011). — **a–h**. conidiogenous cells with one locus; **i–y**. conidiogenous cells with several loci (sympodial); **a–d**, **f**, **j–k**, **o**. conidiophores short; **a–c**. conidiophores one-celled, integrated (non-septate) or reduced (with one basal septum); **e**, **g–h**. conidiophores long and unbranched (acrogenous); **m**, **w**. geniculate upper part of conidiophore (knee-like branching of the conidiogenous cells); **n–o**. conidiophore tip not swollen, without nodules or denticles; **p–s**. conidiogenesis from aggregated denticles (candelabrelloid); **t–y**. conidiogenesis from aggregated nodules on ± swollen nodes (arthrobotryoid), nodes either singly at the conidiophore tip, or at intervals. **— a**. *Trinacrium incurvum* (Matsushima 1980); **b**. *Dicranidion ontariense* (Matsushima 1984); **c**. *D. gracile* (Matsushima 1971); **d**. *D. fragile* (Matsushima 1975); **e**. *D. tenue* (Matsushima 1993); **f**. *D. parapalmicola* (Matsushima 1981); **g**. *Drechslerella bembicodes* (Drechsler 1937a); **h**. *Dactylellina ellipsospora* (Drechsler 1937a); **i**. *D. haptotyla* (Drechsler 1950a); **j**. *Orbilia pleistoeuonymi* (H.B. 6494a); **k**. *Trinacrium gracile* (Matsushima 1975); **l**. *O. epipora* (H.B. 8153); **m**. *Dactylella rhopalota* (Drechsler 1943b); **n**. *Arthrobotrys flagrans* (Cooke 1969); **o**. *Lecophagus muscicola* (Barron et a. 1990); **p**, **s**. *A. musiformis* (Drechsler 1937a); **q**. *A. thaumasius* (Drechsler 1937a); **r**. '*Dactylellina*' *entomopaga* (Drechsler 1944b); **v**, **y**. *A. oligosporus* (Drechsler 1937a); **t**. *A. cladodes* (Drechsler 1937a); **u**. *O. auricolor* (H.B. 5058); **w**. *A. superbus* (Drechsler 1937a); **x**. *A. macroides* (Drechsler 1944a).

Long conidiophores are ± straight in their lower part, sparsely septate, with the septa often more aggregated near the base. Usually, conidiophores get gradually narrower from base towards apex, but may also show short to long cylindrical parts. Short, one-celled conidiophores may rarely be slightly capitate or dumbbell-shaped (*Lecophagus*, Fig. 103: o). Conidiophore width in the lower part is 1.5–9 µm, rarely up to 7–14 µm (*Lecophagus* p.p.). In some species the conidiophores are entirely reduced, consisting merely of an intercalary conidiogenous denticle inserting as a lateral protuberance on a mycelial hypha (Fig. 103: a–b).

Conidiophores may either be unbranched, or they are branched in the lower, middle, or upper part. Branching in the lower and middle part is considered to be of low taxonomic value (Rubner 1996: 9), whereas branching in the upper part, and particularly shape and arrangement of the conidiogenous loci have some taxonomic importance. Four main types of conidiophore apices can be distinguished within the nematophagous species: acrogenous, geniculate, candelabrelloid, and arthrobotryoid (Fig. 103: g–h, l–m, p–s, t–y). These types and terms were used in the past for the distinction of different anamorph-typified genera within the predatory taxa (Jarowaja 1970, Rubner l.c.). Today, these morphological types are considered to be stable only at the species level or within small groups of closely related taxa, and some variation and intergradations may even occur within a species.

Conidiogenesis. In all studied species of *Orbiliomycetes* conidiogenesis is found to be holoblastic: conidia are formed as hyphal outgrowths from the conidiogenous loci, thereby all wall layers of the conidiogenous cell contribute to the conidial cell wall (see also Rubner 1996: 11). The conidia strongly enlarge before a basal septum is formed. Conidial secession is always schizolytic, i. e., conidia separate by disintegration of the middle lamella of the septum between conidium and conidiophore, so that half of the septum remains at the conidiogenous locus. Each locus is able to produce only one conidium.

Conidial production is either monoblastic, i. e., a conidiogenous cell has a single conidiogenous locus (Fig. 103: a–h), or polyblastic when there are multiple conidiogenous loci per conidiogenous cell. Polyblastic conidiogenesis occurs more or less sympodially, i. e., conidia are successively produced from the conidiogenous cell by continued growth of the main axis. In cases of a crowded arrangement of the loci at the conidiophore tip or on more or less swollen nodes, conidiogenesis tends to be synchronously, e. g., in *Arthrobotrys* p.p. and particularly in *Lecophagus*. Each conidiogenous locus is either at the tip of a small projecting branch which is called denticle (Fig. 103: j–k, p–s), or it appears after secession of the conidium as a short protuberance which is referred to as nodule (Fig. 103: t–y). Sometimes the conidia are sessile and the conidiogenous locus more or less invisible and then named scar (Fig. 103: n–o).

Electron microscopic studies of conidiophore tips confirm the holoblastic conidiogenesis in *Orbiliomycetes* (Morikawa et al. 1993: fig. 8, TEM, *Lecophagus longisporus*; Glockling & Dick 1994: fig. 10, SEM, *Drechslerella brochopaga*). Reports

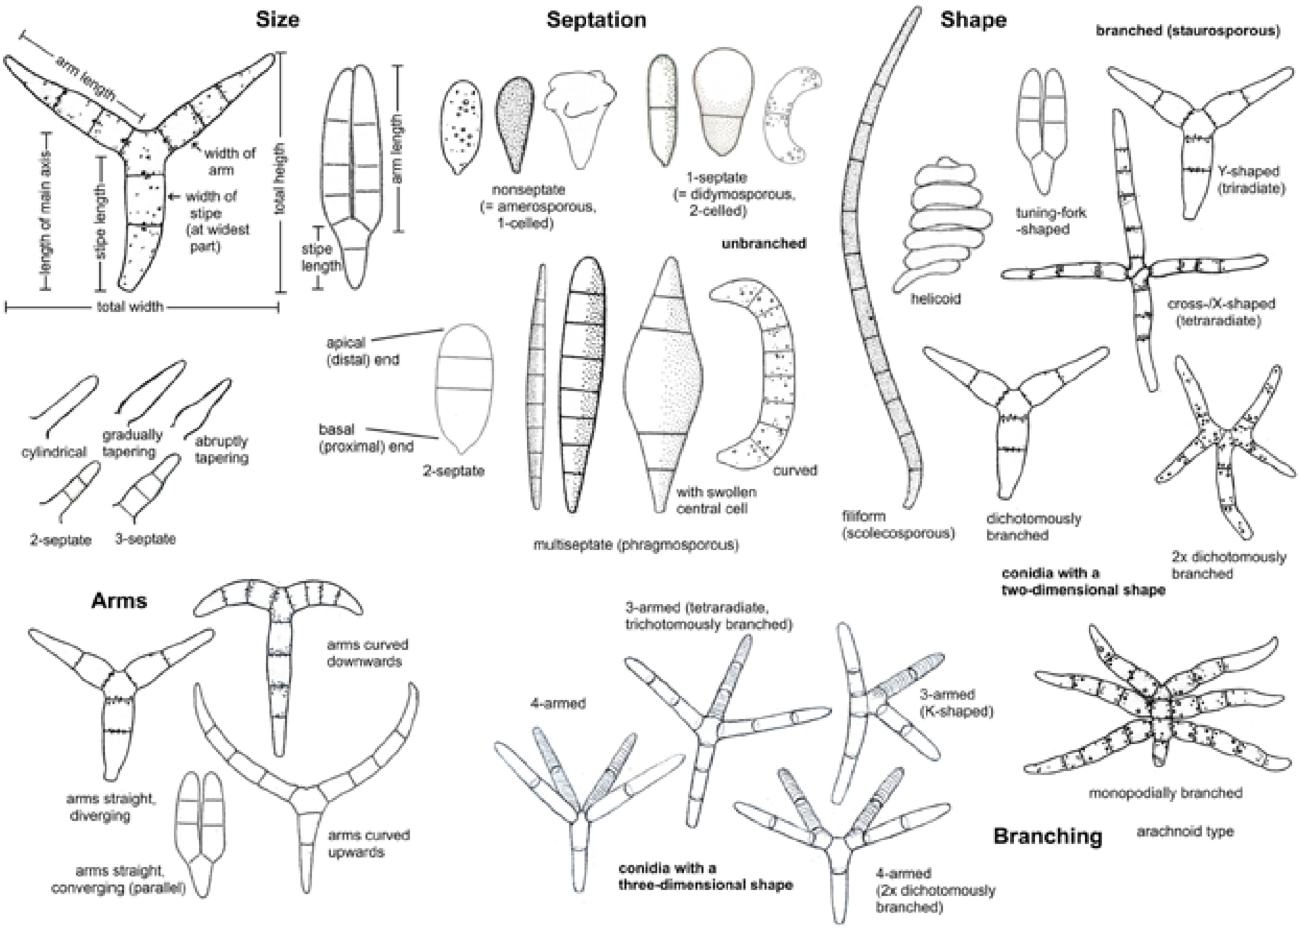

Figure 104: Morphology of conidia (see also Fig. 46 (ascospores) for further shapes).

of phialidic conidiogenesis in the class are either incorrect, e. g., in the recently described *Dactylella bolusanthi* Crous (see under *Orbilia* series *Neodactylella*, p. 1438), or originate from a contamination, as assumed by us in *Amphosoma persooniae* Crous (see under *Amphosoma*, p. 272).

Conidia. Conidia of *Orbiliomycetes* are always hyaline and thin-walled (illustrations of seemingly thick walls are due to plasma detachment in the dead state). At the base they are often somewhat truncate (place of detachment, called hilum) or possess a ± distinct small protrusion with a truncate base. A very wide range of diversity in conidial morphology is observed within the class, the different types being classified in earlier times according to their shape, branching, and curvature (Fig. 104). Similar as with the conidiophore types, different conidial types led in the past or even today to the distinction of different anamorph-typified genera. However, various studies – including ours – showed that conidial morphology is only in some cases correlated with the here presented infrageneric groups of *Orbilia*.

Unbranched conidia vary in shape between ellipsoid, (sub) cylindrical, clavate, obovoid, obpyramidal, fusiform, or top-shaped (see also Fig. 46, spore shape). They are mostly septate, either 1-septate (didymosporous) or with more septa (phragmosporous), rarely non-septate (amerosporous). Conidia which are more than 15 × longer than wide are termed scolecosporous. Branched (staurosporous) conidia are almost always multiseptate. They have usually one stipe and two, three or four (rarely more) arms, and are mainly Y- or T-shaped, more rarely ┼-, H-, K-, U-, V- or tuning fork shaped, thereby forming either 2- (flat) or 3-dimensional (spatial) structures. Conidia or conidial arms are usually straight or, more rarely, distinctly curved (Fig. 104).

Conidia with a spatial structure are frequent among those with more than two arms. The arms usually project at a maximum distance from each other (Fig. 104, 3–4-armed conidia). The natural orientation of the arms is easily overlooked when studying such conidia in a water mount because of the limited space beneath the cover slip and the motility of the arms at their hinge-like base.

The stipe has a truncate base which is formed during secession from the conidiogenous locus. Instead of the word stipe some authors prefer the term main axis which, however, in our understanding includes also the complete upper prolongation of the stipe (Fig. 104), although different authors use main axis differently. Controversy exists also concerning the question whether or not the basal septum of a branch (stipe, arm) is counted, which is complicated by the fact that the proximal septum may occur a varying distance away from the branching point, for which reason we have consistently counted all septa of a branch (see p. 10, Microscopic measurements).

A correlation between conidial branching and desiccation tolerance can be noted within *Orbiliomycetes*. Desiccation-sensitive species possess in almost every case unbranched, straight conidia (exception: *O. multiformis*). In some of these species one conidial cell is much larger than the others. Desiccation-tolerant species have often branched conidia; if unbranched, the conidia are usually more or less curved, and their shape is always ± cylindrical. In *Hyalorbilia*, however, unbranched conidia are generally straight or only slightly curved, often fusiform, irrespective of being desiccation-tolerant or not.

The size of unbranched conidia ranges from ca. 10–20 up to 100–200 µm in length and from ca. 2–3 up to 20–25 µm in width. Broad conidia may attain a maximum length of ca. 100(–130) µm, whereas longer conidia are only ca. 4–6(–10) µm wide. Branched conidia range from ca. 5–20 up to 50–100 µm in their total width.

The cytoplasmic contents of living conidia may show differences between the taxa. The cytoplasm often contains some minute, KOH-resistant lipid guttules (LBs), usually near the septa or the lateral walls, rarely large ones more in the centre of the cells (seen only in some species of *Orbilia* series *Helicoon* and all of series *Pseudotripoconidium*). Non-refractive vacuoles are commonly observed in conidial cells, either many small or a few large ones. One or a few small to large glycogen bodies occur in some taxa. These are only perceptible by their dextrinoidity (Fig. 91: d, Tab. 9), and were so far not observed in desiccation-tolerant species. Strongly refractive non-lipidic bodies (SCBs, Fig. 89: f) were observed in conidia of several *Hyalorbilia* species, which appear to be characteristic of brachyphoris-like anamorphs. They instantly disappear in KOH, and are not stained in $\mathrm{CRB_A}$. Similar bodies are typical of *Lecophagus*, where they are referred to as 'cubical bodies' because of their more or less angular shape, and where they also occur in the vegetative hyphae (Fig. 89: a–e).

In many species, conidia germinate quickly and also form anastomoses among each other, whereas in others germination was rarely observed and germ tubes soon stopped growing on agar. The direct formation of conidia from germinating conidia (microcyclic conidiation) was never observed by us with certainty (see also p. 113, Microconidia), although connections between conidia by anastomoses are sometimes interpreted in such a way.

Differences in conidial morphology between populations. Some variability in conidial size and shape was often noted between collections here referred to the same species. In some cases such variation might support separation into different species, whereas in others it is thought to represent natural variation. In extreme cases the obtained conidia strongly differed between isolates, although their teleomorphs were without any significant morphological deviation. In these cases the two conidial types never occurred mixed within a single strain. For example, in a number of collections referred to *O. ocellata* s.l. and *O. lentiformis* s.l., a group which forms an aggregate of unsharply delimited taxa, two different conidial types are formed in pure culture: some formed vermispora-like phragmoconidia while others formed trinacrium-like stauroconidia. However, these anamorphs were not clearly correlated with differences in the teleomorphs. Instead, strains of both collective species formed either only trinacrium- or only vermispora-like conidia. Our sparse molecular data indicate that about six taxa are involved (including *O. foliicola* and *O. subocellata*) which can hardly be recognized by their teleomorph alone (see Phyl. 8).

A comparable phenomenon of deviating anamorphs characterizes the very complex species aggregate around *O. auricolor*. Eight more or less distinguishable *Arthrobotrys* anamorphs have been found connected to teleomorphs with a rather invariable morphology that strongly resembles the holotype of *O. auricolor* (see p. 1530): *A. superbus* (Pfister 1994), *A. cladodes* var. *macroides* (≡ *A. macroides*) & *A. oligosporus* (Pfister & Liftik 1995), *A. cladodes* & *A. javanicus* (Liu 2006), *Monacrosporium psychrophilum* (≡ *A. oudemansii*) (Rubner 1996), *A. yunnanensis* (Mo et al. 2005a), and *O. menageshae* (present study). *A. oudemansii* (see under *O. elegans*, p. 1554) is very distinctive in acrogenously formed, broadly fusiform, 2–3-septate conidia with inflated middle cell. *A. yunnanensis* was only described from its microconidial stage but is conspecific with isolates with acrogenously formed, narrowly fusiform multiseptate macroconidia (see under *O. multiformis*, p. 1547). The unidentified *Arthrobotrys* state of *O. menageshae* is unique by its acrogenously formed, variable, obpyriform to fusoid, 0–3-septate conidia. The remaining five have similar ellipsoid to obovoid or obpyriform, (0–)1-septate conidia. Among them, *A. javanicus* (see under *O. javanica*, p. 1551) and *A. oligosporus* (see under *O. oligospora*, p. 1540) more or less sharply deviate from the remaining three in conidia with eccentrical septum and broader upper cell, the former also in candelabrelloid conidiophores. Because of the different anamorphs, Pfister & Liftik (1995) and Webster et al. (1998) concluded that *O. auricolor* is an aggregate of different species.

But even cultural results are not always convincing: we have grown cultures from three European collections and observed anamorphs also on the natural substrate of some other samples here referred to *O. auricolor*. They were at first tentatively referred to *A. superbus* (?= *O. auricolor*) or to the very similar *A. cladodes* (≡ *O. cladodes*), in one case (Pl. 948: 5) somewhat resembling *A. oligosporus* (≡ *O. oligospora*), and no sharp separation was possible between them. Due to a more or less strong similarity among these three *Arthrobotrys* species and due to our observation that a certain variation often occurs within a single strain, we concluded that in this case a morphological differentiation is not practicable, contrary to the opinion of Pfister (1994) and Pfister & Liftik (1995). However, molecular data on this group suggest that even strains with a very similar anamorph may belong to different taxa (see p. 1533), and the *O. auricolor*-complex is still far from being solved.

Different conidial types within a species (conidial dimorphism). Strong variation in conidial morphology is frequently observed within a specimen. Particularly in cultures we often recognized two, rarely three or more different conidial types which were even referable to different form genera. For example, a small number of unbranched phragmoconidia more or less regularly occurred among the abundant branched trinacrium-like conidia in a number of species: e.g., in *O. flavida* (Pl. 172: 4), *O. foliicola* (Pl. 168: 1), *O. microserpens* (Pl. 740: 4), *O. ocellata* (Pl. 164: 7), *O. pleiovitalbae* (Pl. 710), *O. spermoides* (Pl. 358: 4), *O. vermiculati* (Pl. 689: 1), and *O. vinosa* (Pls 257: 5; 258: 1). Likewise, in *O. eucalypti* (H.B. 6213), *O. xanthostigma* (H.B. 6745), and *O. tremulae* (H.B. 6963a) a more or less small number of phragmoconidia occurred among the prevailing tuning fork shaped dicranidion-like conidia, and rarely also a few 3-armed conidia of this type. Comparable observations of unbranched conidia have been reported in *Dicranidion* and *Trinacrium* by Berthet (1964a), Tubaki & Yokoyama (1971), Butterfield (1973), Matsushima (1981, 1993, 1995), Magyar & Révay (2008), and others.

Four different conidial types were obtained by us in pure culture of *O. microsoma*: unbranched phragmoconidia, 2-armed conidia (triradiate, trinacrium-like), and 3-armed conidia (tetraradiate, descalsia-like), besides a fourth type with 4-armed

¥-shaped conidia. Comparable cases were observed in series *Hemiorbilia*, e.g., in *O. subaristata* and *O. aristata*: 2- and 3-armed conidia (trinacrium- and descalsia-like) were recorded in pure culture and on the natural substrate, whereas 4-armed dwayaangam-like conidia only on the natural substrate. Similar observations on three to six different conidial types within a strain, comprising dicranidion-, trinacrium- and dwayaangam-like conidia, were made by Drechsler (1938), Ando (1992), Ando & Tubaki (1984b), Matsushima (1981), and Barron (1991c).

Microconidia. Another kind of conidial dimorphism occurs predominantly in nematode-trapping species of section *Arthrobotrys* (Tab. 15), and here especially in taxa of series *Arthrobotrys* and *Drechslerella*. Besides the normal 'macroconidia' which have one or more septa, distinctly smaller, mostly 0–1-septate conidia with often very different shape are formed, which are currently referred to as 'microconidia' (or 'secondary conidia'), sometimes also as 'spore-like bodies' or 'conidioid bodies' (Drechsler 1940). Their size in section *Arthrobotrys* lies in the range of 10–30(–40) × 3.5–10(–15) µm. Either length or width, or both, are distinctly below that of the associated macroconidia, and their volume is about 1/20–1/3 of those. Microconidia are often cylindrical but also long-ellipsoid to clavate. They are formed on similar but mostly shorter conidiophores, which sometimes emerge directly from germinating macroconidia. Microconidia may germinate to produce small trapping organs (*O. brochopaga*, Barron 1979a, as *Drechslerella*), or they produce shorter secondary microconidiophores and microconidia (*O multiformis*, series *Arthrobotrys*, Dowsett et al. 1984, as *Dactylella*). Although usually sharply delimited from macroconidia, cases of unsharp differentiation with intermediate conidial types occur (see Tab. 15).

According to Barron l.c., microconidia in predatory fungi occur 'sporadically and most frequently in association with macroconidia', and were solely obtained in the presence of nematodes. However, in the ex-type culture of *Gamsylella gephyropaga* (CBS 228.37), Rubner (l.c., as *Monacrosporium*) found only microconidia. Apparently, the ability to produce macroconidia was lost in this case. Two cases are worth mentioning here, in which two newly described anamorphs gained from ascospore isolates formed only microconidia, whilst in different strains, which are identical in the ITS region, both micro- and macroconidia were observed. *Drechslerella yunnanensis* was described by Yu et al. (2009b) gained from a teleomorph very similar to *O. orientalis*, but in another strain gained by Liu (2006) also macroconidia occurred (as *O. yunnanensis* in the present study, see Pl. 1014: 2). Likewise, *Arthrobotrys yunnanensis* was described by Mo et al. (2005) gained from a teleomorph that resembles *O. auricolor*. Only microconidia were observed, but molecular data indicates that other strains, which also form macroconidia, are conspecific (as *O. multiformis* in the present study, see p. 1549).

In *A. scaphoides* Peach (1952) obtained microconidia in addition to macroconidia, but in other isolates of the same species they were not observed (Zhang et al. 2010). Likewise, Rubner (1996) figured microconidia in *Monacrosporium*

Table 15. Species of section *Arthrobotrys* in which microconidia have been observed: 11 species of series *Arthrobotrys* (green), three of series *Dactylellina* (blue), one of series *Gamsylella* (red), and 11 of series *Drechslerella* (yellow). elegans (≡ *A. oudemansii*) only in one out of three strains. Due to their inconsistent presence, microconidia are considered to be of limited taxonomic value (Barron l.c.). For *Vermispora cauveriana* Rajashekhar et al. (1991) reported small aseptate microconidia formed on long and thin germ tubes that emerge from the large multiseptate macroconidia. The species is, therefore, perhaps misplaced in *Vermispora* (= *Hyalorbilia*) (see Pl. 24: f).

Within section *Helicoon* of *Orbilia*, short oligoseptate microconidia were reported for the anguillospora-like anamorph of *O. rosea* by Pfister (1997), Webster & Descals (1979), and Descals et al. (1999, & Pl. 528: 1, 4–5). Yet, these microconidia were stated by Descals et al. (1999) to be not sharply differentiated from the scolecosporous macroconidia, rather they seem to form a continuum. Descals & Moralejo (2001: 16) argued that they might combine a spermatial and dispersive function. Also in *O. yuanensis* (0–)1–3-septate microconidia were seen (Qiao et al. 2015, & Pl. 546: 7). Similar but curved microconidia were observed in the present study in the helicoon-like anamorph of *O. luteorubella*, deviating from the coiled barrel-shaped macroconidia in showing max. 1–2 coils (see Pl. 536: 1).

In *O. carpoboloides* (section *Habrostictis*) we obtained small 0–1-septate, C-shaped conidia in pure culture, in concordance with Haines & Egger (1982, as *O. piloboloides*). Although no macroconidia were seen in these strains, we believe that the species is able to form phragmosporous C-shaped macroconidia, which were repeatedly seen by us on the natural substrate. *O. subocellata* (section *Lentiformes*) formed small 1(–3)-septate conidia together with large 3–6-septate ones in pure culture of a paratype, while the holotype culture produced only the large conidial type (see Pl. 166). The two types of conidia did not clearly overlap in size.

Phylogeny of anamorphs. Similar as stated for the ascospores, a logical phylogenetic system of conidial shapes would start from broadly ellipsoid to ovoid, non-septate conidia which might have evolved fusoid, or cylindrical conidia in which one or more septa are included (phragmoconidia). Cylindrical conidia may have further developed from straight to curved (vermispora-like) and/or increased their length/width ratio by forming long and slender, anguillospora-like conidia.

However, the phylogeny of conidial shape undoubtedly took also the opposite direction within *Orbiliomycetes*. This is particularly apparent in *Orbilia* section *Arthrobotrys*. Here the plesiomorphic conidial shape is unquestionably a straight phragmoconidium as represented by the non-nematophagous series *Dactylella*, because this group always formed the first branch in phylogenetic analyses, and similar conidia occur in various other groups of *Orbiliomycetes*. Conidia of the more advanced series *Arthrobotrys*, *Dactylellina*, *Drechslerella*, and *Gamsylella*, which are characterized by nematophagy and desiccation-sensitivity, appear to have evolved from cylindrical to ellipsoid-ovoid or fusiform, and from multi- to biseptate.

In various groups of non-nematophagous, desiccation-tolerant taxa, different types of branching led to a high diversity of staurosporous conidia with a varying number and length of usually multiseptate, sometimes curved arms. A single branch resulted in 2-armed conidia with the shape of a tuning fork (dicranidion-like) or a Y (trinacrium-like). Another branch (secondary dichotomy) of each of the two branches leads to dwayaangam-like conidia, if one of each secondary arm points downwards, to tree-shaped conidia if all arms point upwards, or to psammina-like conidia if the many arms lie in one plane and point in all directions.

Instead of four arms formed by two successive dichotomies, more than two arms may be formed synchronously by a single branching event at the apex of the main axis. Such conidia are always 3-dimensional and often trichotomous but also with more arms, and are referred to as tridentaria-like. A further type forms lateral pairs of 'legs' from a septate main axis reminiscent of spiders.

The evolutionary pathway may actually have started from unbranched to higher-branched. Drechsler (1937) argued in a similar direction when stating that, starting from an unbranched conidium like in *Dactylella*, a single bifurcation results in two-armed conidia like those of '*Pedilospora*' (= *Dicranidion*) *dactylopaga*, and after a second bifurcation in conidia as in '*Triposporina*' (= *Tripoconidium*) *aphanopaga*. On the other hand, tree-like conidia with the highest known (tertiary) dichotomy are characteristic of a monotypic genus with a very basal phylogenetic placement (*Mycoceros*), and also trinacrium-like conidia are found in different basal genera.

Conidiophore length shows a correlation with desiccation tolerance in that long and slender conidia are only found in desiccation-sensitive taxa, mainly in *Orbilia* section *Arthrobotrys*, therefore, they are to be considered as apomorphic. The plesiomorphic conidiophore is an integrated conidiogenous cell or a very short hyphal branch. Conidiophores with apical branches and multilocular conidiogenous cells occur in various groups, so that evolutionary lines are difficult to assess. The arthrobotryoid type of conidiophores, characterized by swollen nodular conidiogenous cells, appears to have evolved within series *Arthrobotrys* from the denticulate type, but since both types occur scattered in various clades of that series, the arthrobotryoid type appears to have emerged polyphyletically.

Differences between pure culture and natural substrate. Conidia collected from natural substrate were sometimes larger or higher-branched than those gained in pure culture. For example, in field samples we sometimes found longer arms and stipes in the trinacrium-like conidia of *O. microserpens* (Pl. 740: 4) and *O. vinosa* (Pl. 258) and in the dicranidion-like conidia of *O. leucostigma*/*xanthostigma* (Pl. 876).

In *O. aristata* we obtained in pure culture conidia with three arms (descalsia-like), whereas on the natural substrate occurred in addition conidia with two arms (trinacrium-like) and conidia with mainly four arms (dwayaangam-like) (Pls 342–343). Similarly, Butterfield (1973) and Matsushima (1975) observed larger conidia from natural substrate in *Dicranidion fragile*, and Matsushima (1987) in *D. ontariense.* However, conidia collected from the natural substrate cannot be attached with final certainty to a teleomorph growing closely adjacent, because *Orbilia* species with similar anamorphs often grow in association and do not always simultaneously form a teleomorph.

Rubner (1996: 26) observed that cultural conditions may influence conidial characters. In *Arthrobotrys oudemansii*, length/width ratio of conidia formed in pure culture depended on the temperature at which they were incubated: conidia were slightly wider and sometimes also longer at 25 °C compared to 15 °C. In four tested species, conidia were often longer and/or wider when grown on CMA:2 compared to water agar to which nematodes were added.

Table 16. Seven main types of trapping organs observed in *Orbiliomycetes*. * = *Hyalorbilia quadridens*; ** = *Dicranidion dactylopagum*, *Tridentaria glossopaga*, *T. tylota* (relationship of these three species within *Orbiliomycetes* uncertain); *** = '*Dactylella*' *passalopaga*.

Trapping organs. During our study we had the albeit rare opportunity to examine several types of trapping organs, either in axenic culture or in the natural environment. Our observations include unpublished or little-known data and a critical study in regard to living cells and their behaviour in killing agents, hence it seems justified to provide here a detailed report on trapping organs in *Orbiliomycetes*.

Several groups of *Orbiliomycetes* have developed different types of trapping organs in order to attract, catch and digest small invertebrates. Within *Orbilia*, all members of four series of section *Arthrobotrys* (*Arthrobotrys*, *Dactylellina*, *Drechslerella*, *Gamsylella*) are known to produce such organs of capture. The fifth series of this section (*Neodactylella*) is characterized by the absence of trapping organs. In all the remaining groups of *Orbiliomycetes* trapping devices are unknown, with only a few exceptions. Sporadically, trapping organs were reported in species with tridentaria-, dicranidion-, and brachyphoris-like anamorphs, and they are characteristic of members of *Lecophagus*. Two species were found to be predacious although they did not form conspicuous trapping organs (*Tripoconidium aphanopagum*, *Tridentaria carnivora*). Besides those fungi being predacious on motile prey, some taxa parasitize non-motile stages of invertebrates (eggs), or they form haustoria in spores and pollen (see p. 144–146).

Trapping organs, especially adhesive networks of series *Arthrobotrys*, are usually formed in pure culture in response to living nematodes. However, Nordbring-Hertz (1968) has shown that in *A. oligosporus* they are also formed in the presence of living earthworms, fly-larvae, or springtails. Members of the other three nematophagous series (*Drechslerella*, *Dactylellina*, *Gamsylella*) are generally capable of forming traps spontaneously (Gray 1987).

The first report of an orbiliaceous trapping organ appears to be that by Zopf (1888) who treated the adhesive nets of *Arthrobotrys oligosporus* (see Drechsler 1937a). About seven main types of orbiliaceous trapping organs can be distinguished (Tab. 16, for a survey see also Barron 1977, Rubner 1996, Scholler et al. 1999). According to molecular data, the different trap types are quite strictly diagnostic for the four nematophagous series of section *Arthrobotrys*. Usually, one species is able to produce only one type of trapping organ. However, in series *Dactylellina* about seven species simultaneously form two types, stalked adhesive knobs and non-constricting rings (Figs 174–176). In the aberrant *Dactylellina parvicollis* (a synonym of *D. phymatopaga*), stalked and sessile knobs are reported to occur with adhesive loops and columns (Figs 106: i–j; 175: d, i; Drechsler 1962; Jarowaja 1968a: figs. 1–22; Rubner 1996: fig. 44). Besides a certain variation in trap morphology and partial absence of certain types, this complicates a clear assignment to an anamorph-typified genus. Hypotheses on the evolution of these trapping organs can be found in Li et al. (2005), Yang et al. (2007, 2012a), and are discussed on p. 121 (Phylogeny of trapping organs).

All these organs of capture are generally formed as lateral, usually upward oriented outgrowths of the mycelial hyphae, but sometimes they may also arise from conidia, either directly or on short germ tubes (see Rubner 1996: 20). Except for those trapping organs that form regularly ring-shaped structures and trap the prey mechanically (constricting and non-constricting rings), apparently all exude an adhesive mucous substance being sticky to various invertebrates. This substance usually forms a thin film but in a few species a very copious sheath (Figs 106: c–e, 107: d–j). Nordbring-Hertz (1988) found that the adhesive substance contains lectins that show affinities to carbohydrates of the invertebrate cuticle with a rather high selectivity. A total of 17 adhesion-associated protein-coding genes were found in the *A. oligosporus* genome (Yang et al. 2014). The studies by Jansson & Nordbring-Hertz (1979) suggest that there may also be a substance that attracts the prey.

Regardless of their thickness, the mucous substance is invisible in water mounts under bright field illumination, therefore, even thick sheaths are easily overlooked and might exist in more species than hitherto known. The mucus can be visualized with CRB by staining lilac (Fig. 107: g–h), but hyphal surfaces of *Orbiliomycetes* generally stain so in that dye. Actually, all parts of an adhesive knob including the supporting hypha stain faintly to bright lilac, without any difference between head, stipe, and hypha. The assimilative hyphae inside the captured nematode did not stain, however, even when squashed out of the nematode.

Constricting rings are generally stated to be non-adhesive, but also here the wall surface stains pale lilac in CRB, while the supporting hyphae and stipes of these ring traps stain medium to deep lilac. Hence, the adhesiveness of a thin mucous layer is only demonstrated when an animal gets attached to it. When the adhesive substance is very abundant it can clearly be seen under the LM in water mounts, but only by using special techniques such as phase contrast, dehydration in ethanol, or staining with CRB. The thickness of such mucus strongly depends on its hydration rate: in water the mucus swells to a maximum diameter, whereas even in an atmosphere of rather high humidity it is quite contracted by showing a crumpled surface (Fig. 107: e, j).

Loop or ring traps are formed by the curved growth of side branches. In adhesive loops (arches and networks) the branch tip generally fuses with the hypha from which it emerged (Figs 106: m, u; 108: b, d), or with adjacent arches or columns (Fig. 106: o, v), rarely with its basal cell (Figs 106: t; 108: c). In contrast to loops, true ring traps are consistently formed by fusion of the branch tip with the lowermost ring cell and, in

Figure 105: **a–e**. constricting rings, in addition also with the upper cell of the stalk (Figs 109, 110: a).

At least in two main trap types (sessile and stalked adhesive knobs, non-constricting rings), the trapping organ may more or less regularly break from the hypha as a consequence of heavy struggling of the prey. In this way the knobs and non-constricting rings do function as diaspores, and contact of the nematode to further traps may occur (Fig. 109: f, Barron 1977, Rubner 1996: 14, 17, Nordbring-Hertz et al. 2011). In series *Dactylellina* sessile or sometimes stalked adhesive knobs are formed on the tip of conidia (Pl. 7: f–g, j–k), even when still attached to the conidiophore, and are thus able to attach to passing nematodes (Barron l.c.).

Apart from adhesive pegs, the course of events after capture is the same in all types of trapping devices: penetration of the cuticle by a narrow tube, and formation of an infection bulb (haustorium) from which assimilative hyphae grow into the prey. The complete consumption of the victim will be accomplished within ~12–24 hours, which may in some cases stay viable for most of this time. In the case of adhesive pegs and knobs in *Lecophagus* and *Hyalorbilia*/*Brachyphoris*, the infection usually takes place in the region of the mouth or the shell opening. The peg apex does not swell or only slightly, when the assimilative hyphae grow out directly from the apex of the peg. However, infection bulbs are produced when adhesive peg-like appendages grow out of conidia and attach to the cuticle away from the mouth region (*Lecophagus navicularis*, Tzean & Barron 1983: fig. 6).

TEM-investigations have shown abundant electron-opaque inclusions (vesicles) ~0.1–0.3 µm diam. near the periphery of the cytoplasm close to all those surfaces which have the potential to trap animals. These vesicles cannot be seen with the LM, and are thought to contain enzymes which disintegrate the host cuticle and digest its protoplasm (Heintz & Pramer 1972, Dowsett et al. 1984, Glockling & Dick 1994).

Trapping organs observed in the present study. In a collection of *Lecophagus muscicola* the trapping of rotifers by adhesive pegs could be observed (Fig. 105: b–d & Pl. 51). Adhesive columns of *Gamsylella gephyropaga* occurred once on the natural substrate in mixture with *O. alba* (H.B. 9051c). Stalked adhesive knobs were obtained in pure culture of *Orbilia rubrovacuolata* (Fig. 106: b) and *O. mammillata* (see Pl. 981 & IVV), and on the natural substrate we saw them in a few cases, e.g., emerging from the apothecial base of *O. mammillata*. A peculiar type of large adhesive knobs with lageniform heads (Fig. 107: d–j) occurred in abundance close to apothecia of *O. alba*. These rather robust organs of capture have very strong adhesive properties, and are adapted for trapping small arthropods. Sessile adhesive knobs were repeatedly seen on conidial cells of *Lecophagus vermicola* (Pl. 52) and *Haptocara* sp. (Pl. 53).

Adhesive networks were obtained by us in *O. auricolor* (Pl. 951: 1), *O. elegans* (H.B. 6972a, not figured), *O. scaphoides* (Pl. 974: 1), and *O. menageshae* (Pl. 965: 2), but we never saw them on the natural substrate. Non-constricting rings we have never obtained in our cultures, nor did we observe them with certainty in the natural environment. Constricting rings were formed in pure culture of *O. orientalis* (H.B. 8146a, IVV) and *O. polybrocha* (Fig. 110: i–j, m–q, Pl. 1005). On other occasions we found them on the natural substrate (e.g., *Drechslerella bembicodes*, Fig. 110: a). A survey on the different types of trapping organs is shown in Tab. 16. A detailed discussion of each type with illustrations of its characteristics is given below.

Adhesive pegs (Fig. 105: a–e). This type of trapping organ is reported within the *Orbiliomycetes* mainly for the genus *Lecophagus* (see p. 238), but the term adhesive peg is also in use for similar organs in the *Zoopagales* ('*Zygomycota*'), with which *Lecophagus* has previously been confused, and small adhesive peg- or knob-like structures occur in *Hyalorbilia* (treated below under adhesive knobs). The trapping organ in *Lecophagus* consists of a single cell which is either cylindrical or often ± lageniform with a bulbous base. The apex often forms a slightly enlarged roundish head. The pegs are 10–24 µm long and in their lower part 3.5–12 µm wide. The adhesive substance is apparently restricted to the apex, but it is not even perceptible under the TEM (see Morikawa et al. 1993: figs 2, 7; Fig. 105: e). The living trap cells contain small refractive cubical bodies similar as the other cells of the fungus (Fig. 105: a–b). The peg apex may sometimes proliferate to form a new peg (Dick 1990).

Adhesive pegs of *Lecophagus* are known to trap rotifers and tardigrades. In contrast to most of the other trap types and

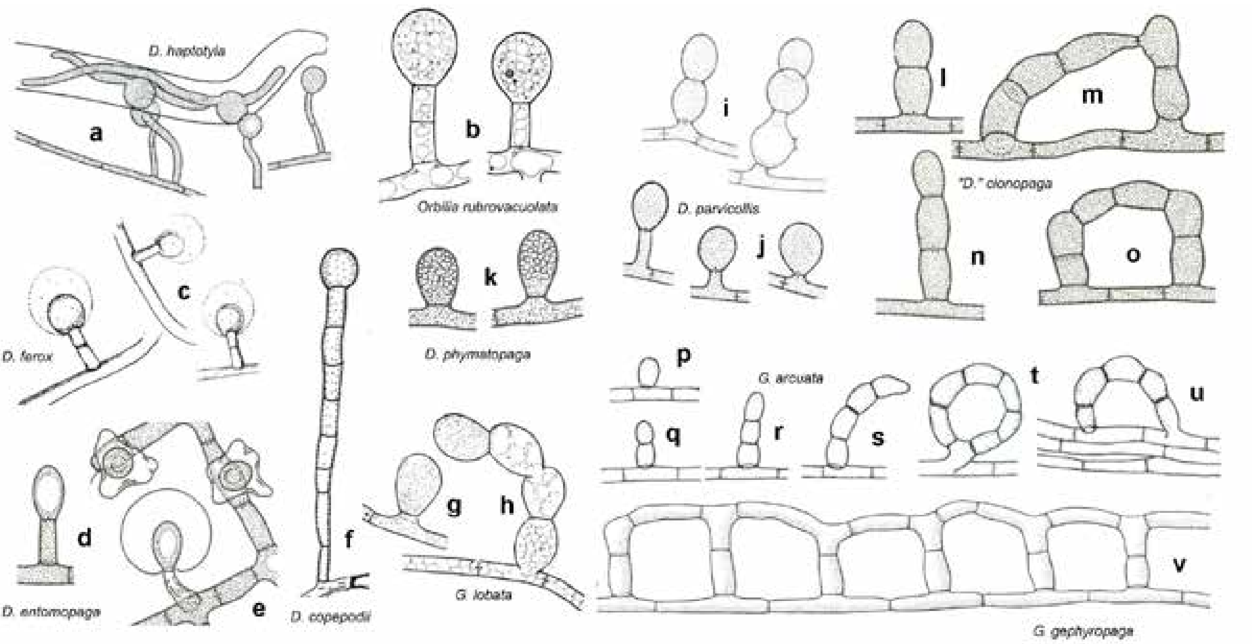

Figure 106: Adhesive knobs and branches (columns and loops) in series *Dactylellina* and *Gamsylella* of *Orbilia* section *Arthrobotrys*. — **a**. with trapped nematode; **a–f**, **j** (left). stalked adhesive knobs (**c–e**. with thick adhesive mucilage); **g**, **k**, **j** (right), **p**. sessile adhesive knobs; **h**, **i**, **l**, **n**, **q–s**. superimposed (proliferating) knobs or adhesive columns; **m**, **o**, **t**, **u–v**. adhesive loops (**v**. ladder-shaped). Note unsharp limits between stalked and sessile knobs, or between knobs, columns, and loops; (**a**. from Drechsler 1950a, **b**. present study, **c**. from Onofri & Tosi 1992, **d–e**. from Drechsler 1944b, **f**. from Barron 1990, **g–h**. from Duddington 1951b, **i–j**. from Drechsler 1962, **k**. from Drechsler 1954, **l–o**. from Drechsler 1950a, **p–u**. from Scheuer & Webster 1990, **v**. from Drechsler 1937a).

despite the aquatic habitat of our studied German collection of *L. muscicola*, the hyphae and trapping organs survived complete drying, which indicates an adaptation to periodically dry environments such as ponds or river banks. Adhesive pegs were also seen on anchoring hyphae of apothecia on xeric bark by D. Magyar (pers. comm.) and one of us (G.M.), referred to the here described desiccation-tolerant species *L. ellipsoideus*.

Sessile adhesive knobs (Figs 105: g–h, 106: g, k, j, p). This rather primitive type of trapping organ is known from a few nematophagous species of series *Dactylellina* (*D. phymatopaga* = *D. parvicollis*) and *Gamsylella* (*G. robusta* and others). Sessile knobs are broadly or narrowly attached to the supporting hypha, cylindrical to clavate-ovoid or globose, 6–10(–13) × 4–5.5 up to 6–8(–12) µm, in *G. robusta* 16–24 × 9–10 µm, and coated by a thin adhesive mucus. In *D. phymatopaga* both sessile and stalked (mainly short-stalked) adhesive knobs occur, but their stalk has never a basal septum (Fig. 106: j–k). In some species the traps may form short, ± strongly constricted chains of superimposed knobs (Fig. 106: h–i), which are referred to as proliferating knobs but cannot sharply be delimited from adhesive columns (Fig. 106: l, n, q–s).

A similar type of adhesive knob (or peg) is adapted to the capture of testaceous rhizopods. It is known from two species of *Brachyphoris* (anamorph of *Hyalorbilia*), namely *B. tenuifusaria* and '*Dactylella*' *passalopaga* (Fig. 105: f), also from *Tridentaria tylota* (Fig. 105: g), *T. glossopaga* (Fig. 105: h), and *Dicranidion dactylopagum*. In their mode of capturing the victim in the region of food intake (here the shell opening) these anamorphs are reminiscent of *Lecophagus*. However, their organs of capture either resemble sessile adhesive knobs though being distinctly smaller (2.5–4 × 1.3–2.2 µm), or closely match stalked adhesive knobs (in '*Dactylella*' *passalopaga*; in *Brachyphoris tenuifusaria* they appear to be sessile). Drechsler (1934, 1962, 1964) named those in *Tridentaria* and *Dicranidion* adhesive protuberances. In *T. glossopaga* he stressed the consistent presence of a basal septum, whereas in the other two he did not figure septa at their place of attachment. Very similar knobs as in the two *Tridentaria* species occur in the basidiomycete *Lactydina tylopaga* (Drechsler) Subram., which consumes non-testaceous amoebae (Saikawa et al. 1994).

Adhesive columns and loops (Fig. 106: l–o, q–v). This type of trapping organ is characteristic of series *Gamsylella*. It originates from sessile adhesive knobs which regularly proliferate at their tip to form further adhesive cells. The resulting ± moniliform rows are either straight (adhesive columns) or tend to get curved by forming loops, either roundish arches, or angular bridges between columns (scalariform = ladder-shaped). Rarely, single cells of such arches may proliferate laterally to form more complex structures similar to adhesive networks (*Gamsylella gephyropaga*, Drechsler 1937a: fig. 12E; Rubner 1996: fig. 31b, in *G. arcuata* the arches even proliferate regularly). All these types may occur within a single strain. The adhesive cells are ~5–8 µm wide and the loops have an outer diameter of ~24–38 µm.

Stalked adhesive knobs (Figs 106: a–f, j (left), 107). Trapping organs of this type are the key character of series *Dactylellina*. The stalks are 1.5–4.5(–5.5) µm wide and mostly have a basal septum (in contrast to sessile adhesive knobs which occasionally form a short stalk). They are usually 4–15(–40) µm long and 1–2(–4)-celled, in one species even 40–280 µm long and multiseptate (*Dactylellina copepodii*). In contrast to adhesive pegs, the swollen terminal cells of adhesive knobs are always segregated from the stalk cells by a septum.

In species which trap nematodes the adhesive cell is ± globose to obovoid, 6–10(–12) × 5–8.5(–10.5) µm, and the mucous layer is, when hydrated, usually very thin (< 1 µm). Yet, in three arthropod-capturing species referred by us to series

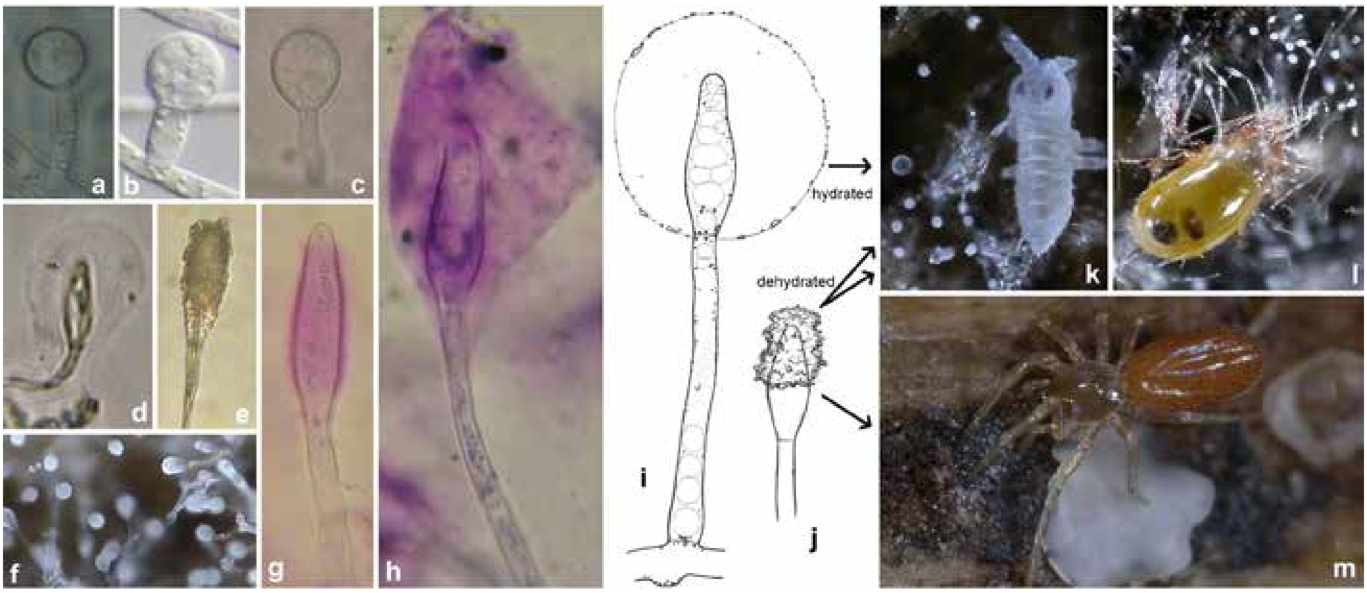

Figure 107: Stalked adhesive knobs in series *Dactylellina* and *Gamsylella* of *Orbilia* section *Arthrobotrys*. — **a–c**. with globose heads (capable to trap nematodes), **d–l**. with lageniform heads (capable to trap arthropods: **k**. springtail, **l**. mite, **m**. spider). **a**. *O. rubrovacuolata* (phot. M. Scholler), **b**. *O. ellipsospora* (from Liu 2006, as *O. quercus* var. *hainanensis*), **c**. *O. mammillata*, **d–m**. *O. alba*. The thick ball of adhesive gel in *O. alba* is invisible in water mounts but quite distinct when dehydrated in alcohol (**d**) or when stained with CRB (**g–h**). Even in a high atmospheric humidity the gel is rather dehydrated (**e**, **f**, **j**). Larger arthropods (**m**) are only temporarily trapped and thus unsuitable as prey.

Gamsylella (‘*Dactylellina*’ *ferox*, ‘*D.*’ *entomopaga*, and *Orbilia alba*) the mucus is much more abundant and strongly swells to 6–10 or even 20 µm in thickness when hydrated. The adhesive heads in these species differ clearly from each other in shape and size (‘*D.*’ *ferox*: globose, 18–31 × 16.5–24.5 µm, ‘*D.*’ *entomopaga*: ellipsoid, 8–13 × 4.5–8 µm, *O. alba*: lageniform, 27–36 × 8–11 µm). Similar balls of strongly adhesive gel characterize *Nematoctonus* (anamorph of *Hohenbuehelia*, *Basidiomycota*) with hourglass-shaped adhesive knobs.

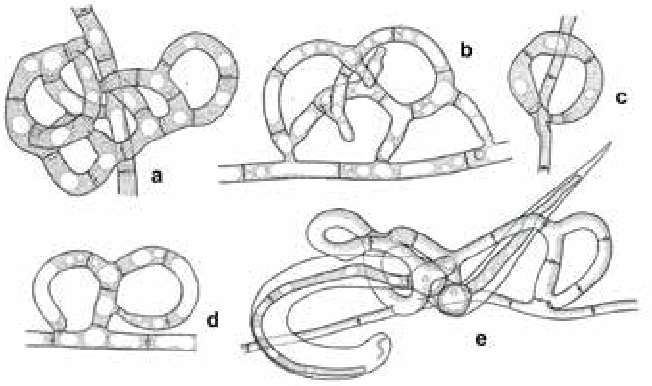

Figure 108: Adhesive networks in *Orbilia* section and series *Arthrobotrys*. — **a**, **d**. *A. eudermatus* (from Drechsler 1950a), **b**. *A. thaumasius* (from Drechsler 1937a), **c**. *A. musiformis* (from Drechsler 1937a), **e**. *A. cladodes* with captured nematode (from Drechsler 1937a); **c–d** are somewhat exceptional or initial stages (that in **c** resembles a constricting ring).

Adhesive networks (Fig. 108). This type of reticulate trapping organ is the key character of series *Arthrobotrys*. Adhesive networks are formed by lateral proliferation from adhesive loops to form a multibranched three-dimensional structure composed of a varying number of arches. Mainly nematodes are trapped, either by external contact, or by entering the perforations of the net. In rare cases only one or a few arches are formed, and the network may predominantly be two-dimensional. Rarely, incomplete arches (‘adhesive loops’) were observed (‘*Arthrobotrys oligosporus*’ CBS 289.82, Scholler et al. 1999: 94, fig. 1) or adhesive hyphae together with adhesive nets (*A. botryosporus*, Barron 1979b). The inner loop diameter ranges at ~10–40 µm, and loop cell width at ~(3–)4–7(–8) µm.

Delimitation from adhesive loops and from non-constricting rings is sometimes not very sharp. True ring traps differ in not including parts of the stalk within the ring, whereas adhesive loops differ in being more constricted at the septa and usually two-dimensional.

Non-constricting rings (Fig. 109). This ring type is known from ca. seven species of series *Dactylellina* (see Figs. 174–176), where it inconsistently occurs in culture, mostly in combination with stalked adhesive knobs. The rings are 3(–4)-celled and supported by a 12–35(–?50) µm long, slender (1.5–2.5 µm), 1–3(–4)-celled stalk. They have an outer diameter of 13–24 µm (inner diameter 7–17 µm), and their cells are 2–5 µm wide. Contrary to constricting rings, the stalk is only connected to one of the ring cells, and the ring cells are in their middle region usually not distinctly thicker than at the septa. Moreover, triangular wall thickenings at the septa typical of constricting rings have so far not been reported. Sherbakoff (1933) believed that the rings developed from stalked adhesive knobs, but this

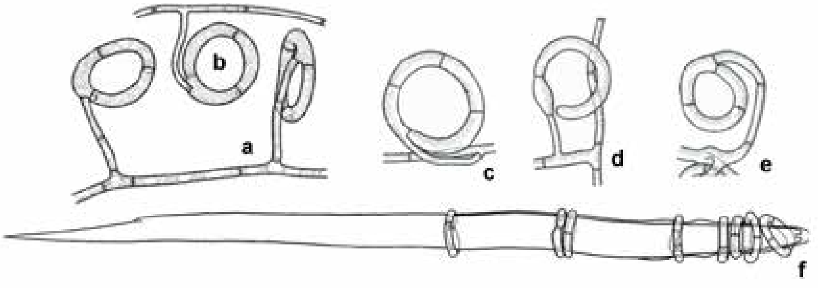

Figure 109: Non-constricting rings in *Orbilia* section *Arthrobotrys* series *Dactylellina*. — **a–b**. *Dactylellina leptospora*, **c–f**. *D. lysipaga* (both from Drechsler 1937a), **f**. a nematode accumulated 8 rings by tearing them off from the stalk.

Cui pers. comm.). Living state (H_2O, **i**: CRB): **a**, **c–f**, **?g–h**, **i–l**, **q**, **u–w**; dead state: **b** (H_2O), **m–o** (KOH+IKI), **p** (KOH), **r** (CRB), **s** (REM), **t** (H_2O).

was never confirmed by later authors. The basal ring cell is actually sometimes markedly swollen (Sherbakoff, pl. 35 fig. A), a feature stressed also by Barron (1977) as characteristic, but this is only rarely clearly seen on illustrations, e.g., on Drechsler's drawings (Fig. 109: d).

This type of trapping organ is passive in its action, i.e., neither constriction nor adhesion occurs. It appears to be solely adapted to the capture of rather small nematodes which, during entering, cause the ring to wedge around their body. Following struggling, the ring easily breaks off at a point of weakness near the stalk apex (Barron 1977). Sherbakoff (l.c.) observed also trapping of larvae of minute flies by non-constricting rings.

Constricting rings (Fig. 110). Constricting rings are a consistent and exclusive characteristic of series *Drechslerella*. The main difference to the preceding type of trapping organ is the ability of a sudden expansion of the ring cells (within less than 0.1 sec, after a lag of 1–2 sec) to a 3(–4)-fold volume (Fig. 110: b, d, f). Constricting rings often capture nematodes at their tapered ends, rarely in the broad middle part, thus they can trap a prey with a body diameter much wider than the ring aperture.

Judging from Drechsler's observations, constricting ring diameters are species-specific to some extent, but vary also considerably within a strain. When micro- or macroconidia germinate to form a single trap, Barron (1979a) found that the diameter was determined by conidial size, i.e., the amount of available nutrients within the conidium. The outer diameter of constricting rings formed on mycelium usually ranges at 20–32(–40) µm, the inner at 12–20(–30) µm (Drechsler 1954). Exceptionally small rings were noted by Barron (l.c., 8–15 µm outer diam., formed from microconidia of *Drechslerella brochopaga*), and unusually large rings occurred in '*Dactylella*' *megalobrocha* (?= *D. bembicodes*, 40–48(–56) µm outer diam., Glockling & Dick 1994). Giant ring traps of 105–130 µm in outer diameter were formed together with the normal rings of 25–40 µm in an authentic strain of *D. brochopaga* incubated under conditions of poor ventilation (Turnbull & Zachariah 1978). In a Chinese strain of *O.* cf. *tonghaiensis* (YMF 1.01829), giant traps of 85 µm outer diam. regularly occurred 1–2 days after the normal rings of 30–42 µm appeared (Z.F. Yu pers. comm.). Cui (2014: fig. 2.4, see Fig. 110: t–u) saw giant traps in *D. dactyloides*, and believed them to be inefficient because their individual ring cells are not much wider than in normal rings and, therefore, do not achieve a closed aperture after full expansion. We assume that suitably large nematodes may well be captured by such giant ring traps.

Unexpanded constricting rings differ in several morphological details from non-constricting rings. The ring cells are with a width of (4–)5–7(–8) µm more swollen in their middle part, which is about twice as thick as at the septa. This usually results in a somewhat triangular shape of the ring aperture (Fig. 110: a, c, i, k, m). However, this feature is rarely also seen in adhesive networks (Fig. 108: c). In some species (*D. acrochaeta*, *D. doedycoides*, *D. heterospora*) each ring cell has an inner bulge-like protrusion (Fig. 110: e). Expanded ring cells attain a width of *10–18 µm. The stalk is (1–)2(–3)-celled and with 9–20(–32) × (2.5–)3–5(–6.5) µm usually shorter and particularly wider than in non-constricting rings. Constricting rings are always reported with three ring cells, but we saw once a ring with five cells (Fig. 110: j). Rubner (1996: 18, fig. 9) observed degenerated constricting rings in three strains of *D. doedycoides*, *D. effusa*, and *D. polybrocha*, showing a spiral shape without

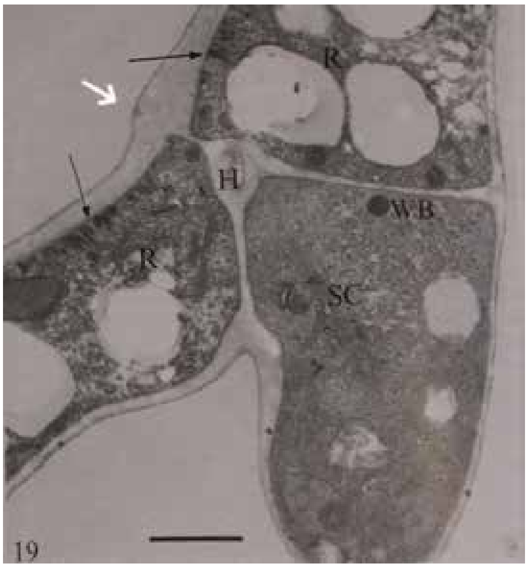

Figure 111: Junction between upper stalk cell (right below), basal ring cell (right above), and terminal ring cell (left), showing three septa surrounding a central hole (H), also a wall thickening over the septum (anastomosis) between the two ring cells (white arrow, after Glockling & Dick 1994, two black arrows pointing to tubular vesicles ('possibly lysosomes', *D. megalobrocha*, TEM). Scale bar = 2 µm.

fusion of the terminal cell. Also Cui (2014: fig. 5.2) reported in *D. brochopaga* similar 'multiple loops', but of helicoid shape.

Another characteristic of constricting rings is that during their formation the terminal ring cell fuses with the upper end of the stalk, and afterwards an anastomosis is formed between the terminal and basal ring cell (Higgins & Pramer 1967; Dowsett et al. 1977: fig. 57; Glockling & Dick 1994: fig. 19). This peculiarity results in the presence of three septa at the junction (Fig. 110: a), in contrast to two septa in non-constricting rings. The feature is often not clearly visible on illustrations, e.g., in many of Drechsler's otherwise very accurate drawings. It is, therefore, still not confirmed for all *Drechslerella* species, e.g., *D. heterospora* (Fig. 110: e).

In all constricting rings which we have studied, a remarkable microstructure is seen under the LM, which is frequently not specifically mentioned in the literature: distinct triangular or sometimes more lens-shaped wall thickenings occur especially at the two distal septa (Fig. 110: a–b, k, m–r, t–w). They are mainly seen at the internal side of the ring but sometimes also at the external side and at the proximal septum. These wall thickenings are present in both living and dead ring cells and do not change their thickness and refractivity in KOH. Undoubtedly, the wall thickenings form an annular structure around the whole margin of the septum by decreasing in thickness towards the outer side of the ring.

On several LM photographs of Zachariah & Insell (1979: figs 2–4, 7, 9), Glockling & Dick (1994), and Cui (2014: figs 2.1, 2.3–4) these triangular wall thickenings can very clearly be seen in the rather large rings of *Drechslerella brochopaga*, *D. dactyloides*, and *D. megalobrocha*. Under dark field fluorescence they appear with strong contrast (Fig. 110: v–w). The wall structure is not mentioned by these authors, however, and a TEM micrograph by Glockling & Dick (Fig. 111) shows only the proximal septum adjacent to the stalk where the wall thickening is more flattened instead of triangular. Likewise, on the TEM micrograph of Dowsett et al. (1977: fig. 16) strong wall thickenings are visible at the septa but are not sharply delimited from the cell walls away from the septa.

For *D. dactyloides* Tzean & Estey (1979: fig. 1–2) illustrated and discussed a thick inner wall layer of the ring cells which is responsible for their expansibility. At the septa the wall is not thicker, but clearly lacks a visible fibrillar structure. In the expanded state (fig. 8) the stretchable inner wall layer gets thin while it retains its thickness at the septa. This illustrates a different nature of the wall at the septa. Muller (1958) figured lens-shaped wall thickenings for the proximal septum (Fig. 110: g) and triangular ones at the three septa of an expanded ring (Fig. 110: b), but saw them only in some rings. During the expansion process, Muller sometimes saw transient wall thickenings at the edge where the cells expand (Fig. 110: h).

In a video showing ring expansion in *D. brochopaga* and *D. dactyloides*, Nordbring-Hertz et al. (1995) reported the peculiar triangular microstructure as T-shaped wall thickenings at all three septa. The authors considered that their function was to avoid interference of the three swelling cells. A more probable explanation could be that the wall thickenings provide a higher mechanical stability of the ring in order to avoid rupture when a nematode tries to escape. This hypothesis is supported by the observation that the wall thickening is usually less developed at the proximal septum, at which the two ring cells are held together also by the fusion between terminal ring cell and upper stalk cell.

Based on TEM-observations, Dowsett et al. (1977: fig. 12), Tzean & Estey (1979) and Glockling & Dick (1994: figs 20, 22) found the wall of unexpanded ring cells to consist of several layers. The mechanism of rapid expansion happens by rupture of the more rigid outer wall layers and a stretching process of the thicker inner layers (Fig. 110: s, Dowsett et al. l.c.: fig. 17; Glockling & Dick l.c.: figs 12, 15; Barron 1979a: fig. 8). The demarcation line where the outer layers ruptured is also visible under the LM (Barron l.c.: fig. 9).

The rupture and swelling of ring cells may be compared with fissitunicate asci with an inner wall layer (endotunica) that is able to swell. Similar as in ascus walls, an increase in wall thickness can be observed under the LM when the unexpanded ring cells are killed, though less significantly than in asci: from about 0.3–0.5 µm when viable (Fig. 110: a, i) to 1 µm when treated with KOH (Fig. 110: n, r). As in asci, the wall appears two-layered in the dead state, with a thin refractive outer layer and a swellable non-refractive inner layer. Our images show this swollen inner layer on both sides of each ring cell (Fig. 110: m–n), whereas Dowsett et al. (l.c.) and Glockling & Dick (l.c.) emphasized the inner side of ring cells to be much thicker-walled than the opposite side.

Like ascus explosion, ring expansion is a physiological process based on internal osmotic pressure. Contrary to asci it does not result in the death of the cells. Instead, due to a rapid conversion of reserve materials, the osmotic pressure is rebuilt after expansion in order to constrict the body of the victim (see Barron 1977: 54), and the ring cells grow out and penetrate the nematode. While still unexpanded, a number of vacuoles can be seen under the LM or TEM in the outer part of each ring cell (Figs 110: a, i,). These rapidly increase by water uptake from the environment during expansion, whereas fusion to one large vacuole (Fig. 110: j, l) is said to take place at a later stage (Muller l.c., Dowsett et al. l.c.). The inner non-vacuolar region of the unexpanded protoplast is slightly denser and more granular under the LM and contains vesicles with possibly enzymes which are only seen under the TEM (Fig. 111).

The process of sudden expansion is triggered by touch when a nematode enters the ring. Triggering is also possible with a micromanipulator, sudden increase in temperature (adding a drop of 33–75 °C warm water), or electric stimulation (Couch 1937, Muller 1958, Higgins & Pramer 1967 and others). Killing agents such as KOH, MLZ, or CB_L added to constricting rings, or temperatures above 80 °C, do not induce expansion, but rather cause a hardly noticeable or very slight shrinkage (see also Muller l.c.: 345 who added HCl, NaOH etc.). Although constricting rings appear to be solely adapted to the capture of nematodes, they are rather unspecific concerning different nematode genera, and were sometimes even seen to catch rotifers (Drechsler 1937a: fig. 18N; Glockling & Dick 1994).

Phylogeny of trapping organs. The phylogenetic origin of trapping organs of *Orbiliomycetes* is unknown. The capture of pollen by hyphal structures or conidial arms in the phylogenetically basal genera *Mycoceros* and *Retiarius* (Magyar et al. 2017a, b) may represent a precursor of these trapping devices, although the ability to invade living pollen appears to be widespread in fungi (see p. 145). The homology between the adhesive organs in the three lineages *Lecophagus*, *Hyalorbilia*, and *Orbilia* series *Arthrobotrys*, *Dactylellina*, and *Gamsylella* seems likely, whereas a polyphyletic origin would be more difficult to conceive.

According to various phylogenetic analyses, the three main trapping organs constricting rings, adhesive networks, and adhesive knobs or columns form monophyletic clades within section *Arthrobotrys* (see Phyl. 25). From a morphological point of view, constricting rings might have evolved from non-constricting rings, as was presumed and illustrated in hypothetical diagrams by Rubner (1996: fig. 13) and Li et al. (2005: fig. 4). Yet, the early analyses by Ahrén (1998) and Tanabe et al. (1999) based on SSU rDNA already showed that species with constricting rings clustered as a basal sister clade of the remaining nematophagous lineages, and various other phylogenetic results contradict the above hypothesis, with a few exceptions (see p. 1433). The two clades with adhesive organs appear to trace back to a common ancestor (Hagedorn & Scholler 1999: 34) which, in turn, descended together with taxa with constricting rings from a common nematophagous ancestor that emerged from the non-nematophagous, paraphyletic series *Neodactylella*.

Hagedorn & Scholler (1999: 36) hypothesized that also taxa with non-constricting rings might form a monophyletic group, given that the only strain of *Dactylellina leptospora*, for which a sequence was available at that time, was misidentified because it did not form non-constricting rings. However, a new unpublished strain with both adhesive knobs and non-constricting rings clustered with rather high support sister to this *D. leptospora* strain, suggesting that non-constricting rings occur in different clades and may get lost during evolution, unlike the other three trapping organs.

Tanabe et al.'s (1999) phylogenetic analysis suggests that the rotifer-capturing adhesive pegs of *Lecophagus* (as *Cephaliophora*) form a basal group within the *Orbiliomycetes*. This would make sense as their structure is more primitive than stalked adhesive knobs, nets, or rings. However, their analysis contains only two non-nematophagous orbiliaceous taxa and cannot answer the question whether trapping devices got lost during evolution or arose independently within the *Orbiliomycetes*. From the basal placement of constricting rings the authors concluded that 'complexity of infection organs is not reflected by the position of nematophagous clades'.

Li et al. (2005) considered adhesive knobs as the ancestral type of trapping organ, because their phylogenetic analyses show a basal placement of adhesive trapping organs. Also they assert a lineage from non-constricting rings to constricting rings, but for this no evidence is seen in the phylograms. Yang et al. (2007: fig. 4) illustrated three hypotheses on the evolution of orbiliaceous trapping organs. Their lower left figure is a modification of Rubner's (1996) hypothesis which also implies that sessile adhesive knobs represent the trapping device of the common ancestor of nematode trappers and have their origin in simple adhesive hyphae. In all three hypotheses the constricting rings diverge early, but only in Yang et al.'s personal hypothesis non-constricting rings developed independently of them, while constricting rings branched off before sessile adhesive knobs appeared for the first time.

MOLECULAR BIOLOGY

Ribosomal DNA (= rDNA) of eukaryotes consists of three main regions: SSU (= 18S), ITS (= ITS1-5.8S-ITS2), and LSU (= 28S). rDNA is generally accepted as the basic gene region for fungal taxonomy, because it demonstrated suitability in many fungal groups and its repetitive occurrence in the genome facilitates amplification. During transcription, rDNA is transformed to rRNA, in which the nucleotide sequence becomes reverse-complementary and T (thymine) is exchanged by its demethylated form U (uracil) while the other three bases (G = guanine, A = adenine, C = cytosine) remain unchanged. DNA sequences are currently processed in correspondence to the 'sense strand' (coding strand) of the double-stranded DNA, which concurs with the messenger RNA and the herefrom produced protein code. Because transcription takes place from the 'antisense strand' (template strand), the reverse-complementary base pair sequence of the produced rRNA is the same as that of the sense strand of DNA. As an example, Fig. 113 shows the stem-loop E23-1 of SSU rRNA, the end-loop of which in *Saccharomyces cerevisiae* is CGA**UUUUU**UCG, which corresponds to CGA**TTTTT**TCG in the rDNA sense strand. In *Orbiliomycetes* the end-loop is CGC**CUAACC**GCG and CGC**CTAACC**GCG, respectively (see Tab. 17). By convention, DNA and RNA sequences are always noted by running from their 5'-end (left) to 3'-end (right). The terms upstream and downstream refer to the direction from 5' to 3' in the sense strand but from 3' (right) to 5' (left) in the antisense strand.

rRNA is a structural biopolymer which constitutes a main part of the ribosomes. Ribosomes are roundish particles of ca. 0.02–0.03 µm diam. that are mainly found on the endoplasmic reticulum and serve as the site of protein synthesis. The two ITS regions are removed from the rRNA after transcription, so that only the three subunits 18S, 5.8S, and 28S form together with proteins the ribosome. The three subunits of rRNA show a secondary structure with numerous loops caused by hydrogen bonds (base pairing: A•T and G•C) between reverse-complementary motifs. Besides stem-loop E23-1, examples mentioned in the following include stem-loop B8 in the 5.8S and stem-loop H700 in the L4 primer of LSU. Therefore, the information in rRNA (and rDNA) contains redundant information, except that occasionally G–U base pairing occurs

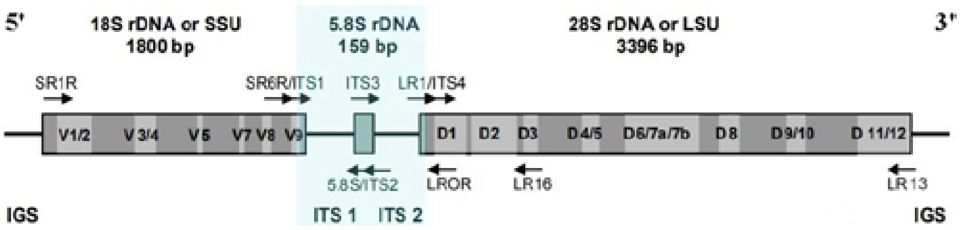

Figure 112: Map of the nuclear ribosomal DNA gene showing three main regions (SSU, ITS, LSU) and location of variable regions in SSU (V1–V9) and LSU (D1–D12) and location of some basic primers (from Meyer et al. 2011).

in these loops (Fig. 113). In addition, the folded rRNA molecule shows a tertiary, 3-dimensional structure. Also the ITS1 and ITS2 regions show a secondary structure of loops and, therefore, redundant information. Because of the limited information in rDNA, other gene regions, mainly protein-coding genes, are today included in multiple phylogenetic analyses.

Molecular data for inferring the phylogeny within the *Orbiliomycetes* have firstly been applied by Liou & Tzean (1997) and Pfister (1997), followed by Ahrén et al. (1998), Tanabe et al. (1999), and Hagedorn & Scholler (1999). Ahrén et al. and Tanabe et al. based their phylogenetic analyses on the SSU rDNA, the preferred marker gene at that time. SSU is a highly conserved gene region of about 1800 nt, showing a low resolution at the species level. Within *Orbiliomycetes* it usually permits distinction between closely related species, because molecular distances in that class are comparatively high in each of the three main subunits of rDNA. Yarza et al. (2014) divided the bacterial SSU into six segments (R1–R6) and recognized nine variable regions (V1–V9), six of which being included in three R-segments (V1 & V2 in R1, V5 & V6 in R4, V7 & V8 in R5). The V-regions occur dispersed within the more conserved core segments of SSU which include, e. g., the primers SR1–SR6, and are currently also adopted in eukaryotes. Within *Orbiliomycetes*, variation in the SSU only occurred at a few positions of these V-regions and some regions did not vary at all, especially V2 and V6 (Tab. S1), but also the conserved segments between the V regions may show some variable positions.

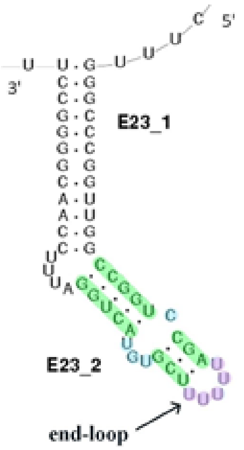

Figure 113: Stem-loop E23-1 formed by base pairing in the V4 variable region of the R3 segment of SSU rRNA of *Saccharomyces cerevisiae*, its upper half (25 nt) showing the motif CCGGTCCGATTTTTTCGTGTACTGG. In comparison, the motif of *Orbiliomycetes* is TCGGTCCGCCTAACCGCGTGCACTGA. Note that thymine (T) in DNA is replaced by uracil (U) in RNA, and that the unusual (wobble) base pair G-U occurs twice in this stem-loop. Green: paired elements of the loop, blue/lilac: unpaired elements. From http://bioinformatics.psb.ugent.be/webtools/rRNA/secmodel/Scer_SSU.html, modified.

Liou & Tzean (1997) based their analyses on the ITS region, also Pfister (1997) and Hagedorn & Scholler (1999) mainly relied on this gene region, and most later workers included it in their studies. It is the most widely used phylogenetic marker, which was proposed as the barcoding gene of fungi by Nilsson et al. (2008) and Schoch et al. (2012). The entire ITS region of *Orbiliomycetes* comprises around 490–525 nt and includes in the middle the highly conserved, 155 nt long 5.8S rDNA subunit with the 5.8S primer motif, flanked by the ITS1 and ITS2 regions which are of about equal length (Fig. 112). Because ITS1 and ITS2 are not part of the ribosome but disintegrate after their removal, they are considered to be of low functional importance and, therefore, subjected to a constant mutation rate that is little influenced by selection. Anyway, some orders of pyrenocarpous ascomycetes show extremely low rates of divergence between species in this barcoding gene region (see p. 18, Taxa concepts).

The LSU has a length of over 3300 nt and contains twelve variable domains (D1–D12) which occur dispersed among more conserved core segments that include the primers LR1–LR13 (see Ki & Han 2007). Distances in the LSU of *Orbiliomycetes* are generally slightly higher than in the SSU, except that the short D4 and D9 domains are highly conserved and also the D10 and D11 domains show little varation in the few available sequences. Li et al. (2005) analysed the LSU in combination with *TUBB* in nematode-trapping *Orbiliomycetes*. Also Liu et al. (2006a) and Smith & Jaffee (2009) used LSU in addition to ITS by including also many non-nematophagous species of the class. Generally, only the D1–D2 regions are selected for analysis (ca. 600 nt) by using the NL4 (LR3) primer, sometimes also D3 (LR4) and D4 (LR5) (see Tab. S1).

In the present study, sequences were generated from the partial or sometimes the entire nuclear rDNA. The ITS region was generally sequenced, usually with a primer (ITS1-F, SF16a) that encompasses the frequently present S1506 intron. Often also the partial SSU and LSU were obtained. The SSU included either only the V7 region (primer NS7 [G. Hagedorn]) or also V6 (NS23 [M. Weiß]). The partial LSU either comprised the D1–D2 domains [NL4, M. Weiß] or D1–D4, rarely D1–D6 [G. Hagedorn, G. Marson]). A few of our sequences include the entire LSU and often also the entire SSU region (see Tabs 27–28).

The ITS region is easily recognized in a sequence by conserved motifs at the 3'-end of SSU (ATCATTA) and 5'-end of LSU (TGACCT), between which it is located, and the conserved 5.8S subunit by AAAACTTT at its 5'-end and GAGCGTC at its 3'-end (see Tab. S1). These motifs are fairly constant in most groups of ascomycetes but show rare exceptions: within *Orbiliomycetes*: ATCATT**G** (possibly ATCATT–**G**) was exclusively observed in *Mycoceros*, GAGCGT**G** and T**C**ACCT only in *Hyalorbilia erythrostigma* and *H. orbiliicola* (and the associated but distant clone 3674), GAGC**A**TC and TGA**T**CT only in *H. hergiswiliana* s.l. (GAGC**A**TC also in KY687852/3, U2 clone from Amazonas), and GAG**A**GT**G** and T**A**AC**T**T only in two species of uncultured fungi (clones B1–B2) forming a basal clade with *Bryorbilia arenicola*. The definition of the ITS region and the included 5.8S subunit is adopted here from Kim et al. (2006) and results in 155 nucleotides for the 5.8S. Some authors define these regions differently: their 5.8S subunit starts 2 nt upstream or 1–2 or even 5 nt downstream and ends 1–4 or even 12 nt downstream compared to the above definition. For instance, in O'Donnell & Gray (1995) and Bengtsson-Palme et al. (2013) the 5.8S starts with AAACTTT and ends with GAGCGTCATTA, resulting in a length of 158 nt. The four additional nucleotides downstream of the 5.8S, which are assigned by Kim et al. to the

ITS2 region, show in *Orbiliomycetes* a lot of variants (see Tab. 20). A very wide definition of the 5.8S subunit is that of Katsu et al. (2004), who included 2 nt at the 5'-end and 12 nt at the 3'-end, resulting in 169 nt. Different definitions exist also for the LSU which starts with TTGACCT in O'Donnell & Gray (l.c.) and with NNTTGACCT in Bengtsson-Palme et al. (l.c.).

Specific nucleotides and motifs

Various examples of critical taxa illustrate the taxonomic value of specific nucleotide positions in the frequently recorded regions of the rDNA. Besides the species level, this concerns taxa at the series and section but also higher level. Specific positions may occur in variable or medium to highly conservative regions. If a position is consistent within a taxonomic unit, the character appears to trace back to a common ancestor and never changed since the ancestor evolved by speciation. If a position varies between, e. g., C and T across different taxonomic units, this must be interpreted as consecutive forth and back mutations, not as indication of a phylogenetic relationship. Such variable, rather unreliable molecular information appears to be frequent in fungal DNA.

SSU rDNA. Besides results from phylogenetic analyses, characteristic molecular motifs in the rDNA may supply additional information on phylogenetic relationships. One of them was discovered by Eriksson (in Eriksson et al. 2003) in each of the 21 sequences of *Orbiliomycetes* available at that time (mainly desiccation-sensitive members of *Orbilia* section *Arthrobotrys*): a characteristic signature of six nucleotides (CTAACC) in the end-loop of the stem-loop E23-1 in the V4 region of SSU (Fig. 113, lilac element) provides additional evidence for the rather isolated phylogenetic position of *Orbiliomycetes*. At present, about 55 orbiliaceous sequences exist in GenBank which cover this region by consistently showing this motif. They include ca. 38 species of *Orbilia*, one of *Hyalorbilia* (*H. inflatula*), two of *Lilapila*, two of *Lecophagus*, and two basal clades of uncultured clones (U5, U6).

When considering the entire upper half of this loop (marked in colour in Fig. 113), interesting further positions are informative (Tab. 17). Those parts marked in green represent paired elements, so that a change at one position usually requires a complementary change of its counterpart. One such deviation is observed at the two ends of this motif: the available sequences of *Lecophagus* (*L. longisporus*, *L. muscicola*) and *Hyalorbilia* (*H. inflatula*), including two clades of unidentified environmental samples distantly related to them, show here C•G compared to T•A as occurring in *Lilapila* and *Orbilia*. As an exception, the type strain of *Dactylellina sichuanensis* (= *O. lysipaga*) has C–G, and a strain of *Arthrobotrys thaumasius* (EU107342) the rare variants CT**C**ACC and T•G. The variant C•G is also observed in many other classes of *Ascomycota* and appears to be characteristic of this phylum, whereas *Basidiomycota* generally differ in having G•T (Tab. 17).

The paucity of available sequences is due to the fact that this gene region is outside the 562 nt long V6–V9 or 362 nt long V8–V9 region of SSU which was frequently sequenced in the present study by using the primers NS23 or NS7, respectively. Since we have rarely sequenced the V1–V5 region of SSU, most sequences which include the signature CTAACC were obtained by other workers. Within *Orbilia*, sequences of V1–V5 were available for various species from all five series of section *Arthrobotrys*, but only for a few species from other sections (see Phyl. S1): three from section *Orbilia* (*O. leucostigma*, *O. xanthostigma*, *O.* cf. xanth*ostigma* D.H.P. 111), four from section *Helicoon*, three from section *Aurantiorubrae* (*O. nemaspora*, *O. aradi*, *O. ficicola*), one from section *Habrostictis* (*O. septispora*), and one from section *Lentiformes* (*O. euonymi*), the latter four being the only species with a pronounced desiccation tolerance.

Other classes of *Ascomycota*, such as *Pezizomycetes*, *Leotiomycetes*, *Dothideomycetes*, *Sordariomycetes*, and *Lecanoromycetes*, mostly show the signature CT**C**ACC. However, as already stated by Eriksson (l.c.), a few non-orbiliaceous species from some lichenized (*Arthoniales*, *Lecanorales*, *Lecideales*, *Peltigerales*, *Rhizocarpales*, *Teloschistales*, *Umbilicariales*) but also non-lichenized orders (*Acrospermales*, *Botryosphaeriales*, *Dyfrolomycetales*, *Stigmatodiscales*, *Symbiotaphrinales*) possess the signature of *Orbiliomycetes*, as can be evaluated from BLAST searches in GenBank for the loop motif (26 nt). This reduces the taxonomic value of the signature and raises the question whether it might have independently arisen in different lineages, as was assumed by Eriksson. In *Taphrinomycotina* (*Neolecta* and *Taphrina*) the signature is CTAAC**G**, whereas in *Saccharomycotina* it is CT**TTGA** (*Dipodascus*) or **TTTTT–** (*Saccharomycetaceae*).

Some positions in the SSU V8–V9 provide characteristic motifs within *Orbiliomycetes*. A remarkable symmetric pair

Table 17. Comparison of upper half of stem-loop E23-1 in SSU V4 region (26 nt, shown in Fig. 113) between *Orbiliomycetes* (in bold) and other selected fungal groups, with paired nucleotides in green and unpaired nucleotides in blue (small side-loops) and lilac (end-loop signature). Motifs are highly consistent within *Orbiliomycetes*, but also within *Symbiotaphrinales*, *Xylonales*, *Leotiomycetes*, *Taphrinomycetes*, and *Neolectomycetes*, but more variable in other groups, where often a lot of variants occur. Nucleotides deviating from the motif of *Orbilia*/*Lilapila* are highlighted in bold. Note symmetry in deviating characters within the green parts due to predominant base pairing A•T or G•C. For further variants of the end-loop signature in *Ascomycota* see Eriksson et al. (2003).

of nucleotides is found at pos. 154 & 166 (when starting after primer N7 with CCTTAGATGTT), which belong to the loop at pos. 1360 of *Escherichia coli*. Here section *Habrostictis* (**G**AGTCATCAGCT**C**) differs from most other orbiliaceous groups (**A**AGTCATCAGCT**T**). The latter motif is also characteristic of *Helotiales* and most *Pezizales*, but **G**AGTCATCAGCT**C** also occurs, e. g., in *Thelebolales* and some *Lecanorales*. A similar pair of nucleotides occurs at pos. 109 and 126: here the genus *Hyalorbilia* and members of section *Arthrobotrys* with adhesive traps have AG**G**GC and GC**C**CT but all other *Orbiliomycetes* AG**A**GC and GC**T**CT (Tab. 60). Also pos. 141–142 is diagnostic, separating the genus *Orbilia* (AT**AT**CT) from other orbiliaceous groups (AT**TC**CT, a few *Hyalorbilia* spp. have AT**AC**CT) (Tab. 60).

5.8S and LSU rDNA. Smith & Jaffee (2009) developed '*Orbiliales*-specific' PCR primers for the 5.8S and 28S rDNA in order to directly detect nematode-trapping fungi in soil or plant substrate without culturing. The three primers (Orb5.8s1F, Orb5.8s3F, Orb28s2R) have a length of 18–21 nucleotides and differ from non-orbiliaceous ascomycetes and basidiomycetes at 1–3 positions (see Tabs 18–19). The investigated groups were mainly those of *Hyalorbilia* ('*Brachyphoris* clade') and section *Arthrobotrys* ('*Orbilia* clade'). When including all orbiliaceous sequences available at present, the primer Orb5.8s1F exactly matches almost all taxa of *Orbiliomycetes*, but only when omitting one nucleotide at its 3'-end. The other two primers match around 90 % of the available orbiliaceous sequences.

Our sequence data show that a fairly large number of orbiliaceous taxa deviate at 1–2 or sometimes 3–4 positions in a given primer region (Tabs 18–19). Even some nematode-trapping *Orbilia* species deviate from primer Orb28s2R (*Dactylellina appendiculata*, *D. lysipaga* = *D. sichuanensis*, *Gamsylella cionopaga*). However, these deviating motifs are usually still different from non-orbiliaceous fungi, with the exception of *Mycoceros* in Orb5.8s1F, and *Lecophagus* and some species of *Amphosoma*, *Retiarius*, and *Orbilia* in Orb28s2R.

Smith & Jaffee's three primer regions provide interesting character patterns which permit distinction between orbiliaceous genera. For instance, *Hyalorbilia* shows some peculiarities in which the genus differs from *Orbilia*, with the exception that *H. erythrostigma*, *H. orbiliicola*, and *H. latispora* deviate in some of these conserved regions. In the following, the main characteristics are summarized:

(1) In primer Orb5.8s1F (pos. 47–64), *Orbilia* and *Hyalorbilia* are identical (GCAGCGAAACGCGATAG**T**, see Tab. 18), with the exception of (a) *H. erythrostigma*, *H. orbiliicola*, and *H. latispora*, which deviate by one nucleotide at the 3'-end (GCAGCGAAACGCGATAG**G**) by concurring with all the remaining orbiliaceous genera, and (b) *Mycoceros*, which deviates also at two further positions (GCAGCGAAA**T**GCGATA**AG**). *Mycoceros* exactly matches many non-orbiliaceous ascomycetes as well as basidiomycetes, but variant (a) also occurs, e. g., in *Malasseziales* and *Trichosporonales* (*Basidiomycota*). As a consequence, primer Orb5.8s1F does not cover various basal taxa of *Orbiliomycetes*, but would do so (except for *Mycoceros*) if it were shortened at its 3'-end by one nucleotide.

(2) At pos. 83–85 of 5.8S ('unnamed') the most frequent signature is TCA, but some rare variants exist (see Tab. 18). CTA is characteristic of *H. erythrostigma* and *H. orbiliicola* and a clade loosely associated with them, CCA occurs in some uncultured isolates belonging to *Hyalorbilia*, TTA was observed in some strains of series *Dactylellina* and in two environmental isolates near *Bryorbilia* and *H. ulicicola*, TTC in a strain of *O. blumenaviensis*, and TCC in *Lecophagus longisporus* and the *Vermispora* clade of *Hyalorbilia*.

(3) Another region in the 5.8S represents stem-loop B8, with 2 × nine positions (117–125 with 130–138) being rather strictly complementary by base pairing (G•C or A•T, see Tab. S4). Many of the observed motifs of *Hyalorbilia* and *Orbilia* occur here in more or less distantly related taxa of *Orbiliomycetes*, suggesting a polyphyletic origin of some of these motifs. Those of the genus *Lecophagus*, however, are unique within *Orbiliomycetes*. Likewise, members of *Orbilia* differ at pos. 121•134 by A•T or G•C from the other orbiliaceous genera which have C•G (like various other fungi) or T•G, rarely T•A (the latter case also occurs in some *Orbilia* species, including all of section *Helicoon*). Series *Pseudotripoconidium* and *O. yuana* differ at pos. 117•138 from other *Orbiliomycetes* by A•T vs. G•C.

(4) In the primer Orb5.8s3F (pos. 137–157), which includes the motif GAGCGTC at the 3'-end of 5.8S, the nucleotide at its 3'-end (157) varies within orbiliaceous fungi in having T in *Orbilia* (very rarely A or C), *Lilapila*, *Mycoceros*, and *Bryorbilia*, but G in *Amphosoma*, *Lecophagus*, *Retiarius*, and *Hyalorbilia* (including the *Vermispora* clade). Non-orbiliaceous ascomycetes have T or C, and several of their variants of primer Orb5.8s3F also occur in a few orbiliaceous taxa. When including the next two positions downstream which were assigned to the 5.8S subunit by some authors, different sections and series of *Orbilia* show highly characteristic signatures (see Tab. 20).

(5) At one position in the middle of Orb28s2R (Tab. 19, pos. 616), mainly three character states are observed within orbiliaceous fungi: GC**T**TA in *Orbilia* and the *Vermispora* clade of *Hyalorbilia* p.p., **C** in *Hyalorbilia* (incl. *Vermispora* clade p.p.), and **G** in *Amphosoma*, *Lecophagus*, *Lilapila*, *Mycoceros*, *Retiarius*, and a number of species of *Orbilia* section *Habrostictis*. Exceptions are *Hyalorbilia erythrostigma*, *H. orbiliicola*, and *H. latispora* (**T**) and a few species of *Orbilia* section *Aurantiorubrae* (**A**). Non-orbiliaceous ascomycetes show the character **G**, basidiomycetes **A**. Many orbiliaceous taxa showing **G** fully concur in the Orb28s2R with non-orbiliaceous ascomycetes.

In ascomycetes associated with ectomycorrhizas, Tedersoo et al. (2009: appendix 1) listed deviations from the newly designed *Pezizomycotina*-specific (reverse) primer LR3-Asc (forward: CG**CT**TGGATTTGAGTA**R**G**T**G), which is located in the D3 domain of LSU (pos. 761–780). One such deviation was observed by these authors in a single species of *Orbiliomycetes* (CG**GA**TGGATTTGAGTA**T**G**A**G). In fact, this motif is widespread in *Orbiliomycetes* but also occurs in at least two further variants in that class (CG**GA**TGGATTTGAGTA**G**G**A**G, rarely CG**GA**TGGATTTGAGTA**A**G**A**G). All these variants also occur in helotialean and other groups, e. g., the variant with T is typical of *Chaetomellaceae* (*Helotiales* s.l.) and some other taxa with distant position, *Corticifraga* (*Graphidales*) and *Symbiotaphrina* (*Xylonomycetes*).

Introns in the rDNA

Introns are non-coding nucleotide sequences of different length which are inconsistently present at various positions in the genome, in contrast to the non-coding internal transcribed spacer DNA (ITS1, ITS2) that every fungus has. Almost all

Table 18. Variation in three semiconserved regions of the 5.8S rDNA, with indication of the species or group of species where they occur. Those variants which predominate within *Orbiliomycetes* are highlighted in bold. Two of these predominant variants (Orb5.8s1F, Orb5.8s3F) were proposed by Smith & Jaffee (2009) as '*Orbiliales*-specific' primers. Position numbers start with AAAACTTT (5.8S) by omitting rare inserts (in Orb5.8s3F: GAGCGTC**T**AC). Non-orbiliaceous taxa found with BLAST in GenBank as having the same motif are given in the middle column, indicating independent convergent mutations at the same loci. For the numbering of uncultured clones see phylogenetic analyses of respective group [B = *Bryorbilia*, H = *Hyalorbilia*, L = *Lecophagus*, M = *Mycoceros*, O = *Orbilia*, R = *Retiarius*, V = *Vermispora* (= *Hyalorbilia*), U = unknown genus].

introns found in fungal rDNA appear to be self-splicing group I introns. These occur across the eukaryotes and are excised from the rDNA during RNA processing. The number of insertion sites within the rDNA is limited to about 77. Group I introns occur only in highly conserved segments of SSU and LSU, and never in the 5.8S region (Johansen & Haugen 2001). A single species may contain 0–8 introns in the SSU and 0–5 in the LSU. The majority of these introns appear to to be species-specific, but in some species a given intron was either absent or present depending on the strain.

Group I introns have a length of ~200–450 nt, exceptionally up to ~1500 nt. They can be used for phylogenetic analyses of closely related taxa because they are subjected to a similar mutation rate as ITS1 and ITS2. Group I introns are even alignable when they are excised from different positions within the rDNA, apparently because a transfer of introns from one to another position rarely occurred during evolution. Not understood seems to be the fact that an intron at a given position may either get lost or reappear during evolution, judging from the inferred phylogeny in a given taxonomic group.

Group I introns are classified by their position number in the rDNA, which is evaluated by alignment with a reference sequence of *Escherichia coli* (J01695, Gutell 1993, http://www.rna.icmb.utexas.edu/SAE/2C/rRNA_Introns/), a method of intron nomenclature being broadly accepted for all kinds of organisms. Based on this method, Johansen & Haugen (2001) introduced a system of naming a group I intron of a given species by an abbreviation code of the species name, the character S (SSU) or L (LSU), and the position left (upstream) of the intron in the *E. coli* rDNA by using another *E. coli* strain (AB035922). This system is adopted here, though by using J01695 and omitting the abbreviation code. Hereafter, the frequently sequenced intron at the 3'-end of SSU is called S1506.

Due to some infraspecific variation among the different strains of *E. coli* it is necessary to evaluate positions by a standard strain. Johansen & Haugen (l.c.) and Hafez et al. (2012) used *E. coli* AB035922 which shows the same SSU positions as Gutell's J01695 but differs in the LSU by two inserts and one gap. Because position numbers based on *E. coli* J01695 were also used, e. g., by Gargas et al. (1995), Takashima & Nakase (1997), Hambleton & Sigler (2005), Gutiérrez et al. (2007), and Xu et al. (2013), we here follow Gutell's sequence J01695 as standard.

Saccharomyces cerevisiae (J01353) was alternatively used as reference organism for fungi, e. g., by Medjedović et al. (2014), because it gives a better alignment. When aligning herewith, the S1506 intron occurs after pos. 1767 (Medjedović et al. l.c.), although with Réblová & Réblová (2013: suppl. fig. 1) it would be at pos. 1769 of the same sequence. Since group I introns occur only in conserved regions, evaluation of position numbers based on *E. coli* is rarely problematic, and also Medjedović et al. used the intron nomenclature based on *E. coli*.

The secondary structure diagram of rRNA available at the link of the Texas University (http://www.rna.icmb.utexas.edu/SAE/2C/rRNA_Introns/) includes 38 positions of group I introns in SSU and 39 in LSU. Within *Eumycota*, Gargas et al. (1995: tab. 1) observed 17 different positions in SSU at which group I introns may occur. Twelve of them were found in lichen-forming fungi (including calicioid taxa), seven in *Chlorophyta*, but only one in *Rhodophyta* (S1506). Within *Xylonomycetes* nine group I intron positions were observed in the SSU and six in the LSU (Baral et al. 2017a: tab. 3). Multiple introns may occur within a species: a maximum of seven SSU- and five LSU-introns were observed in *Symbiotaphrina microtheca* (Baral et al. l.c.) and eight SSU-introns in *Lecanora dispersa* (Gargas et al. l.c.).

Comparative phylogenetic analyses of group I introns and ITS or SSU were carried out by, e. g., Holst-Jensen et al. (1999) in *Sclerotiniaceae* (L798), Feau et al. (2007) in *Mycosphaerella* (S1199 & S1506), and Hafez et al. (2012) in some *Microascales* (S943 & S1199). Feu et al. and Hafez et al. obtained a partly different tree topology between ITS and S1199, or SSU and S1199/S943, respectively. Holst-Jensen et al. observed more

incongruent tree topologies and speculated about a transfer of introns between closely related species by viruses. In order to verify such intron transfers, Bhattacharya et al. (2005) included group I introns from 16 different positions of SSU and 10 of LSU from 84 species of *Ascomycota* in a single alignment and compared it with an analysis of the SSU+LSU+*RPB2* region of these species. In their fig. 3 they report seven putative cases of intron movement between distant positions of SSU and/or LSU, which occurred between different classes or also within a class.

Intron S1506. When obtaining sequences of the ITS1-5.8S-ITS2 region, a group I intron at the 3'-end of SSU is often included in the sequence when using forward primers such as ITS5, ITS1-F, or SF16a, whereas the intron is missed when using the forward primer ITS1. The intron always occurs at the very same gene locus between the primers ITS5 and ITS1 (Tab. 22). Strains which lack the intron show near the 3'-end of SSU the motif GGTTT, whereas strains which possess the intron show this motif much more upstreams, but instead GTT near the 3'-end. Due to the tandem repeat of TT at the 5'-end and TT at the 3'-end of the intron, the exact position of the intron is ambiguous when comparing rDNA sequences with and without intron. According to Gargas et al. (1995) and Hagedorn & Scholler (1999), the intron is positioned between GT and TT, because group I introns generally have G at their 3'-end (P. Haugen pers. comm.) and consequently TT at their 5'-end, which fixes the intron position as given in Tab. 22. The NS24 primer, which ends with its forward version as GGTTT, includes the intron position but, because of the tandem repeat of TT, it works also with sequences that possess the intron.

Various taxa of *Ascomycota*, but none of *Orbiliomycetes*, show the much less frequent variant GGTCT instead of GGTTT. In this variant the NS24 primer would possibly fail in binding to the DNA. Because of this variant, two cases can be observed in sequences which possess the S1506 intron (see Tab. 22): (1) the 3'-end of the intron ends as G|TT; (2) the 3'-end of the intron ends as G|CT. Interestingly the intron in the second variant starts with the tandem repeat CT, as GGT|CT at its 5'-end. However, a rare case was observed in which the intron

starts with GGT|CT but ends with G|TT. This rare case was so far only detected in *Calycina citrina* (KY462815) and *Calycina* sp. (?= *Mollisia caespiticia*, KY965813). Other sequences of *C. citrina* agg. show the variant GGTTT by lacking the intron (e. g., AY789386), which concurs with the currently accepted intron position GGT|TT.

Liu & Tzean (1997: tab. 2) referred to this intron as ‘insert’ and observed it in 10 out of 29 orbiliaceous species by listing a length between 391 (*Geniculifera cystosporia*) and 428 (*Arthrobotrys botryosporus*), rarely 1294 nt (*A. superbus*). Hagedorn & Scholler (1999: fig. 3), who named it ‘second insert’, found it with a length of 385–416 nt in 15 species of section *Arthrobotrys* and provided a neighbour joining analysis of the alignable part of this insert for them. We have observed the S1506 intron in 150 species of *Orbiliomycetes* and in 262 its absence, including data retrieved from GenBank (Tab. 23). Within a section or series of *Orbilia* the intron may be present or absent in a similar frequency, but in some groups and particularly in other orbiliaceous genera it was rare or even absent, with the exception of *Hyalorbilia* (Tab. 23). In a number of cases we observed that closely related species consistently differed in the presence vs. absence of the intron (Tab. 25), whereas in others it showed variation within a species (Tab. 26).

Table 23. Presence of S1506 intron in the genera of *Orbiliomycetes* and subgroups of *Orbilia*. The two right columns indicate the number of species in which the intron was absent or present (data from Tab. S5).

The S1506 intron may occur in two very different length variants: the long variant ranges between 1266 and 2053 nt, rarely only 547 or 701, and was observed in eight strains of eight rather distant species of *Orbilia*. In all other orbiliaceous species, in which the intron occurred, it had a length of 381–459, rarely 330–366 nt (*Hyalorbilia*) (Tab. 24). However, the two categories are not sharply separated. The frequent short variant aligns more or less well and can be used for phylogenetic analyses. When aligning the short with the long variant, it aligns to the 5’-end of the latter.

The S1506 intron was observed with varying frequency in most groups of ascomycetes, also in the exobasidiomycete *Tilletiopsis flava* and in *Rhodophyta* (*Porphyra spiralis* var. *amplifolia*, *Hildenbrandia rubra*). The two length variants chiefly contain six conserved motifs which occur with minor variation also in other classes of ascomycetes, for instance in *Leotiomycetes*. One of them is located near the 3’-end of the short variant and usually looks like this: GCTTAAGATATAGTCGGGC, but some strains showed some variation. Sometimes it starts with **A**CTTAAG or ends with GTCGGG**T** or GTCGG**T**C, or it may show some rare other variants. In *Hyalorbilia* the motif was predominantly GC**C**TAAGATATA**A**TCGG**GT**. The right, downstream part of the long variant appears to represent an intron of its own. In two species (*O. quaestiformis* of section *Habrostictis*, *O. zhongdianensis* of series *Neodactylella*) both length variants occurred in different strains (Tab. 24).

Intron S1506 in other classes. The S1506 intron also occurs in various members of *Helotiales* by usually showing exactly the motif GCTTAAGATATAGTCGGGC near its 3’-end, though also some other variants. Also various *Dothideomycetes* exactly concur with this motif, according to BLAST search for this motif in GenBank. This indicates homology of the S1506 intron region across the *Ascomycota*. Also in the *Rhodophyta* the intron occurs, with the conserved motif deviating at three positions from the current motif of *Ascomycota*: GCTTAAGA**GAC**AGTCGGT, which suggests that this intron is a very old gene region that traces back to a common ancestor of both phyla.

Gargas et al. (1995) observed intron S1506 in *Helotiales*, *Taphrinomycotina* (*Pneumocystis*), *Dothideomycetes* (*Cenococcum*), *Chaetothyriales* (*Phialophora americana*), also in *Chlorophyta* and *Rhodophyta*, but not in lichens. Gutiérrez et al. (2007), however, found intron S1506 in various *Parmeliaceae*, with three size ranges between 224 and 614 nt. Takashima & Nakase (1997) observed intron S1506 in *Tilletiopsis flava* (*Exobasidiomycetes*) and Xu et al. (2013) in *Botryosphaeria dothidea* (*Dothideomycetes*), and both classified it as group IC1 intron.

Other SSU introns in *Orbiliomycetes*. Apart from intron S1506, *Orbiliomycetes* did not show any further introns in the SSU region in most of those taxa which comprise more than the V6–V9 regions, with a few exceptions. Hagedorn & Scholler (1999) observed the S943 intron in two species of section *Arthrobotrys* (*Dactylella cylindrospora*, *Gamsylella arcuata*) and named it 'first insert' in reference to S1506 as the 'second insert' in orbiliaceous taxa. We found intron S943 also in *Lilapila oculispora*, five species of *Hyalorbilia*, and in 11 of *Orbilia* from five different sections (see Tab. 27). However, sequences that include the V6 region were at pesent predominantly available for nematode-trapping taxa. The intron S943 is located between the motives CACCAGAWGT[intron]GGAGCCTGCG.

Orbilia ovoidea (H.B. 6489a) possesses the intron S1516 with a length of only 70 nt, which is located in the region of the ITS1 primer. These two exceptional group I intron positions were also reported by Gargas et al. (1995), the former in various orders of fungi, the latter in *Cladonia chlorophaea* and *Lecanora dispersa*, though here with 210–228 nt. Because the S1516 intron of *O. ovoidea* is much shorter and ends with an A, it is probably not a group I intron; its position could also be 1517, in which case it would actually end with a G.

LSU introns in *Orbiliomycetes*. Three group I introns were observed in the LSU of *Orbiliomycetes*, one occurring in the D9 domain (L1921), one between D10 and D11 (L2449), and one in D11 (L2563) (Tab. S1). At present, sequences from 15 species of *Orbiliomycetes* comprise the complete D9 domain, from 14 species the complete D10 domain, and from 13 species the D11 domain (Tab. 28). These introns are recognized when aligning the LSU with orbiliaceous or other LSU sequences which lack the introns. Their length varied between 429 and 738 nt. The strong length difference in L2449 is due to more and longer (up to 68 nt) inserts in *O. xanthostigma*, and in L2563 it is an insert of 54 nt in *O. leucostigma*. No intron was observed in the D1–D8 domain.

BLAST searches of the L1921 intron yielded alignments with the L798 intron of *Dothideomycetes* (*Pseudorobillarda siamensis*, *Wiesneriomyces laurinus*) or *Saccharomycetes* (*Diddensiella* ['*Candida*'] spp.), but also with the S943 intron of *Dothideomycetes* (*Botryosphaeria* spp.) and even *Chlorophyceae* (*Spermatozopsis exsultans*). These alignments are very fragmentary, but they may include regions of up to 150 nt which align without gaps though with a high distance. This result, which can hardly be accidental, supports the hypothesis that group I introns in the fungal genome may have a viral origin. The general presence of 'G' at the 3'-end of group I introns has a special role in their splicing as mobile genetic elements (P. Haugen pers. comm.).

Protein-coding genes

Different gene regions of the DNA that code for proteins have been investigated by different authors regarding members of *Orbiliomycetes*, particularly nematode-trapping taxa (Tab. 29). They were used in multigene analyses in order to obtain a better backbone phylogeny with higher bootstrap support at the main branches.

The affiliation of *Orbiliomycetes* in the *Ascomycota* was explored by various authors based on two or rarely three species of *Orbilia* (*O.* aff. *sinensis* [as *O. vinosa*], *O.* aff. *elegans* [as *O. auricolor*], *O. elegans* (as *Arthrobotrys elegans*]) by using rDNA in combination with protein-coding genes: James et al. (2006), Spatafora et al. (2007), Schoch et al. (2009), and Gueidan et al. (2011) with *RPB1*, *RPB2*, and *TEF1*; Prieto & Wedin (2013) with *RPB1*, mtSSU, and *MCM7* (the latter two lacking for *Orbilia*); Gazis et al. (2012) with mtSSU, *RPB1*, and *RPB2*; and Beimforde et al. (2014) with *RPB1* and *RPB2*.

Different Asian workers have investigated protein-coding genes of larger data sets of *Orbiliomycetes*. Li et al. (2005) analysed LSU in combination with two *TUBB* genes (1A/1B, 2A/2B) in nematophagous taxa. Yang & Liu (2006) and Yang et al. (2007) combined ITS, *RPB2*, *TEF1*, and *TUBB* (2A/2B); Swe et al. (2008b) ITS and *TUBB* (2A/2B); Yang et al. (2012a) *RPB2*, *TEF1*, *TUBB* (2A/2B), *mapk*, and *sp*; and Zhang et al. (ined.) mtLSU, *RPB2*, *TEF1*, and *TUBB* (2A/2B). Li et al. (2016) found in the MAD1 gene (uncombined) a correlation with the adhesive properties of trapping organs as a support for the monophyly of the different trapping devices.

Whole-genome sequences

Up to the present, the whole genome from three nematophagous species of *Orbilia* is available in GenBank, being sequenced in the 'Gold Project' (Gp, https://gold.jgi.doe.gov/): *Orbilia oligospora* (Gp0005961, ATCC 24927, CBS 115.81, as *O. auricolor*/*Arthrobotrys oligosporus*, accession number ADOT00000000, Yang et al. 2011), *Dactylellina haptotyla* (Gp0047799, CBS 200.50, as *Monacrosporium haptotylum*, AQGS00000000, Meerupati et al. 2013), and *Drechslerella stenobrocha* (Gp0005661, strain 248, YNWS02-9-1, AS/CGMCC 3.6768, ASQI00000000, Yang et al. 2007, Liu et al. 2014). The size of the genome varied strongly among the species, ranging between 29.02 Mb (millions of basepairs, *D. stenobrocha*) up to 40.07 Mb (*A. oligosporus*) or 40.4 Mb (*D. haptotyla*).

Usually rDNA is not available in whole-genome data, since repetitive genes are hard to assemble with confidence (D. Ahrén pers. comm.), but it is often separately supplied to enable identification at the species level. Only for *Drechslerella stenobrocha* the complete SSU-ITS-LSU could be retrieved from the whole-genome data (ASQI01000343, W.W. Zhang pers. comm.). Available rDNA data are for *O. oligospora*: complete SSU (AJ001986), SSU V8–V9, ITS, and LSU D1–D2 (KY463695); for *Dactylellina haptotyla*: complete SSU (AJ001990), ITS (U51957), and LSU D2–D4 (AQGS01000586); and for *Drechslerella stenobrocha*: ITS (AY773460).

Further 18 nematode-trapping *Orbilia* species, being among those treated in Yang et al. (2007), have been investigated for the whole genome (W.W. Zhang & X.Z. Liu, pers. comm.), for instance, *O. auricolor* (Gp0004966, NCBI 53381, as *O. auricolor*/*A. cladodes*, CBS 433.81). However, uploads and a published report were not yet available.

Phylogenetic position of *Orbiliomycetes* within the *Ascomycota*

Historical review. When Nannfeldt (1932) erected the family *Orbiliaceae* as a member of *Helotiales*, he included three genera: *Orbilia*, *Hyalinia*, and *Patinella*. Benny et al. (1978) suggested to remove the family from the *Helotiales* by tentatively transferring it to the *Lecanorales* and within this order to members with iodine-negative asci. The authors based their

Table 24. Total length of S1506 intron in *Hyalorbilia* and different sections and series of *Orbilia*. Only those species are listed in which the intron was obtained in full length or when its length was approximately certain.

conclusion on the study of two species, *Orbilia sarraziniana* (as *O. luteorubella*) and *O.* cf. *pulviscula* (the latter species in its original sense represents a *Calycellina*, see p. 1682). Their criteria were (1) the exceptional ultrastructure of the ascus apex being truncate and thin-walled, without an amyloid apical ring structure, and (2) the basal anchoring hyphae forming haustoria in blue-green algae. This tempted the authors to speculate 'that many, if not all, species of *Orbilia* are lichenized'. However, a connection of any member of *Orbiliomycetes* to algae by haustoria could never be demonstrated in the present study (see also p. 148–150).

Although Hawksworth et al. (1996) retained the *Orbiliaceae* in the '*Leotiales*' (*Helotiales*), the authors mentioned Sherwood's opinion who asserted (in litt.) that the family is better included in the *Gyalectales* (*Ostropomycetidae*, *Lecanoromycetes*). This opinion was one of the stimuli for a comparative study of these two groups by Müller (1998). However, Müller's observations on ascus structure and spore morphology did not reveal convincing similarities between *Orbiliaceae* and *Gyalectaceae*, a result which is supported by later molecular analyses which identified a great distance between these families

In Eriksson et al. (2003) the new order *Orbiliales* and class *Orbiliomycetes* were proposed to accomodate the only family *Orbiliaceae*. Morphological data and a specific molecular signature in the SSU rDNA supported removal from the *Helotiales*. The *Orbiliomycetes* were thought to represent a class separate from the other two classes of non-lichenized discomycetes, roughly represented by the operculate (*Pezizomycetes*) and inoperculate discomycetes (*Leotiomycetes*). Later, Eriksson (2005) presented arguments for a primitive, lichenized, fruitbody forming common ancestor of all main groups of *Ascomycota*, with the exception of *Saccharomycotina* and *Taphrinomycotina*. This so-called 'Protolichenes Hypothesis' implies that classes like *Orbiliomycetes* or *Pezizomycetes* lost their photosynthesising symbiont and became saprobionts, parasites, or symbionts on various substrates, including animals. Eriksson also compared the truncate thin-walled ascus apex of *Orbilia*, *Taphrina*, and *Neolecta* with Chadefaud's hypothetical, primitive 'préarchaeascé' type with uniformly thickened ascus wall, from which the lecanoralean ascus type was said to have evolved.

Molecular phylogenetic analyses. According to Spatafora et al. (2007) and Thorn et al. (2008), the classes *Orbiliomycetes* and *Pezizomycetes* are among the oldest of the phylum *Ascomycota* and the 'two most basal or early diverging branches of *Pezizomycotina*', by far the largest subphylum of *Ascomycota*. The node separating the two classes is generally weakly supported, therefore, it is uncertain which of the two were the first to separate from the large rest of *Pezizomycotina*. In Winka & Eriksson's (2000) analysis of the entire nuclear SSU rDNA region, the *Orbiliomycetes*, represented by a single sequence (*O. fimicola* s. Pfister, D.H.P. 60, = *O. auricolor*), clustered near the base of the tree that comprised a broad scope of *Ascomycota.* Apart from some even more basal taxa now recognized in *Taphrinomycotina* and *Saccharomycotina*, the class formed a sister group to all remaining clades of the phylum, including the *Pezizales* which separated next, and the *Helotiales* to which they are only very distantly related. In two further analyses of the entire SSU (Berbee 2001, Tehler et al. 2003), the *Orbiliomycetes*, represented by 10–16 sequences, clustered within the paraphyletic *Pezizomycetes* clade in an unsupported sister group of *Helvellaceae*, *Morchellaceae*, and *Tuberaceae*, whereas members with amyloid operculate asci (*Ascobolaceae* and *Pezizaceae*) branched off earlier and next to *Saccharomycotina*.

Later molecular studies included further rDNA gene regions and verified the basal placement of *Orbiliomycetes*, but varied in the relationship to *Pezizomycetes*. In analyses of nuSSU+5.8S+LSU by Wang et al. (2006: figs 1–4), based on two chimeric sequences under the names *Orbilia delicatula* and *O. auricolor* which belong to at least three species from six different strains representing series *Orbilia* and *Arthrobotrys* [*O. leuco-* & *xanthostigma* s.l. (D.H.P. 108, 111, YNUCC 6028), *O. oligospora* (*Arthrobotrys oligosporus*, CBS 115.81, YNUCC 2829), *O. auricolor* (*A. cladodes*, CBS 433.81)], the genus *Orbilia* branched off either after (parsimonious trees) or before (Bayesian trees) the *Pezizomycetes*. A similar set of *Orbilia* species from three different strains [*O. xanthostigma* s.l. (D.H.P. 111, YNUCC 6028), *A.* cf. *pyriformis* (as *O. auricolor*/*A. psychrophilus*: AFTOL-ID 906, CBS 547.63)] diverged after the *Pezizomycetes* in Zhuang & Liu's (2012) maximum likelihood or parsimony analysis of SSU+LSU, whereby this result was not altered when the secondary structure of rRNA was included in the analysis. In Liu & Zhuang's (2013) Bayesian analysis of SSU, however, which included the secondary structure, *Pezizomycetes*

and *Orbiliomycetes*, based on *O. auricolor* s.l. (as *O. auricolor* and *O. fimicola*, probably D.H.P. 55 and 60), formed a supported clade of their own, with the remaining *Pezizomycotina* as sister clade. In the Bayesian analysis by Ekanayaka et al. (2017: fig. 25) based on nuSSU, nuLSU, and *RPB2*, the *Orbiliomycetes* diverged shortly before the *Pezizomycetes*. As representative taxa the authors used *Orbilia sinensis* (type, YMF 1.01843, as *O. luteorubella*) and *O. tenuispora* (B.L. 691, HMAS 139703, as *O. rectispora*) for which, however, only LSU data was available. In our ML analysis based on 5.8S+LSU (D1–D6), the orbiliaceous group branched off after the *Pezizomycetes*, but without support at the branches (Phyl. 1), and this was also the case in Magyar et al.'s (2017b) Bayesian analysis of ITS+LSU which included many orbiliaceous taxa.

In two multigene analyses by James et al. (2006) and Spatafora et al. (2007) (see Fig. 114), the *Orbiliomycetes* diverged shortly

Table 28. Presence/absence of three LSU group I introns (yellow) in the few available sequences of *Orbiliomycetes* which include the D9–D11 domain. The length of the intron is given in parenthesis. ? = number of nt uncertain or unknown.

mitogen-activated protein kinase	*mapk*	some nematode-trapping spp. of section *Arthrobotrys*
subtilisin-like serine protease	*sp*	some nematode-trapping spp. of section *Arthrobotrys*
mini-chromosome maintenance proteins	*MCM7*	none found
cell wall adhesin protein MAD1 mRNA	*MAD1*	various spp. of section *Arthrobotrys* including *Neodactylella*
small subunit of mitochondrial rDNA	mtSSU	none found
large subunit of mitochondrial rDNA	mtLSU	many spp. of section *Arthrobotrys*, some of series *Pseudotripoconidium*, *O. laevimarginata*, *O. xiushanensis*

before the *Pezizomycetes*, but the bootstrap support for this was not high. The analyses were based on nuSSU+(5.8S+) LSU, *RPB1*, *RPB2*, and *TEF1*, and the two included *Orbilia* species were *Arthrobotrys* cf. *pyriformis* (CBS 547.63) and *O.* aff. *sinensis* (as *O. vinosa*: AFTOL-ID 905, CBS 917.72). Also in three more recent multigene analyses by Gueidan et al. (2011, nuSSU+LSU, *RPB1*, *RPB2*, *TEF1*), Prieto & Wedin (2013, nuSSU+5.8S+LSU, mtSSU, *RPB1*, *MCM7*), and Gazis et al. (2012, nuSSU+LSU, mtSSU, *RPB1*, *RPB2*), the same two *Orbilia* species diverged with high support distinctly before the *Pezizomycetes*. However, in Gazis et al. the genus *Peziza* clustered in a clade separate from the remaining *Pezizomycetes* which diverged before *Orbilia*, whereas in James et al. and Spatafora et al. also *Peziza* diverged after *Orbilia*. In contrast to this, *Orbiliomycetes* diverged shortly after *Pezizomycetes* in the analyses of Schoch et al. (2009, based on *RPB1*+*RPB2*+*TEF1*) and Beimforde et al. (2014, based on nuSSU, nuLSU, *RPB1*, *RPB2*). The authors used again the same two *Orbilia* species, but Schoch et al. included also *O. elegans* (as *Arthrobotrys elegans*, AFTOL-ID 1252, CBS 397.93).

In a whole-genome sequencing study by Gazis et al. (2016: fig. 1), which included two species of *Pezizomycetes* (*Pyronema confluens*, *Tuber melanosporum*) and one of *Orbiliomycetes* (*Orbilia oligospora*, ATCC 24927), 174 single-copy-orthologs were aligned. The resulting phylogram with 25809 amino acid positions of well-aligned regions trimmed with gBlocks (R. Gazis pers. comm.) shows high support at all main branches. As in Liu & Zhuang's (2013) SSU analysis, *Pezizomycetes* and *Orbiliomycetes* clustered in a monophyletic clade, representing the first segregate within the *Pezizomycotina* superclade. The same result has been obtained in a Bayesian analysis of 14 mitochondrial protein-coding genes, which included 8 mainly nematophagous *Orbilia* spp. (Zhang et al. 2020b).

In a morphological phylogenetic analysis based on four characters of ascus apex and septal pore, Kumar et al. (2012: tabs I–II) confirmed that the *Orbiliomycetes* and *Pezizomycetes* are among the earliest diverging branches of *Pezizomycotina*. The authors also interpreted the closed nuclear division (retention of an intact nuclear envelope throughout mitosis) and the two-layered disk-shaped spindle pole body as ancestral state characters for *Ascomycota*.

Molecular clock. Segregation of *Orbiliomycetes* must have occurred much earlier than in the Cretaceous era, which dates 145–66 myr before present. According to phylogenetic analyses, calibrated mainly by pyrenocarpous, lichenized, and calicioid (mazaediate) ascomycetous fossils from amber and chert dating between around 460 and 15 myr ago, the earliest diversification of *Pezizomycotina*, which resulted in the *Orbiliomycetes* and *Pezizomycetes*, took place about 550–350 myr ago (see following references).

In three diversification studies on the major lineages of fungi and particularly ascomycetes, the *Orbiliomycetes*, represented by *O.* '*auricolor*' (= *Arthrobotrys* cf. *pyriformis*) and *O.* '*vinosa*' (= *O.* aff. *sinensis*), diverged either during late Ordovician (~455 myr, Gueidan et al. 2011, Prieto & Wedin 2013, calibrated using 5–8 fossils) or during middle Silurian (~430 myr, Beimforde et al. 2014, using 13 fossils). However, the variance of these results regarding the first diversification of *Pezizomycotina* spread between middle Cambrian (516 myr) and early Devonian (396 myr) in the first two studies and between late Neoproterozoic (554 myr) and early Carboniferous (353 myr) in the third study.

The divergence time, during which the lineages of these two *Orbilia* species had separated from their common ancestor, was estimated as 225 myr (Gueidan et al. 2011), 150 myr (Beimforde et al. 2014), or 106 myr (Prieto & Wedin 2013) before present. In our taxonomic concept, these two *Orbilia* species represent the lineages of sections *Arthrobotrys* and *Aurantiorubrae*, respectively.

In the analysis of Ekanayaka et al. (2017: fig. 25, tab. 4), which was calibrated based on four ascomycetous fossils, the *Orbiliomycetes* diverged ~443 (410–523) myr ago, in concordance with Gueidan et al. (2011) and Prieto & Wedin (2013). Within the class a divergence time of only 30 myr was determined by Ekanayaka et al., who incorrectly concluded that all members of the class are so young by representing 'recently evolved taxa'. Instead, Ekanayaka et al.'s result only says that the two very closely related taxa *O. sinensis* (YMF 1.01843) and *O. tenuispora* (B.L. 691), which are both members of series *Pseudotripoconidium*, trace back to a common ancestor of about that age.

Yang et al. (2012a), in their phylogenetic analysis of five protein-coding genes, used two fossils of carnivorous ascomycetes as calibration points for their evaluation of divergence times

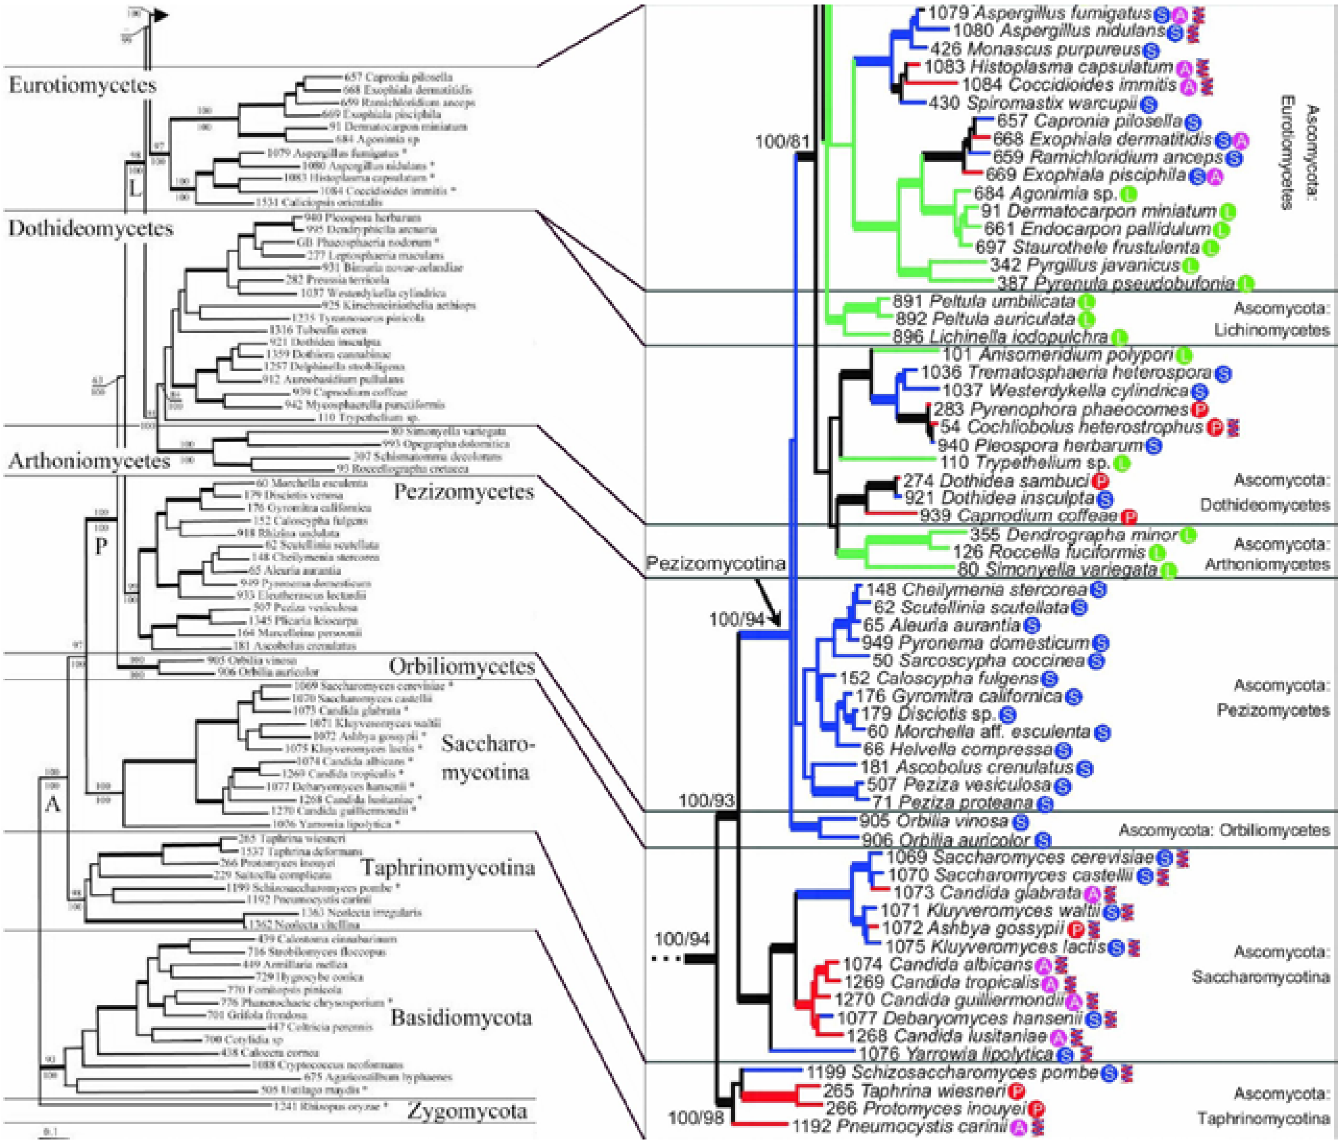

Figure 114: Phylogenetic placement of *Orbiliomycetes* within the fungi; **left**: lower part of the phylogram in Spatafora et al. (2007: fig. 2, five-gene dataset); **right**: upper part of the phylogram in James et al. (2006: fig. 1. six-gene dataset). The used gene regions were nuclear rDNA (SSU, 5.8S, LSU), *RPB1*, *RPB2*, and *TEF1*; in Spatafora et al. no 5.8S was included.

of the major lineages of predacious *Orbiliomycetes*. One of them, *Palaeoanellus dimorphus* Schmidt et al., represents a hyphomycete with unicellular, non-constricting, apparently nematophagous rings and a blastosporous, yeast-like anamorph, reported from fossil amber by Schmidt et al. (2007, 2008) and dated to 100 myr (middle Cretaceous). The other fossil concerns a member of series *Dactylellina* with conidia and adhesive, apparently stalked knobs capturing nematodes, which was dated to ~22.5–26 myr (Oligocene) (Jansson & Poinar 1986). Yang et al. interpreted the former fossil as the last common ancestor of species with septate adhesive networks (series *Arthrobotrys*) and three-celled non-constricting rings (series *Dactylellina*), and the latter fossil as the last common ancestor of two species with stalked adhesive knobs, *Dactylellina drechsleri* (CBS 549.63, as '546.63') and *D. ellipsospora* (YNWS02-8-1), included in their phylogenetic analysis.

However, there are some doubts about the correct calibration in this analysis. Regarding the first fossil, the conidial state does not resemble known anamorphs of *Orbiliomycetes*. Instead, Thorn et al. (2008) compared it with *Debaryomyces*, a member of *Saccharomycetales*, and doubted whether it belongs to the fungus that produced the rings. The authors were also sceptical about the rings being homologous to non-constricting rings of *Orbiliomycetes*. Schmidt et al. (2009), in their replica, assumed that the fossil represents an unknown, perhaps extinct type of adhesive ring trap, whereas Thorn et al. (2009) even doubted that the rings were nematophagous. The second fossil appears to be trustworthy, but the two *Dactylellina* taxa used by Yang et al. (2012a) are undoubtedly conspecific, based on a 1.7% ITS distance between them. CBS 549.63 is an authentic, probably ex-type strain of *D. drechsleri* (Rubner 1996: 58), and its sequence appears to be erroneous at the 5'-end of ITS1, which would mean an even lower distance (?1%) to YNWS02-8-1. In contrast, the neotype strain of *D. ellipsospora* (CBS 302.94, Rubner 1996) deviates hereof by ~10%. Moreover, it seems risky to assume that the fossil was a species that does not form non-constricting rings. Besides, taxa with and without non-constricting rings did not cluster in different clades in our analyses, contrary to the assumption of Yang et al. (2012a). In conclusion, the affiliation of this fossil with the *Dactylellina* clade seems to be unquestionable, but its identity and position within this series remains unknown.

When comparing rDNA phylogenetic analyses of a larger number of species of *Orbiliomycetes* (Magyar et al. 2017b, Baral et al. 2017b), it appears that the different types of nematode traps of section *Arthrobotrys* diverged fairly late in the evolutionary history of the class, and also their first appearance within that section would have happened only a few myr earlier, judging from the fact that its basal taxa represented by the paraphyletic series *Neodactylella* are found to be invariably non-predacious. According to Yang et al. (2012a), nematodes and other major invertebrate clades were proposed to have appeared during the Cambrian Explosion 600–550 myr ago, long before the first *Orbiliomycetes* emerged 419 myr ago. Under the latter premise we conclude that section *Arthrobotrys* separated into adhesive trap and constricting ring formers after the Triassic/Jurassic mass extinction 201 myr ago, not shortly after the Permian/Triassic mass extinction 252 myr ago as suggested by Yang et al. (2012a) and Liu et al. (2014). Ahrén et al. (2004) even gave for this event 77 myr (late Cretaceous), based on analysis of SSU rDNA. The predacious genera *Lecophagus* and *Hyalorbilia* diverged distinctly earlier than section *Arthrobotrys* but perhaps also less than 250 myr ago. However, it might be disputable whether rDNA is a suitable gene region for estimating divergence times.

The striking preference of the genera *Lilapila*, *Amphosoma*, *Retiarius*, and *Mycoceros* for gymnospermous substrates (resin or pollen) could be interpreted as an ecological relict of the Carboniferous and Permian 350–250 myr ago when the first conifers appeared. In the above-mentioned phylogenetic analyses, *Lilapila* and *Mycoceros* diverged earlier than any of the invertebrate-capturing genera. Possibly, carnivorism emerged independently in three different lineages of *Orbiliomycetes* from ancestors that parasitized pollen. Liu et al. (2014) hypothesized that nematode trapping fungi originated from efficient cellulolytic fungi and lost this saprotrophic capacity to a varying degree when developing into predatory fungi, the constricting ring formers more and the adhesive trap formers less.

At the present state of knowledge, the origin of *Orbiliomycetes* could therefore be sought in the Carboniferous era. Interesting in this respect is the soil-inhabiting *Bryorbilia arenicola* which appears to be connected to a bryophyte. Considering its basal affiliation in the class, this fungus might represent an old group adapted to an ecological niche in which *Orbiliomycetes* could have emerged.

Did *Orbiliomycetes* evolve from *Taphrinomycotina*? Similarities in the truncate, bilateral-symmetrical ascus apex prompted authors to assume a relationship between *Orbilia* and *Neolecta* or *Taphrina* (see p. 54). However, further similarities are largely absent.

Neolecta was referred to the *Taphrinomycotina* on account of sequence data (Eriksson & Winka 1997), and constitutes the only genus in this subphylum which is able to form ascomata. Apart from the orbiliaceous ascus apex, *Neolecta* strongly differs from *Orbiliomycetes* in a number of characteristics such as (1) club-shaped (geoglossoid) apothecia, (2) the complete ascus wall reacting faintly hemiamyloid, (3) the absence of paraphyses, (4) curious semiglobose refractive caps ~2–4 µm diam. on both sides of the septa of tissue hyphae, being KOH-insoluble and strongly dextrinoid. The caps are unknown in any other group of ascomycetes, and were observed by Landvik et al. in *N. flavovirescens* and by the first author in *N. vitellina* (IVV: H.B. 7428). The 'plasmalemmasome-like body' at the septum of the ascus base described by Landvik et al. (2003, fig. 24) perhaps refers to the same structure. A further difference to *Orbiliomycetes* might lie in the multinucleate ascogenous hyphae of *Neolecta*.

Taphrina differs from *Orbilia* in the asci having short and thick, unbranched stalks arising from simple septa. According to Martin (1940) there is an intermediate nuclear division between the ascus mother cell containing the fusion nucleus and the young ascus in which meiosis takes place. This intermediate nuclear division results in the formation of a basal cell below the ascus stipe, which is unknown in both *Neolectomycetes* and *Orbiliomycetes*.

The truncate ascus apex of *Taphrina* and *Orbilia* p.p. lacking an endoascal thickening is reminiscent of the *Pezizomycetes*, near which *Orbiliomycetes* cluster, but *Pezizomycetes* asci are never bilateral-symmetrical (see p. 54).

In both *Neolecta* and *Taphrina* yeast-like budding from the ascospores and also from the produced conidia occurs, whereas this ability is completely absent in the *Orbiliomycetes* and *Pezizomycetes*. Polyspory of asci in the latter two classes consistently originates from multiple nuclear divisions that take place inside living asci (see p. 56). True polyspory is also observed in *Saccharomycetes*. In contrast, polyspory in *Taphrinomycetes* is artificial as it occurs only inside dead asci, or on ejected ascospores. This indicates that the asci discharge only ascospores, not conidia.

BIOLOGY AND ECOLOGY

The *Orbiliomycetes* exhibit a broad ecological amplitude that comprises subarctic to tropical vegetation types. Included are more or less humid boreal, nemoral, and evergreen forests as well as cold to hot semideserts or arctic-alpine dwarf shrubs. Many species inhabit such harsh environments as the latter, which require a high tolerance against dryness and/or extreme temperatures. The species composition that is established on a given piece of substrate at a given sampling site is determined by the macroclimate on the one hand, which includes temperature (thermotype) and precipitation (ombrotype), but also by the microclimate, i. e., exposure of the substrate to desiccation and insolation, the degree of substrate decay by other fungi, and biochemical properties of the host organism.

Orbiliaceous fungi generally grow as saprobionts on a wide range of phanerogamic, rarely cryptogamic plants. However, for various species a parasitic or endophytic phase in living tissue of plants, fungi, or animals is known. Apart from pollen invasion by orbiliaceous mycelia (Magyar et al. 2017a, b; this study p. 108, Tab. 14), some rDNA isolates of *Orbiliomycetes* have been reported recently from living and necrotic pine needles, either surface sterilized (Bowman & Arnold 2018) or not (Lazarević & Menkis 2020, Lynikienė et al. 2020). Mycorrhizal associations did not come to our notice, but isolates from partly surface sterilized roots were reported for some orbiliaceous clones in GenBank, e.g., for the grass *Bouteloua* by Herrera et al. (2010, GenBank GQ924028). Some saprobic or parasitic *Orbiliomycetes* are known to be fungicolous and, last not least, many species of *Orbilia* section *Arthrobotrys* trap living invertebrates as additional, and several species of *Lecophagus* as more or less exclusive food source.

Reversely, apothecia of *Orbiliomycetes* serve as nutrient source for invertebrates, but also provide a niche for some parasitic fungi, including two *Hyalorbilia* spp. that grow on apothecia of *Orbilia* spp. The role that the ascospores and conidia play in the colonization of new substrate is little understood. They are transported by wind, water, and animals, but the circumstances where they germinate under natural condition is unknown, as is the biological function of the spore body in the ascospores.

Substrate specificity

A large number of substrates on which *Orbiliomycetes*, mainly teleomorphs, were found are reported in this monograph (see Appendix 1). They comprise various kinds of woody and herbaceous land plants, though apparently never annual herbs, exceptionally also ferns (*Polypodiopsida*) and bryophytes (*Marchantiophyta* and *Bryophyta*). A wide range of fungal substrates is observed, including aphyllophoralean or tremellalean *Basidiomycota* and pyrenocarpous or discocarpous *Ascomycota*. An overview of the plant orders and families known as hosts of *Orbiliomycetes* is shown in Tab. 30.

Particularly because of the frequent neglect of semiarid to arid regions by mycological expeditions, a lot of plant taxa are reported here for the first time as substrate of *Orbiliomycetes*. For instance, the North American *Juniperus osteosperma*, a widespread shrub in the Rocky Mountains and Colorado Plateau, was found to carry at least 14 species of *Orbilia* and 8 further non-lichenized ascomycetes, but in the fungus-host database of the United States Department of Agriculture (Farr & Rossman 2006) it is only mentioned as host of basidiomycetes. This applies also to a lot of other plants which are adapted to regions of comparatively low annual precipitation. For instance, also for *Quercus gambelii* (8 *Orbilia* spp.), *Larrea tridentata* (21 *Orbilia* spp.), and *Carnegiea gigantea* (3 *Orbilia* spp.) no discomycetes are listed in this database.

The great majority of *Orbiliomycetes* with at least about 4–8 known collections are plurivorous species growing on various phylogenetically distant hosts. Many of them can be expected to occur on all kinds of either woody or herbaceous plants that grow within a given climate region. They were often recorded on both angio- and gymnosperms, and some even on both woody and herbaceous, or even fungal substrates and dung (see Tab. 31). This results in the common experience that the list of recorded host plants increases with the collecting activities. Instead of a substrate specificity, these species merely exhibit a more or less significant climatic preference. As a result, different ecoregions are characterized by different species compositions. The substrate index given in this study is, therefore, to be considered as tentative and accidental to a certain degree, and the host spectrum known at present can only be considered as more or less final for a comparatively small minority of host-specific taxa.

Many species of *Orbilia* and also *Hyalorbilia* were named according to a host genus or sometimes a host species, and some of the names might have been given in the assumption of a certain host specificity. However, too much taxonomic weight has often been put on the inhabited substrate. Based on later research, most of these species turned out to be plurivorous by showing no limits to a host genus or family, thus having a much wider ecological amplitude than previously believed. For instance, *Orbilia euonymi* was for a long time only known from the type specimen. In the present study this species was observed on a total of 43 different genera of woody gymno- (14) and angiosperms (29), but was never recollected on *Euonymus europaeus*. On the other hand, 9 further species of *Orbiliomycetes* are reported for this host plant here. Similarly, *O. ebuli* was described from herbaceous stems of *Sambucus ebulus*, and *O. vitalbae* from bark of *Clematis vitalba*. However, they occur in fact on a wide variety of substrates (*O. ebuli*: 5 plant genera, including petioles of *Acer*; *O. vitalbae* s.l.: 24 plant genera, including woody angiosperm and herbaceous mono- and dicot substrate). Reversely, *Sambucus ebulus* and *Clematis vitalba* were found to carry at least 9 and 24 orbiliaceous species, respectively. Mainly because of the difficulty to contrive appropriate names for new species, we also followed this tradition in naming many of them after the substrate, although evidence for a host specificity was lacking (see Etymology/taxa concepts, p. 19–20).

In some cases, very closely related *Orbilia* spp. inhabit more or less closely related host plants. This is mainly observed in taxa restricted to conifers, but also, for instance, in *O. comma* and *O. neocomma* (see below). Frequently, however, more or less host-specific sibling taxa occur on very distant hosts, e.g., *O. spermoides* on bark (rarely wood) of different conifers and the very similar *O. occulta* and *O. austroocculta* on angiosperm bark (rarely wood). Likewise, the strictly conifericolous *O. sphaerospora*, here reported from 11 collections on wood (rarely bark) of different conifers is a sibling taxon of *O. subsphaerospora*, which is so far known from 16 samples on wood and bark of various angiosperm hosts. Difficult to understand is the pronounced restriction of *Orbilia carpoboloides* and *O. aurantiorubra* to the same three rather distant host families (*Ulmaceae*, *Salicaceae*, *Fabaceae*, see below).

Can fungal species richness be estimated from species richness of host plants? According to Hawksworth (1997), 'we know perhaps as few as 5% of the fungi on the planet'. This hypothesis of species richness of fungi was based on the observation that plants have on average 5–6 fungal species more or less confined to them, and results in a total number of 1,500,000 species worldwide. Others estimate up to 5,000,000 or 12,000,000 fungal species, although only around 100,000 are described and accepted (see Dayarathne et al. 2016, Wu et al. 2019). Hawksworth enumerated some unexpected habitats serving as 'untapped sources of novel fungi', like marine fungi or those growing on insects in the tropics. However, no mention is made of arid regions and air-exposed, xeric substrates, their fungi being highly underrepresented in most taxonomic and floristic treatments.

In our experience, Hawksworth's theory appears inapplicable to every climatic zone. In tropical rainforests which are known to harbour the richest species diversity in higher plants, we have so far recognized a comparatively low number of *Orbiliomycetes*, perhaps due to a paucity of collections. Available samples, particularly from southern China, northeastern Australia, and Antilles comprised predominantly hygrobiotic taxa collected, sometimes also xerobiotic ones collected either on the ground or in 1–2 m above the ground. As a possibility, dead branches in the rainforest canopy provide an important, so far completely unexplored niche of *Orbiliomycetes*.

We are also in doubt about Hawksworth's method of estimating species numbers, because many members of ascomycetes inhabit a considerably wide range of hosts, and some are not even restricted to woody versus herbaceous, or gymno- versus angiosperm substrates. This contradicts a current believe in a narrow ecological adaptation of a taxon at a time when only a few collections are available. Various new species appear to have been described mainly because they occurred on

Table 30. Total numbers of records and accepted species of *Orbiliomycetes* observed on the different lineages of plant taxa, based on data of the taxonomic part and host list (Appendix 1). Species numbers include also the mentioned undescribed taxa with or without a provisional name. Uncertain identifications of plants or *Orbiliomycetes* are counted as if certain. High record and species numbers in this table are to be considered as approximate.

Host genus or higher entity	Records	Species
BRYOPHYTA (*Ceratodon*, *Frullania*, *Hypnum*, *Radula*)	4	4
POLYPODIOPSIDA (*Angiopteris*, *Equisetum*)	2	2

an exceptional host. In fact, only a few *Orbiliomycetes* are more or less host-specific, such as *O. comma* and *O. pilifera* to *Ulmus*, *O. aradi* to *Fagus*, and *O. sarcobati* to *Sarcobatus*.

Gymnosperms comprise *Pinales* (conifers), *Ginkgoales*, *Gnetales*, and *Cycadales*. They are generally less rich in *Orbiliomycetes* compared to angiosperms. So far, about 147 orbiliaceous species were recorded on gymnosperm substrate. At least 18 of them are apparently confined to gymnosperms, while a majority also occur on angiosperms. Those *Orbiliomycetes* which seem to be restricted to gymnosperms are all xerobiotic, whereas plurivorous species are either xero- or hygrobiotic.

For the following species a restriction to coniferous substrate is very probable: *Orbilia alpigena* (14×, mainly *Picea*), *O. clavipisca* (4×, *Abies*, *Juniperus*, *Pinus*), *O. coniferarum* (7×, *Abies*, *Juniperus*, *Picea*, *Pinus*, *Pseudotsuga*), *O. crenatovinosa* (5×, mainly *Pinus*), *O. cucumispora* (5×, *Juniperus*, *Pinus*), *O. cylindrospora* (16×, *Juniperus*, *Larix*, *Picea*, *Pinus*), *O. magnifica* (5×, *Abies*, *Picea*), *O. ophiosoma* (6×, *Abies*, *Juniperus*), *O. patellarioides* (17×, mainly *Pinus*), *O. spermoides* (8×, *Cedrus*, *Pinus*, *Pseudotsuga*), *O. sphaerospora* (11×, mainly *Pinus*), *O. subvinosa* (24×, mainly *Pinus*). Except for *O. cucumispora*, *O. spermoides*, and *O. magnifica*, which strongly prefer bark, these species inhabit predominantly decorticated wood. Some other species being restricted to conifers were mainly found in close association with cankers and resin flow: *Lilapila* spp. (46 ×, *Picea*, *Pinus*), *Amphosoma resinicola* (9 ×, *Abies*, *Picea*, *Pinus*, *Pseudotsuga*), *A. atroolivaceum* (40 ×, *Larix*, *Picea*, *Pinus*), *Hyalorbilia resinae* (4 ×, *Larix*), and *Orbilia olivacea* (3 ×, *Pinus*). Their apothecia usually grew on old resin covered by a ± dense layer of black hyphomycetes in which the often dark-coloured apothecia are difficult to discern. In the small genus *Amphosoma*, three species known from the northern hemisphere are strictly conifericolous, and it was a surprise when a fourth species was detected on bark of an indet. *Fabaceae* in South Africa. Different non-orbiliaceous ascomycetes belonging to *Leotiomycetes, Dothideomycetes*, and *Lecanoromycetes* (*Sarea*) show the same restriction to blackened resin of conifers. Various further, possibly conifer-restricted *Orbiliomycetes* are only known from one or two collections (*Amphosoma macrosporum*, *Lecophagus pini*, *Hyalorbilia sibirica*, *Orbilia acuum*, *O. atrolentiformis*, *O. battenii*, *O. cupressi*, *O. dalmatica*, *O. edulis*, *O. liliputiana*, *O. macroasca*, *O. microlentiformis*, *O. osteospermae*, *O. pileosoma*, *O. ponderosae*, *O. subdelphinus*).

A few xerobiotic *Orbilia* species have been collected on members of *Cycadales*, *Gnetales*, and *Ginkgoales*, but all are plurivorous and inhabit predominantly angiosperms. Three of them were found on *Macrozamia riedlei* (*Cycadales*) in Australia (*O. eucalypti*, *O. myrioobliqua*, *O. nothovinosa*), 1 on *Ginkgo* (*O. euonymi*), and 7 on *Ephedra* (*Gnetales*, 6 of section *Habrostictis* and 1 of section *Hemiorbilia*).

Dicotyledonous angiosperms. The majority of *Orbiliomycetes* (ca. 437 species) have been collected on dicotyledonous angiosperms. Most of them are plurivorous, and many were even occasionally observed on gymnosperms or fungal substrates, rarely on dung (Tabs 30, 31). Only a few species appear to be restricted to dicots. Most of these dicot-specific taxa are more or less specific to one or a few host genera. Others are specific to woody dicots, e. g., *O. epipora* (40 ×) and *O. montigena* (16 ×).

The European *O. comma* is almost strictly confined to xeric bark of different species of *Ulmus* (*U. minor* and *U. glabra*, 65 ×), with two exceptions: *Broussonetia* (from central France) and *Robinia* (from southern France). An extra-European sibling, *O. neocomma*, was recorded once on *Ficus* (*Moraceae*) and three times on an unidentified climber. In this species pair the host families *Ulmaceae* and *Moraceae* belong with *Urticaceae* in a close relationship within the *Rosales*. Likewise, the atlantic *O. pilifera* seems to be restricted to bark (rarely wood) of *Ulmus* (36 records, one exception on ?*Populus*) in western and southern Europe. *O. aradi* was exclusively detected on bark of *Fagus* (18 ×), and *O. fraxini* on bark of *Fraxinus* (7 ×). *O. fraxini* deserves further attention to clarify its host spectrum, because two not included samples on *Populus* are possibly not conspecific.

Interestingly, these 5 host-specific taxa more or less exclusively inhabit xeric bark. Likewise, *O. aurantiorubra* and *O. carpoboloides* inhabit xeric bark and they share a preference for the very same group of host genera. *O. aurantiorubra* is frequently found on *Salix* (*Malpighiales*, 70 ×) and *Ulmus* (*Rosales*, 30 ×), but slightly shorter-spored records were mainly on woody *Fabales* (25 ×, especially *Cytisus*). *O. carpoboloides* prefers *Ulmus* (43 ×), but also occurs on different *Fabales* (17 ×), *Salix* (8 ×), and some other angiosperm genera. Similarly, *O. cercidicola* is so far only known from bark of *Fabales* (3 × *Cercis*), from which the first collections derive, and from *Ulmus* (3 ×).

The following two here described taxa suggest host specificity from their names but turned out to be plurivorous on bark and wood of various woody plants. *O. fabacearum* (section *Orbilia*) was at first believed to be restricted to *Fabaceae* (5 ×, on *Laburnum*, *Lupinus*, *Ulex*) but was later also found on *Clematis*, *Pinus*, *Quercus*, *Ulmus*, and *Salix*. *Hyalorbilia ulicicola* was mainly found on *Ulex* (21 ×), but later also on various other angiosperms, and even on *Pinus*, large polypores, and pyrenomycetes (see Tab. 31). Seemingly narrow host ranges may be due to the paucity of collections, and will be extended when records, especially from other geographic regions, become available.

Some xerobiotic species appear to be restricted to succulent plants. Host-specific to *Euphorbiaceae* appear to be, e. g., *O. pseudeuphorbiae* (23 ×), *O. pisciformis* (11 ×, mainly *E. canariensis*), *O. succulenticola* (10 ×), and *O. asomatica* (7 ×, mainly *E. canariensis*). However, these observations were so far made on a single Macaronesian island (Tenerife), and *O. succulenticola* occurred there once also on *Opuntia* (*Cactaceae*). Regarding *Cactaceae* in North America at least *O. cactacearum* (4 ×) seems to be specific.

The very different number of species recorded for each host genus suggests preferences but reflects to some extent also unbalanced collecting. Among the predominantly European substrates, worldwide 89 species were found on *Quercus*, 81 on *Salix*, 60 on *Fagus* (mainly *F. sylvatica*), 46 on *Ulmus*, 54 on *Populus*, 36 on *Ulex* (mainly *U. europaeus*), 31 on *Rosa*, 29 on *Cornus*, 28 on *Rubus*, 28 on *Cytisus* (mainly *C. scoparius*), and 26 on *Sambucus*. Among the predominantly Australian collections, worldwide 84 species were recorded on *Acacia*, 45 on *Eucalyptus*, 13 on *Vachellia*, 11 on *Melaleuca*, 11 on *Livistona* (*nitida*), and 11 on *Banksia*. In the semiarid to arid southwestern part of Northern America, 21 species were found on *Larrea* (*tridentata*), 16 on *Purshia*, 15 on *Cercocarpus*, 13 on *Ericameria* (*nauseosa*), 10 on woody *Artemisia*, 11 on *Cactaceae*, 9 on *Chrysothamnus*, 8 on *Sarcobatus* (*vermiculatus*), 6 on *Krascheninnikovia* (*lanata*), and 5 on woody *Atriplex*.

All of the more frequently collected herbicolous species have rarely or even frequently also been found on woody substrates (e. g., *O. atlantis*, *O. auricolor*, *O. caulicola*, *O. cylindrosoma*, *O. flavidorosella*, *O. cardui*, *O. quaestiformis*, *O. septispora*). Among the 5 xerobiotic species so far recorded on *Reynoutria*, one appears to be predominantly herbicolous (*O. caulicola*), 2 occur at a similar frequency on herbs and woody substrates (*O. quaestiformis*, *O. ungulata*), and 2 were otherwise nearly exclusively found on woody substrates (*O. cotoneastri* s.l., *O. gambelii*).

Monocotyledonous angiosperms. About 85 orbiliaceous species have been collected on monocots. Many of them were only once recorded, therefore, their actual ecological amplitude is unknown. Among the repeatedly encountered species only a few appear to be restricted to monocots. *O. junci* was so far only found on leaves of *Juncus roemerianus* (6 ×). *O. rectispora* on large, more or less aquatic monocots (25 ×, mainly *Typha* and *Scirpus*, also *Glyceria*, *Iris*, and *Sparganium*), but one was on hare dung which contained grass remnants. *O. graminis* and *O. septispora* were at first believed to grow predominantly on *Phragmites* (8 × and 27 ×, respectively). However, this seems to be a result of unbalanced collecting, as they were once also found on another monocot (*O. graminis* on *Ammophila*, *O. septispora* on *Typha*). In addition, *O. septispora* was 3× found on woody plants (*Juglans*, *Lonicera*, *Rosa*), and the type collection was on *Melilotus*, a herbaceous dicot.

Large monocots of the subtropics and tropics, such as palms (*Arecales*), bamboo (*Bambusoideae*), *Zingiberales* (*Elettaria*), *Asparagales* (*Agave*, *Yucca*, *Xanthorrhoea*), or *Bromeliaceae* (*Puya*), were found to carry some rather unique species but, due to the paucity of collections, nothing is known about their host specificity. For instance, the large and bright-coloured apothecia of *O. anigozanthi* grew on herbaceous stems of *Anigozanthos* (*Haemodoraceae*), but this *Orbilia* is only known from two abundant collections in the Kings Park of Perth in southwestern Australia.

Introduced hosts. The fact that many species exhibit little host specificity is illustrated by the observation that they also colonize introduced plants. For example, six species of *Orbiliomycetes* were detected on the large perennial herbs *Reynoutria japonica* and *R. sachalinensis* (*Polygonaceae*) being introduced from northeastern Asia to Europe (Host list). None of them are confined to this host genus, but all occur on various indigenous, often woody hosts and appear to have colonized *Reynoutria* from there. Likewise, woody plants introduced to Europe exclusively carry indigenous species that are more or less frequent in Europe, e.g., *Sequoiadendron giganteum* (*O. aprilis*, *O. euonymi*), *Cryptomeria japonica* (*Hyalorbilia subfusispora*, *O.* cf. *aristata*, *O. euonymi*), *Pseudotsuga menziesii* (*H. berberidis*, *H. polypori*, *O. aprilis*, *O. euonymi*, *O. rubrovacuolata*), or *Thuja plicata* (*O. aprilis*, *O. aristata*, *O. euonymi*). On the North American *Robinia pseudoacacia* no less than 25 different plurivorous and native species of *Hyalorbilia* and *Orbilia* were detected in Europe. Similarly, on two native European hosts planted in the mediterranean Kings Park in Perth (southwestern Australia), *Quercus robur* and *Arbutus andrachne*, three species otherwise only known from Australian hosts adapted to semihumid to arid regions were collected: *O. octoserpentina*, *O. curvativitalbae*, and *O. serpentina*.

It is obviously a characteristic feature of species with a very wide host range to colonize introduced plants. For instance, the frequent central European *Orbilia aristata* was found on various genera of gymno- and angiosperms, almost all of them being indigenous to that region, but a few times on genera introduced from southern Europe or North America (*Cotinus*, *Rhus*, *Robinia*, *Thuja*, *Syringa*). Likewise, *O. euonymi* was mainly found on indigenous woody plants, but also on some from southern Europe, eastern Asia, and North America (*Aesculus*, *Cryptomeria*, *Ginkgo*, *Juglans*, *Pseudotsuga*, *Robinia*, *Sequoiadendron*, *Syringa*, *Taxodium*, *Thuja*, *Tsuga*).

Table 31. Number of records of 17 frequently collected plurivorous species of *Hyalorbilia* and *Orbilia* regarding five main types of substrates.

Species	Angio-sperms	Mono-cots	Gymno-sperms	Basidio-mycetes	Asco-mycetes	Dung
Hyalorbilia inflatula	184	1	7	12	16	–
H. ulicicola	49	–	1	8	3	–
H. polypori	27	–	7	4	1	–

O. ovoidea	*Ovoideae*	0	10	100	tolerant

Specificity to plant organs. Many species of *Orbiliomycetes* that occur on woody substrates are able to grow on both wood and bark, but some are more or less specific to either wood or bark (Tab. 32). Such preferences possibly avoid competition and might originate from different enzymatic abilities. As a rule, bark-inhabiting species are more often restricted to one or a few host genera in comparison with those growing on wood. However, within a given collection that includes different *Orbilia* species, it is often the case that one species is exclusively found on bark and the other on wood, although in other collections the preferences of the very same species may be different.

Whether the apothecia occur on bark or wood is not always easy to determine, unless the bark is very distinctly coloured or ± detached from the wood. When growing on bark, apothecia usually insert on bast (phloem), i. e., the inner and often much thicker layer of the bark. They may either occur on the inner surface of detached bark (Fig. 115: d) or at its broken edges, e. g., in emergence holes (Fig. 115: g–h), or they may grow on the outer bast surface at places where the covering periderm got ruptured (Fig. 115: e–f). In many genera of woody plants the periderm forms a thin paper-like layer which tends to roll outwards when it detaches from the bast (Fig. 115: c, f). When also the bast more or less disappeared by decay, its remnants are often found attached to the wood surface. Apothecia growing on such remnants are assumed to use both bark and wood as nutrient source (Fig. 115: a, c). Likewise, apothecia growing on boring dust (Fig. 115: l), might use nutrients from this mixture of wood and bark secreted by the bark beetle larvae. Apothecia may also occur on the outer or inner surface of the periderm, but often their insertion on the outer surface is only seemingly so as their stipe base inserts on the bast below by smaller or larger holes in the periderm.

Also the thickness of a branch may determine to some extent its species composition. Apothecia of xerobiotic taxa, e. g. many of sections *Lentiformes* or *Hemiorbilia*, often occurred on thin twigs of 1–5 mm diam., but also on much thicker branches, whereas others were never seen on twigs, e. g. *O. aradi* grows on 4–70 cm thick branches and trunks though always on the detaching bark that easily dries out. Hygrobiotic species were usually not found on twigs, e. g. *O. leucostigma* and *O. xanthostigma* occurred on (1–)3–35 cm thick branches, logs and stumps, and *O. epipora* on 3.5–30 cm thick branches and logs, though once in China on a 3–4 mm thin twig.

In a few collections the apothecia grew on leaves of different woody plants, and some of the involved species might be specific to them. This mainly concerns two species on coriaceous leaves of *Quercus ilex*/*Q. rotundifolia*, *O. quercus-ilicis* and *O. foliicola*, which are possibly host-specific to such leaves. *O. flagellispora* was described on leaves of *Rhus laurina*, but in the present circumscription it is a plurivorous species on bark (and wood) of gymno- and angiosperms. Two records on non-coriaceous leaves of angiosperms are known (*O.* cf. *mammillata* on lamina of *Quercus* leaves, *O. ebuli* on petiole of *Acer*) and two *Orbilia* species of unclear identity on *Dryas* leaves (*O.* cf. *angustoaristata*, *O. inconspicua*). Leaves of conifers were only rarely observed as substrate: *Liladisca acicola* and *O. acuum* might be restricted to needles (and bark) of *Pinus*, but the species are only known from their type collections. The plurivorous *O. aristata* and *O. auricolor* were exceptionally found on pine needles.

Beetle and ant galleries. Xerobiotic species of *Orbilia* are frequently found in and around galleries of bark beetles. Apothecia are formed in empty galleries, either on the wood surface (e. g., *O. patellarioides*, *O. microsoma*, *O. sphaerospora*, Fig. 115: i, m–n), or on the underside of detached pieces of bark of standing trunks (e. g., *O. aradi*, *O. pilifera* Fig. 115: d). Dead, decorticated, still-attached branches of gymno- and angiosperms rich in galleries are frequently associated with *Orbiliomycetes*. Some beetle species build galleries deep into the wood core, and the apothecia then occur inside the holes close to the surface (Fig. 115: j–k). Old galleries often contain boring dust on which apothecia may also grow (Fig. 115: d, l).

Whether there exists an interconnection between *Orbilia* and bark beetles is not clear. None of the more frequently collected species showed a constant association with such galleries. For example, in a collection of *O. pseudobrevistipitata* from the Philippines on xeric branch of unidentified angiosperm, the apothecia grew with striking consistency in small groups in galleries just below the scattered emergence holes through the slightly detached bark (Pls 453: 1d; 154: 1c, e). A similar situation was seen in a collection of *O. cejpii* on a dead standing young tree of *Sorbus aucuparia* in Germany: the apothecia occurred only on slightly detached bark below and in the emergence holes (Fig. 115: g–h). Yet, other collections of this plurivorous species did not show an association with bark beetles.

Kerrigan & Rogers (2003) isolated *Arthrobotrys oligosporus*, *A. superbus*, and *Drechslerella* (‘*Arthrobotrys*’) *brochopaga* from xeric branches of *Populus* and *Salix* in association with wood-boring beetles, although the teleomorphs of these species probably show little desiccation tolerance. We repeatedly observed ants colonizing tunnelled wood in dead stubs, where xerobiotic species of *Orbilia* grew on decorticated areas and exposed old galleries above the ant colony, therefore, it seems imaginable that also ants play a role in the life cycle of *Orbiliomycetes*.

Bryophytes, **lycopods**, **and ferns as hosts**. Within the large group of lycopods and ferns only two records of *Orbiliomycetes* came to our notice: Wu (1998) reported *Orbilia auricolor* on *Angiopteris lygodiifolia* (*Marattiidae*), and E. Rubio (pers. comm.) *O. auricolor* on *Equisetum* sp. (*Equisetidae*). Very few records were on bryophytes. Apothecia of the single known collection of *O. frullaniae* grew on leaves of *Frullania dilatata* (*Marchantiophyta*, Fig. 116: d) in western Europe, but this species is only tentatively separated from similar lignicolous species, therefore, the occurrence on a bryophyte might be accidental. Likewise, a collection from western France referred to *Pseudorbilia bipolaris* grew on ?*Hypnum* (*Bryophyta*), whereas the Chinese type collection was on coniferous wood and a sample from Norway on dung. In a similar case, the lignicolous *O. eucalypti* once grew on *Frullania* (J.P. Priou pers. comm.). The inhabited leaves of these bryophytes either showed signs of necrosis or entirely lost their green pigment.

Textile. Sixteen species of *Orbilia* were so far found growing on textile (see Appendix 1 & Fig. 116: e–h). This artificial substrate either consisted solely of plant fibres like cotton (*Gossypium*) or hemp (*Cannabis*) or was mixed with synthetics. Like natural substrates, textile requires constant or periodical moisture for fungal growth. Under xeric conditions in central Europe, textile must be subjected to rainfalls for several years in order to carry apothecia, whereas under hygric conditions less than a year might be sufficient.

Figure 115: Desiccation-tolerant *Orbilia* species growing on bast in clefts of bark or on the inner surface of bark (**a–f**), or in cavities of bark and wood caused by bark beetles or on their boring dust (**g–n**). — **a**. *O. lentiformis* (H.B. 9578a) on bast of *Abies* in transversal clefts of periderm; **b**. *O. magnifica* (H.B. 9578b), id., with *Melanohalea* on periderm; **c**. *O. obtusispora* (H.B. 8691), on decayed remnants of bast, partly on wood of *Quercus*; **d**. *O. pilifera* (H.B. 8362a), on inner surface of *Ulmus* bark, with cocoons of larvae; **e–f**. *O. carpoboloides* (H.B. 9233), on outer surface of bast of *Ulmus*; **g–h**. *O. cejpii* (H.B. 9135) in emergence hole in detached bark of *Sorbus* (**g**. outside view, **h**. from below); **i**. *O. microsoma* (H.B. 7518), growing in bark beetle galleries shaped in wood of *Pinus*; **j–k**. *O. vinosa* (19.VIII.2010), growing around emergence hole in wood of *Cornus*; **l**. *O. poitevinica* (H.B. 8131), growing on bark beetle boring dust of *Fraxinus* covered by algae; **m–n**. *O. patellarioides* (H.B. 9173a), growing in galleries shaped in wood of *Pinus*.

All species detected so far on textile are typically lignicolous or herbicolous and do not show a distinct restriction to a host genus. Plurivorous *Helotiales*, pyrenomycetes, and mitotic fungi are also able to grow on textile (e.g., *Neodasyscypha cerina* and *Patellaria atrata*, Baral ined.). Undoubtedly, many more species of *Orbilia* will be found on textile when more thoroughly investigated. Similarly as on natural xeric substrate, apothecia on xeric textile often occurred in sparse small groups only and were then difficult to detect. Ropes and twines or woven fabric of different natural fibres are famous substrates for xerobiotic species of *Orbilia*. They provided the substrate in the old type collections of *O. carpoboloides*, *O. chordicola* (named after the substrate), *O. decipiens*, and *O. brasiliensis*, which all belong to the *O. carpoboloides* aggregate. In association with *O. brasiliensis* grew also hundreds of rather large (0.5–1.5 mm), gregarious apothecia of *O. neocomma*.

Fungi (mycoparasitism). Some species of *Orbiliomycetes*, especially *Hyalorbilia*, were found to grow occasionally on perennial basidiocarps of either resupinate species or bracket-forming ones (Fig. 116: c, Tab. 31). With exception of *Orbilia cardui* these are all predominantly lignicolous species which are sometimes found on basidiocarps, either on the pores and lamellae, or more rarely on top of the pileus. For instance, *H. polypori* was named by Velenovský after the inhabited *Ganoderma lucidum* (as *Polyporus lucidus*), but he only knew this taxon from a single apothecium. In recent times the species was mainly discovered on woody substrates besides polypores (*Fomes*, *Ischnoderma*, *Phellinus*). Also the lignicolous *H. berberidis*, *H. inflatula*, *H. ulicicola*, and *O. epipora* (named after its growth on a polypore), may exceptionally occur on bracket fungi.

Species confined to basidiocarps are not known with certainty. The two collections of *H. fomentarii* were on *Fomes fomentarius*, but this here newly described species is only tentatively separated by ascospore size from long-spored populations of the lignicolous *H. juliae*, therefore, more collections and DNA-data are needed to clarify whether *H. fomentarii* is a separate species restricted to polypores. Many xerobiotic species of *Orbilia* (e.g., *O. trapeziformis, O. obtusispora, O. vinosa*, *O. eucalypti*) sometimes occurred on old, almost completely decayed fructifications of *Vuilleminia*, mainly in temperate Europe and often together with dark ascomycetes such as *Capronia*, *Deltopyxis*, and *Sclerococcum*, but a restriction to this ecological niche could not be verified in any of them.

Occurrence of *Orbiliomycetes* on ascomata or stromata of ascomycetes, mainly pyrenomycetes, was likewise occasionally observed. As with basidiomycetous hosts, a strong preference for pyrenomycetes cannot with certainty be seen in most of the species. *H. inflatula* infrequently forms some or all of its apothecia on pyrenomycetes, mainly when they are in a final stage of decay. When growing on old, very decayed stromata of erumpent pyrenomycetes or *Rhytismatales*, the apothecia seemingly break through the raised bark (e.g., *O. carpoboloides*, *O. eucalypti*). Lichenicolous collections of *Orbiliomycetes* were not encountered during the present study, with a single exception: one of the collections reported by Pfister & Liftik (1995) as *O. auricolor* and reidentified in the present study as *O. oligospora* (Pl. 955: 1) was on a black crustose thallus of an unidentified lichen (*Lecanorales*) growing on a rock.

H. erythrostigma and *H. orbiliicola* are the only known species of *Orbiliomycetes* for which an obligate connection to a fungal host is obvious. The former species forms its apothecia on or close to various living or ± senescent *Sordariomycetes*, but also *Auriculariales* and *Tremellales*, and the latter on living apothecia of different species of *Orbilia* (Fig. 116: b). Some collections here assigned to *H. erythrostigma* on bark and wood without a clear connection to a fungus might deserve separation based on deviating DNA data.

Drechsler (1938, 1943a, 1952, 1962, 1963, 1964) reported several orbiliaceous anamorphic species currently included in *Brachyphoris*, *Dactylella, Vermispora*, *Tridentaria*, and *Trinacrium*, which parasitize spores of oomycetes (mainly *Pythium*) or rarely zygomycetes (see Tabs 43, 45, 53–55, Fig. 118). The mode of invasion closely resembles that of pollen (Fig. 117). Mycoparasitism was also observed in species of section *Arthrobotrys*. Li et al. (2003) described the nematode-trapping *Monacrosporium janus* (≡ *Arthrobotrys janus*) as parasitizing sclerotia and hyphae of *Sclerotinia sclerotiorum* and other fungi in soybean fields. Hyphae of various nematode-trapping species may coil around hyphae of other fungi, such as *Rhizoctonia solani* (Rubner 1996: 21, fig. 11; Li et al. 2003). Such hyphal coiling is explained in terms of competition for nutrients rather than representing a true mycoparasitic relationship (see Park et al. 2002).

Dung and bones. About 12 species of *Orbiliomycetes* are known at present to form their apothecia on dung (Host list). None of them appear to be strictly coprophilous, although names such as *Orbilia fimicola* (= *O.* ?*oxyspora*), *O. fimicoloides* (= *O. oxyspora*), and *O. leporina* suggest such preference. Our morphological taxa concepts indicate that a few plurivorous species of *Orbilia* and *Hyalorbilia* occasionally colonize dung. Molecular results confirmed this view for *O. auricolor* s.l. (= *O. fimicola* s. Pfister 1994, see p. 1527).

In her study of coprophilous ascomycetes in Australia, Bell (2005: 19, pers. comm.) reported *Hyalorbilia inflatula* (as *O. inflatula*) and *O.* ?*tremulae* (as *O. alnea*) on marsupial dung (kangaroo and wallaby). She obtained apothecia generally only after incubation for 2–3 months. Within section *Arthrobotrys*, five species are known at present to occur on dung: *O. auricolor* s.l. (*Equus*, *Capreolus*, *Oryctolagus*, H.B. 4835, 5441, 6544, 6722), *O. leporina* (*Lepus*, type), *O. oxyspora* s.l. (*Equus*, type of *O. fimicola*; ?mouse, type of *O. fimicoloides*), *O. rectispora* (*Lepus*, H.B. 10049), and *Orbilia* sp. (*Ovis*, H.B. 8749).

Apothecia of two species, *O. auricolor* (Poland, Fig. 116: a) and *O. sarraziniana* (Germany, 24.X.2017, IVV), were found growing in abundance on bones of wild boar (*Sus scrofa*) lying on the moist forest floor, which is surprising because they usually grow on woody or herbaceous substrates.

Soil. The only known collection of *Orbilia terrestris* (see p. 1583) derives from the bottom of a gorge where apothecia grew on fine sandy soil containing a few organic particles. Whether this species may also occur on wood or other plant parts is unknown. The lignicolous *O. sarraziniana* was once collected in association of acrocarpous mosses on a sand bank of an artificial small lake, where the small population was occasionally flooded (IVV: H.B. 9728). In the soil below the apothecia some remains of rotten leaves occurred, but no wood debris which would be expected for this species. On the other hand, nematophagous and other orbiliaceous anamorphs have frequently been isolated from soil all over the world, but possibly all these species do not generally form apothecia on soil.

Figure 116: Extraordinary substrates of *Orbiliomycetes*. — **a**. *Orbilia auricolor* on a bone of wild boar (P.P. 20070827-1, phot. P. Perz); **b**. *Hyalorbilia orbiliicola* (pale cream) on apothecial margin of *Orbilia subaristata* (greyish-rose-orange), 28.III.07; **c**: *H. ulicicola*, on hymenophore of a polypore (*Ganoderma australe*, H.B. 8656); **d**. *O. frullaniae* on a liverwort (*Frullania dilatata*, H.B. 8760); **e**. *O. auricolor* on textile (H.B. 7912); **f**. *O. aristata* on a rope (H.B. 9226a); **g–h**. *O. auricolor* on a tennis ball (L.R. 02-206, phot. L. Rommelaars).

Nutrition

Degradation of plant substrate. Apothecia of *Orbiliomycetes* are usually formed on dead parts of plants being in an advanced stage of decomposition and, therefore, probably poor in nutrients. When growing on decorticated wood, a 0.1–0.5 or sometimes 1–2 mm thick outer layer is usually medium to strongly decayed while the wood beneath is quite undecayed. This is especially true for xeric wood which shows a permanently low internal water content, whereas hygric, internally moist wood tends to be more deeply decayed. The strong decay of the outermost region appears to be caused by earlier colonizers of the wood.

Only a few orbiliaceous species were found to form apothecia preferably or exclusively on undecayed substrate. For example, *Orbilia aradi* grows on the inner surface of detached bark of living or recently dead *Fagus* trunks, but rapidly disappears in an advanced stage of decay. There is no evidence that the fungus obtains its nutrients from other sources than the bark. Likewise, resinicolous *Orbiliomycetes* occur on living or recently dead wounds of conifers, but disappear when the substrate is too rotten. Whether these early colonizers have an endophytic phase inside the living plant tissue is unknown. In any case, plant parasitic *Orbiliomycetes* appear not to exist.

Basically, it is not clear which substrate component and how much of it is used for mycelial growth and apothecial production. When apothecia are found on substrates such as wood and bark, or basidiocarps, the mycelium appears to be able to degrade cellulose, lignin, or chitin, but might also gain nutrients from a biofilm of green algae and brown fungal cells, which often covers the substrate in a varying thickness, or it invades and degrades living pollen or microscopic animals which occur in the biofilm. About xeric woody substrate Sherwood (1981: 19) speculated that ‘many lignicolous discomycetes appear to scarcely alter the structure or appearance of the wood on which they grow, indeed the possibility that the wood itself is not the main source of nutrients for all cannot be excluded’. As a possible source of fixed carbon and especially nitrogen she suggested populations of algae, insect exudates and bird droppings, leachates from foliage and epiphytic lichens, and resin.

Observations of apothecia growing on decayed bones lying on the forest floor for some years suggest that orbiliaceous fungi may alternatively use animal proteins or fats. However, these might well have been decomposed before the *Orbilia* colonized the bone, and nematodes, bacteria, algae, or pollen could instead have been the main food source. One reason for the capture of invertebrates is seen in the supply of nitrogen, which is probably poorly present in strongly decayed plant substrate (see Barron 2003, Yang et al. 2012a). On the other hand, Scholler & Rubner (1994) found a very low predatory activity of *Arthrobotrys oligosporus* when grown in nitrogen-poor agar media, whereas predatory activity was high when the carbon source was in short supply.

It appears beyond doubt, however, that cellulose is used by the mycelium: for instance, various non-lichenized ascomycetes, including *Orbiliomycetes*, are able to form apothecia on decaying textile composed of natural plant fibres (Fig. 116), whereas such fungi have never been seen on completely synthetic fabric, or on rock, even if covered by a biofilm. Rubner (1996) observed a pronounced cellulolytic activity in most of the 44 strains of 28 orbiliaceous, mainly predacious species tested, most of them belonging to section *Arthrobotrys*. Yet, in the five *Drechslerella* species of that section the degradation of cellulose was less evident. A distinct lignolytic activity (decay of lignin) was only obtained in two of the 30 strains tested (*Brachyphoris oviparasitica*, *Drechslerella effusa*). Genes coding for cellulolytic enzymes have been found, e. g., in *A. oligosporus* (Yang et al. 2011) and *Drechslerella stenobrocha* (Li et al. 2014). A different result was obtained by Park et al. (2002) who observed in various orbiliaceous nematode-trapping species high protease and low ligninase, but no cellulase and chitinase activity.

Parasitism on animals (invertebrates) and pollen

Capture of invertebrates. A minority of *Orbiliomycetes* are known as predators of different microscopic animals such as nematodes, rhizopods, rotifers, and tardigrades, but also arthropods like copepods and springtails (see Tab. 16). The animals are captured by different types of trapping organs, and the predatory fungi have currently been classified into different anamorph-typified genera according to these organs (see p. 115 ff.)

Among the ca. 470 orbiliaceous species with a known teleomorph reported in this monograph, only about 30 are known to be predacious. However, for many further predacious species a teleomorph is so far unknown: Yu et al. (2014) list a total of 95 species within section *Arthrobotrys* being predacious. The absence of predacious activity in other groups might be due to the current routine tests with nematodes as prey. On the other hand, Nordbring-Hertz (1968) has shown that in *A. oligosporus* adhesive nets are also formed in the presence of living earthworms, fly-larvae, or springtails. It is, therefore, well possible that the majority of *Orbiliomycetes* are unable to catch animals by means of trapping organs. The trapping activities in the distant genus *Lecophagus* could even mean that predacious capabilities of orbiliaceous fungi developed independently by parallel evolution. Yet, a more conceivable scenario considers trapping organs as a plesiomorphic character within the class, being later abandoned in many taxa, or reawakened from a latent state (see p. 121).

Nematophagous orbiliaceous fungi seem to show little host specificity to certain genera of nematodes (Rosenzweig et al. 1985, Gray 1987, Scholler & Rubner 1999). Therefore, various nematode genera can be used to induce traps (for the isolation and cultivation of nematodes see Li et al. 2014). As an exception, *Dactylellina hertziana* exhibits a rather limited host range in trapping only one of the tested nematode species (Scholler & Rubner 1999). As a further example, the rhizopod-capturing '*Dactylella*' *passalopaga*, a possible synonym of *Hyalorbilia inflatula*, captures different genera of testaceous rhizopods (*Geococcus*, *Euglypha*, Drechsler 1936, see Fig. 105: f). *Lecophagus muscicola* and *L. longisporus* are known to capture both rotifers and tardigrades (Barron et al. 1990), and *Drechslerella bembicodes* nematodes but occasionally also rotifers (Drechsler 1937a: 487). Within the mainly nematophagous genus *Dactylellina*, Scholler et al. (1999: 96) emphasized that some species abandoned consumption of nematodes by switching to other hosts like copepods and springtails (fungi preying on springtails now assigned to *Gamsylella*)

Among the predatory nematophagous fungi, two main categories can be distinguished (Jansson 1982, Gray 1987): the net-formers (*Arthrobotrys*) with high saprotrophic ability, capturing nematodes not primarily for food but perhaps as a defense against mycophagous nematodes, and the constricting ring-, adhesive branch- and knob-formers (*Drechslerella*, *Gamsylella*, *Dactylellina*) which regularly capture nematodes as a main food source. The latter are more slow-growing but predaciously more efficient than the former. Despite this predacious ability, nematode-trapping fungi have been shown to effectively use plant material as saprobionts.

A few *Orbiliomycetes* are able to use animals as the main food source for apothecial production. An apothecium of the small-sized *Lecophagus ellipsoideus* (0.08–0.35 mm diam.) appears to obtain most of its nutrients from a single contracted rotifer body (0.13–0.2 mm diam.), the complete interior of which it replaced by broad hyphae (Pl. 45: 2e). It seems that the broad hyphae of *Lecophagus* spp. appear unsuitable for invading plant tissue. However, a clear evidence for this cannot be provided without experiments under controlled condition. The much larger invertebrates (insects, mites) captured by *Orbilia alba* correlate with the comparatively large apothecia (1–5 mm) in this species, but its anchoring hyphae are much narrower than in *Lecophagus*, though wider than in non-predacious groups of *Orbilia*.

Infection by ingestion. Although many species of *Orbilia* section *Arthrobotrys* possess trapping devices for a percutan infection of the captured animal (i.e., via the cuticle), their falcate ascospores with acute bases indicate a further possible strategy: infection by ingestion. Also in the four series *Hyalinia*, *Xanthoguttulatae*, *Aurantiorubrae*, and *Abutilones* (section *Aurantiorubrae*), in which organs of capture are unknown, the frequently helicoid and/or geniculate, apically acute ascospores suggest such a strategy. Also the spore base is here often acute and/or characteristically bent or nearly reflexed. In their shape and size such ascospores resemble falcate or helicoid conidia of certain species of *Harposporium* Lohde (teleomorph: *Podocrella* Seaver, *Clavicipitaceae*, Chaverri et al. 2005) which thrive as endoparasites in nematodes (Barron 1977: 73 ff.). This similarity prompted us to speculate that *Orbiliomycetes* might infect small invertebrates through peroral ingestion of ascospores (see p. 69 and 78). However, there is still no experimental evidence for this hypothesis. In *Harposporium* the peculiar shape of the conidia enables them to lodge in the oesophagus of the nematode and to penetrate with their acute and often reflexed and hooked ends between the muscle fibres during the process of swallowing.

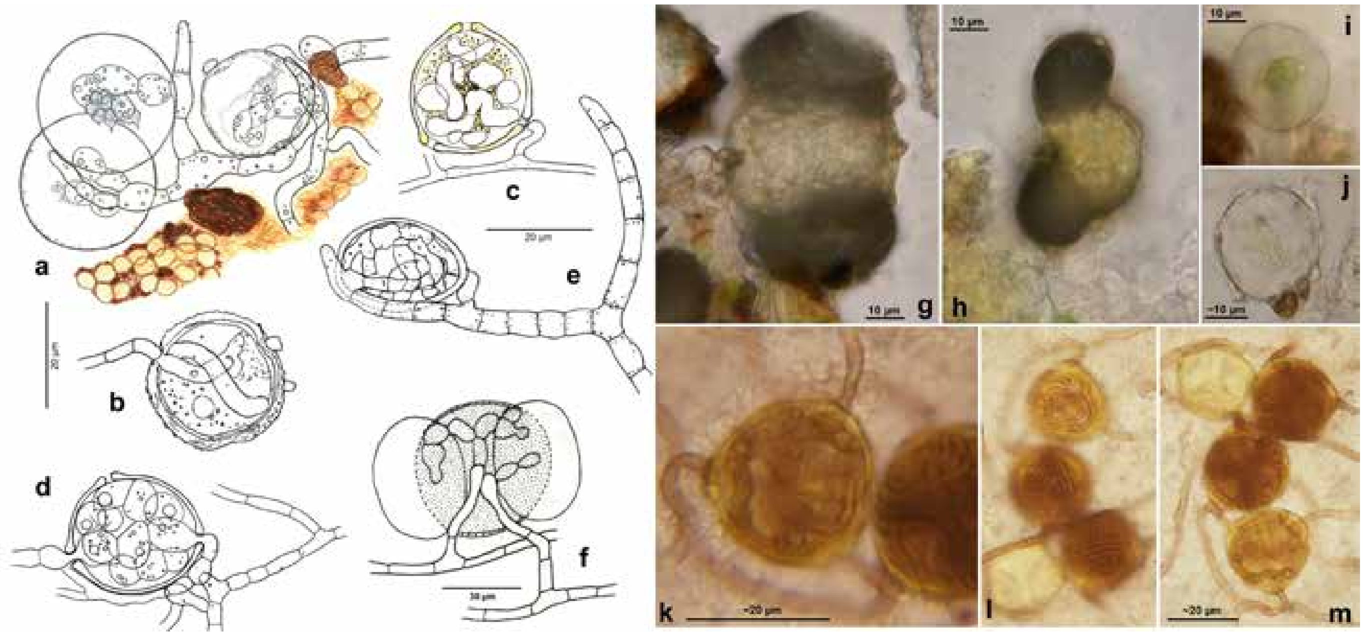

Figure 117: Parasitism on pollen grains. — **a**, **i–j**. Unidentified globose cells with very thick swollen inner wall (?pollen): **a**. invaded by mycelium, **i–j**. uninfected, **a**, **i**. close to apothecia of *O. palmicola* (H.B. 6424a), **j**. below apothecium of *O. helicovinosa* (H.B. 9050b); **b–c**. mycelium grown on water agar, invading living pollen grains: **b**. *O.* cf. *vinosa* (H.B. 6748g, pollen of *Sambucus nigra*), **c**. *O. rubrovacuolata* (H.B. 6598a, pollen of *Corylus avellana*); **d**. pollen of *Corylus* on natural substrate, invaded by *O. aristata* (H.B. 6453); **e**. ellipsoid pollen of ?*Salix* invaded by *Retiarius* cf. *bovicornutus* (11.III.2001); **f**. mycelium of *Retiarius superficiaris* invading pollen of *Pinus radiata* (from Olivier 1978); **g–h**. infected *Pinus* pollen: **g**. near *Amphosoma resinicola* (H.B. 9162e), **h**. near *O. montigena* (H.B. 7874a); **k–m**. pollen of *Corylus* added to agar culture of *Rhizodiscina lignyota* (20.V.2001). – In any of these examples the cytoplasm of the invaded host cells was always dead when the living hyphae had fully occupied it.

Up to five conidia were seen stuck in a single oesophagus. Similarly, T- to Y-shaped conidia of *Haptospora* G.L. Barron (*Hypocreales*) lodge with their hooked basal end in the mastax of rotifers (Barron 1991b).

Similar to curved ascospores, those with long and straight tails, mainly of series *Albovinosae* (section *Aurantiorubrae*) and *Hemiorbilia* (section *Hemiorbilia*), might lodge in an abruptly geniculate gullet or intestine. Also a warted spore surface might permit lodging in the narrow elastic tube of animal oesophagi during ingestion (cashew-shaped spores of the *xanthostigma-leucostigma* complex). In this context it can be speculated that spore bodies might function as some kind of poison vial (see p. 77–78). The peculiarity that ascospores of some *Orbiliomycetes* are curved or hooked, or sometimes have warts on their dorsal side, must have a functional background in the life cycle of these fungi, as it can hardly support the efficiency of spore discharge (see p. 60).

Another strategy occurs, in members of *Lecophagus* and *Hyalorbilia* (= *Brachyphoris*) which capture invertebrates in the mouth region by means of adhesive pegs or knobs. Their ellipsoid to rod-shaped ascospores appear to lack properties for lodging in the ingestion tractus. However, it is known that rotifers feed on ellipsoidal ascospores of lichens, and only some of the spores excreted by these animals are still viable (Pyatt 1968). Possibly, *Lecophagus* imitates the shape of lichen spores, but how would the fungus then be able to infect the rotifer? The function which the spore body plays in *Lecophagus* and in many other species of *Orbiliomycetes* thus remains a mystery.

Parasitism on pollen. Comparable to parasitism on fungal spores, our tests with pollen indicate, together with observations on natural substrate, that *Orbiliomycetes* may use pollen grains as food source (Fig. 117, Tab. 14). This confirms a study by Olivier (1978, see also Fig. 117: f) from South Africa on two orbiliaceous hyphomycetes growing on living leaves, where they capture wind-borne pollen grains ‘by means of short spike-shaped hyphae projecting vertically from the mycelium’, and parasitize on them. Olivier placed the two species in the new genus *Retiarius* (see Pl. 20). Magyar et al. (2017a, b) described two further species in *Retiarius* that prey on living pollen and erected the new genus *Mycoceros* for *M. antennatissimus* capturing pollen grains by means of their multibranched conidia (Pl. 18).

However, the ability to prey on pollen is not a unique feature of *Orbiliomycetes*. We found infected pollen grains also in cultures of other fungal groups, for instance, in *Rhizodiscina lignyota* (Fr.) Hafellner (*Dothideomycetes*, Fig. 117: k–m). The invasion of pollen was here very conspicuous because of the brown mycelial colour of this species. Parasitism on pollen seems to be a widespread feature. Hutchison & Barron (1997) observed this kind of nutrition mainly in basidiomycetes and considered it as a supplementary seasonal source of nutrients, particularly nitrogen. These findings are confirmed by Czeczuga & Orlowska (2001) who observed 82 species of hyphomycetes, four of which being apparently orbiliaceous, to colonize floating plant spores and pollen in stagnant and running water in Poland. Classen et al. (2000) gave an ultrastructural description of the infection of *Malva* pollen by a *Cercospora malvicola* Ellis & G. Martin (*Dothideomycetes*).

In addition to cultural studies, our field observations show that various *Orbilia* species are capable of using pollen as food source. Pollen grains launched on dead plant substrate are commonly observed on xeric branches when viewed under the dissecting microscope, most easily the large pollen of *Pinaceae* with their two air sacs (Fig. 117: f–h; Pls 264: 3c–d; 690: 2a–e). Pollen is often detected very close to apothecia of *Orbilia*, and sometimes it was found to be infected. The hyphae thereby penetrate the apertures and consume the cytoplasm by entirely colonizing the lumen of the pollen grain. It is not always clear whether the mycelium infecting the pollen belongs to the associated apothecia of *Orbilia*. Yet, the connection could often be demonstrated, not only by the close vicinity of anchoring hyphae of the apothecia, but also by the property of the hyphal surface to stain deep lilac in Cresyl blue, whereas associated mycelia of other fungal groups often remained unstained.

In two Australian samples, unidentified globose, hyaline, dead cells of ca. 22–27 µm diam., with a smooth outer and a strongly thickened (imbibed) inner wall, occur rather scattered in close proximity to apothecia of *Orbilia*. They could be pollen, oospores, or something else. In *O. palmicola* growing on petioles of *Livistona* most of these cells were found to be infected by haustoria (Fig. 117: a). The haustoria and the mycelium outside these cells were still viable when the dry sample was rehydrated 9 months after being collected. The wall surface of the emerging hyphae stains deep lilac in CRB. Particularly this feature suggests that they are anchoring hyphae of an *Orbilia*. *O. palmicola* occurs in abundance on the petioles, whereas the other associated *Orbilia* species were only rather sparsely found more remote from these cells, so we think that the haustoria-forming hyphae belong to *O. palmicola*.

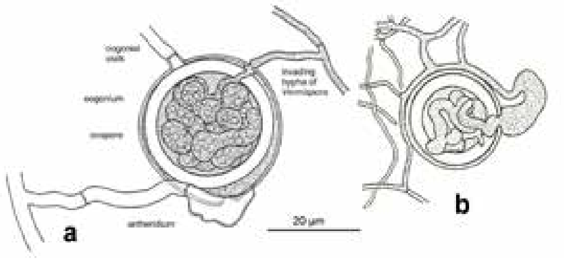

Figure 118: Parasitism on spores of oomycetes. — **a**. *Pythium oedochilum* oospore inside oogonium fertilized by antheridium, invaded by *Hyalorbilia spermatophaga* (from Drechsler 1938); **b**. oospore of *Pythium graminicola* penetrated by *Dactylella arrhenopa* (from Drechsler 1943a).

Communities with other fungi, lichens, algae, bryophytes

When collecting *Orbiliomycetes* on their natural substrate, species of other classes of fungi, besides algae and bryophytes, are often observed in more or less close association. Moreover, different orbiliaceous species frequently occur mixed on the same piece of substrate (Fig. 119). Data on such associations may help in future research to clarify the possible predominance of mycosynusia on different host plants or in different ecoregions. Due to the often intimate growth, mycelial competition can be expected to occur, either between different species of *Orbiliomycetes* or with other fungi, and symbiotic to parasitic connections, e.g. with algae, cannot be excluded.

Because of the frequency of plurivorous species, associations of fungal species on a given host are to a considerable degree accidental, and the number of species associated with a given orbiliomycete increases with the number of collections. Nevertheless, a certain correlation in the species composition on a given host is apparent, which is also determined by the climatic region. Therefore, some orbiliaceous species have considerably often been observed to grow in association with each other or with some non-orbiliaceous taxa.

A methodological problem with associations of lignicolous or herbicolous fungi is the distance between the populations, either on a given organ of the plant (branch, stem, leaf) or between different organs of the same or adjacent plants. Often, several plant parts are collected from a single plant individual, or from different individuals at the same site. If two fungal species are detected on two different branches emerging from the same tree individual, they are clearly not closely associated although they obviously prefer the same habitat, given that the branches are in a comparable exposure and state of decay. Sometimes, a third fungus grows on both of these branches, which supports the ecological similarity of the habitat. Another problem is that xeric branches were usually cut into ~10–30 cm long pieces when taken from a tree in greater quantities to facilitate transport in bags and later screening in the laboratory. During examination it is then quite impossible to say which pieces belonged to a single branch, or to determine the ends that belonged together.

A special case of association is when *Orbiliomycetes* grow as parasites or saprobionts on sporocarps of other fungi, or when parasitic fungi grow on or in apothecia of *Orbiliomycetes*. Sometimes, an orbiliomycete simultaneously forms apothecia on a fungus and also nearby on the plant substrate, which can be explained either by a low substrate specificity or by assuming that nutrient sources are not always located just below the apothecium.

Lichenized ascomycetes are very frequent companions of xerobiotic *Orbiliomycetes* on xeric woody substrates. Lichens predominantly inhabit the outer layer of bark (periderm) whereas non-lichenized ascomycetes prefer areas where the periderm or the complete bark is removed by growing on bast or wood (Fig. 115: a–b). Lichen communities start colonization of the dead outer bark layer long before the branches and trunks die off. Lichens found in association with *Orbiliomycetes* represent the remains of these communities. The occurrence of orbiliaceous taxa frequently marks the final phase of decomposition of dead xeric substrate, whereas the lichen community gradually disappears during bark decay.

Intermixed growth of orbiliaceous species. Particularly desiccation-tolerant species of *Orbiliomycetes* very often grow in mixed populations. 2–5, in rare cases even 10–15 orbiliaceous species were found on plant parts collected from one or several individuals of a given host plant at a given site. The frequent occurrence of such mixed populations is a consequence of the low host specificity of the majority of *Orbiliomycetes*. Each species thereby forms its apothecia in a more or less recognizable population. However, these populations are often very close to each other and may show a more or less strongly pronounced mosaic-like pattern (Fig. 119). Frequently, the involved species look macroscopically very similar (Fig. 119: a, c–d), which makes taxonomic work highly problematic and inevitably results in herbarium specimens containing a mixture of species (see also p. 17, Taxa concepts).

Three out of many examples illustrate the situation of species diversity within a collection. (1) About 30 petioles of a palm (*Livistona nitida*) endemic to eastern Australia (near Taroom) have been collected from 3–4 plant individuals. On these petioles 11 different species of *Orbilia* were discovered together with two other ascomycetes (*Gloniopsis* sp. and *Mellitiosporiella* sp.), all of them being preserved under the number H.B. 6424 (a–m). We assume that some further species escaped our notice and others were left uncollected at the site. (2) On branches of *Acacia* sp. collected in western Australia (near Mt. Gibson), 15 different species of *Orbilia* and 5 other ascomycetes were detected (preserved as H.B. 7204a–t). (3) On branches of

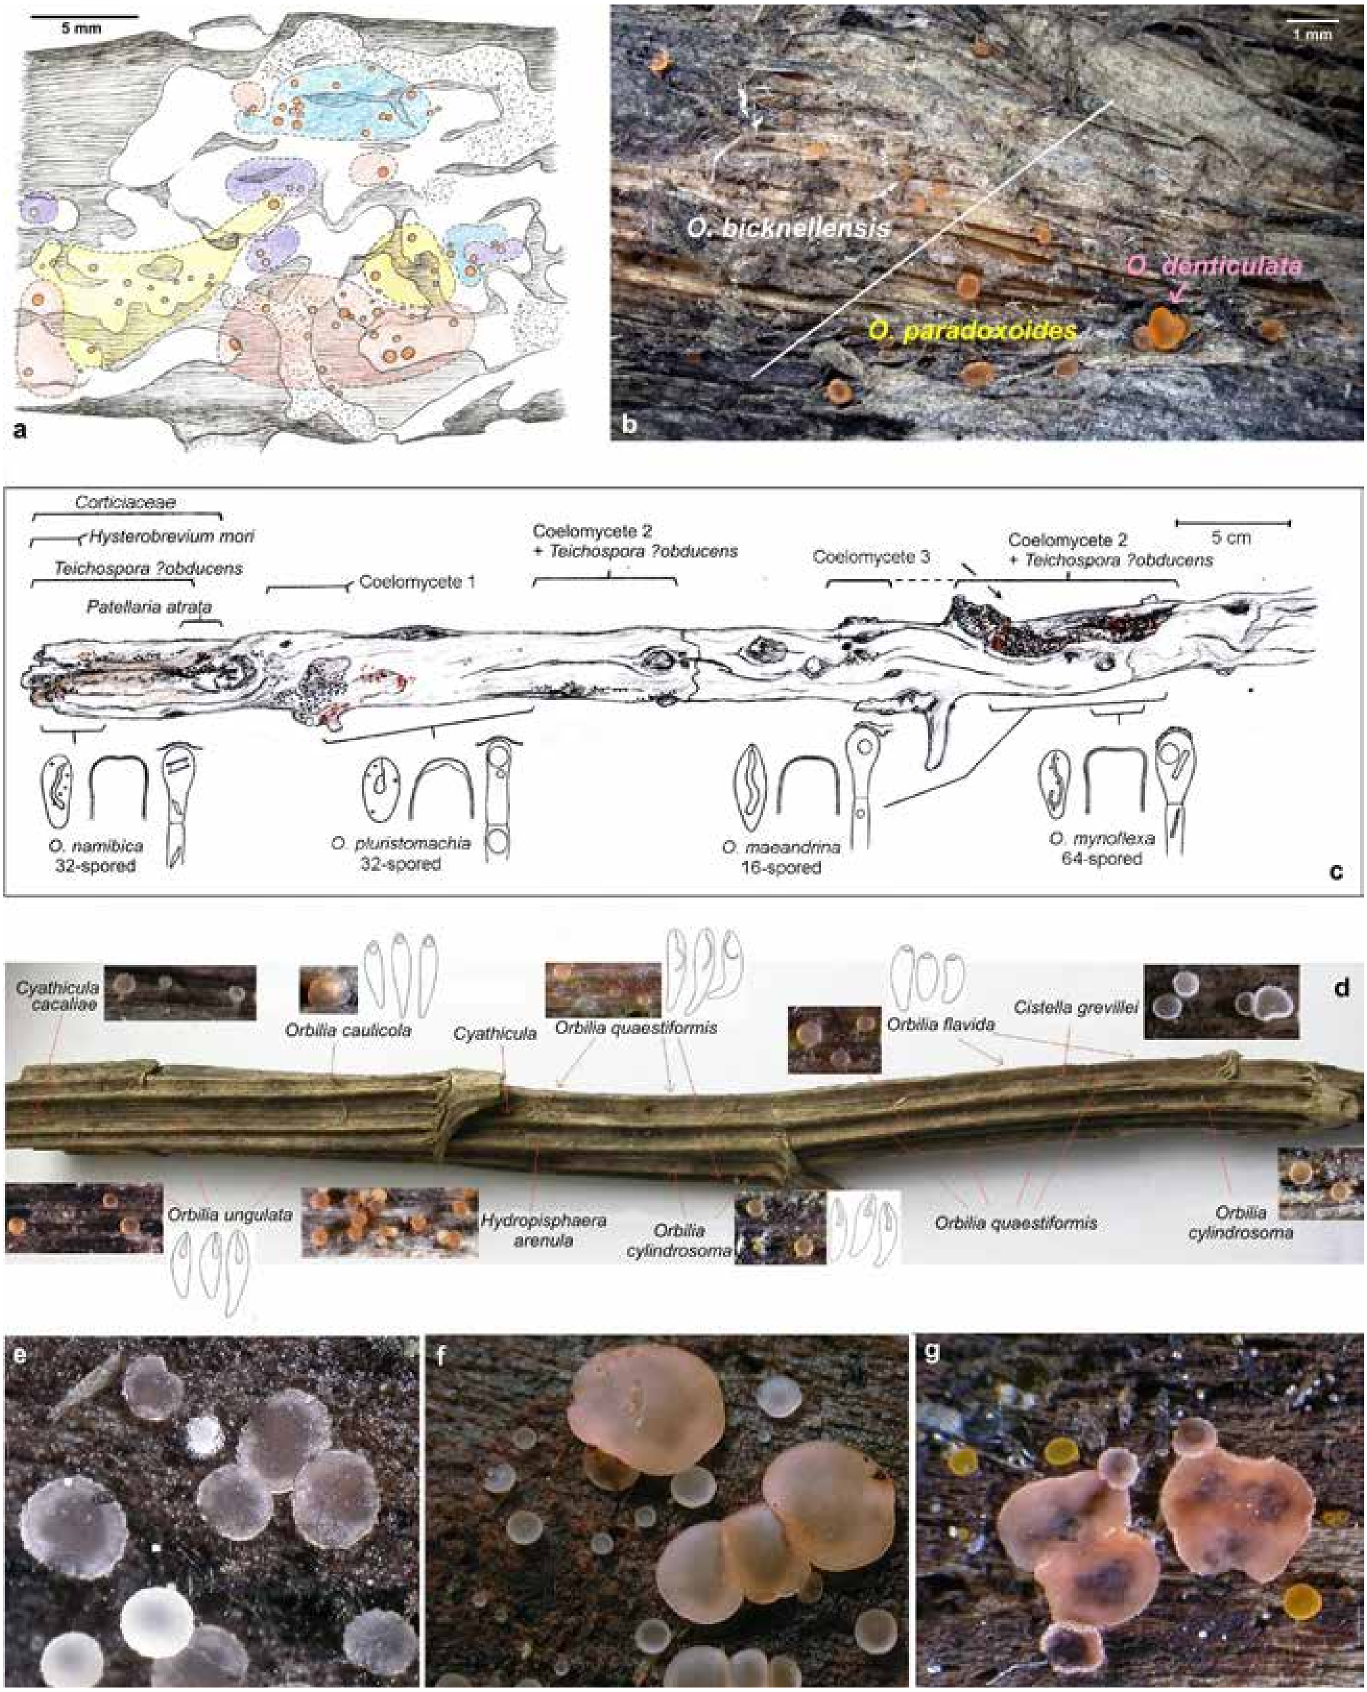

Figure 119: Intermingled growth of *Orbilia* species. — **a**. Four species growing in beetle galleries (partly filled with boring dust) of a decorticated xeric branch of *Pinus sylvestris* (yellow = *O. aprilis*, blue = *O. eucalypti*, red = *O. vinosa*, violet = *O. cylindrospora* (France, Drôme, H.B. 5626); **b**. xeric inflorescence stem of *Yucca elata* with 3 *Orbilia* spp. (Arizona, Chihuahuan Desert, H.B. 7880); **c**. decorticated xeric branch of ?*Vachellia* with 4 *Orbilia* spp. and some other fungi (Namibia, Auas Mts., H.B. 5388a–d, 5390a–c, 5398a–b); **d**. xeric stem of *Heracleum sphondylium* with five *Orbilia* spp. and 5 other ascomycetes (Luxembourg, H.B. 7869a–j, 3 spp. not shown); **e**. hygric decorticated *Carpinus betulus* branch with *O. crenatomarginata* (rosaceous-violaceous) and *O. orientalis* (white) (France, Charente-Maritime, H.B. 8146a–b); **f**. hygric decorticated angiosperm branch with *O. nemaspora* (pale rose-orange) and *O. ?brochopaga* (white) (Antilles, Martinique, H.B. 8034a–b); **g**. inner side of detached xeric *Salix* branch with *O. phragmotricha* (rose) and *O. xanthoguttulata* (yellow) (France, Savoie, H.B. 7915a–b).

Acacia cyperophylla in western Australia (Gascoyne River) 9 different species of *Orbilia* and 4 other ascomycetes were detected (preserved as H.B. 9695a–k), whereas at the same site on branches of *Eucalyptus* 5 different species of *Orbilia* occurred (preserved as H.B. 9772a–e), and only one of them (*O. pleioaustraliensis*) was found on both hosts.

In principle, every apothecium of such collections should be examined in order to avoid overlooking of a species. Since apothecia of *Orbiliomycetes* are often smaller than 0.5 mm, this would in the worst case result in a total consumption of the collection. However, small groups of apothecia looking quite homogeneous usually belong to a single species, and we recommend to examine only one out of each group. Generally about 4 to 5 microscopic spot checks on each larger piece of substrate appear to be necessary as a minimum. In other words, we found that testing 20–30 % of the apothecia of a collection consisting of couple of xeric branches is unavoidable when they occur more or less scattered over the substrate and lack characteristic macroscopic features.

In many of these interesting cases of intermingled growth, a larger proportion of apothecia was examined and the spatial distribution of the different taxa documented. Survey photographs of the populations need to be taken in advance and later cautiously marked and labelled by the resulting identifications. Preliminary spot checks are advisable in order to get a first idea of the complexity of a collection, but their spots need to be documented from the beginning.

Accidental discovery of a species plays a significant role in the study of xeric branches. When working on a given collection, the firstly examined apothecium may belong to a species that later does not show up again within this sample or turn out to occur only sporadically. As an example, the firstly examined apothecium in a collection on *Sambucus nigra* from Luxembourg was *Hyalorbilia erythrostigma* (H.B. 6908a, with subglobose ascospores), but all later tested apothecia, which superficially looked identical, turned out to be *H. rotifera* (H.B. 6908b, with fusoid ascospores). Therefore, we recommend workers to gather as many data as possible from the first preparation because, in the worst case, no further apothecium of the species in question will later be discovered.

The frequency of mixed populations is a severe problem in terms of preservation of type material, pure cultures, and molecular research. When describing a new species, the question is how many apothecia should be examined in order to recognize all occurring taxa, but without completely destroying the material? When restudying a type specimen that represents a mixed population, workers may easily doubt the correctness of the protologue. In the worst case, they overlook the presence of a mixture because the involved taxa differ mainly in vital characters, while looking virtually identical in the dead state. Reports of anamorph-teleomorph connections as well as molecular studies likewise require careful examination of the apothecium from which the isolate or extract was gained.

Associated black yeasts and other dematiaceous hyphomycetes. Light to dark brown mycelia are very frequently present among the hyaline anchoring hyphae of *Orbiliomycetes* growing on xeric substrate (Fig. 120). In median sections of apothecia they are often very conspicuous on photographs, especially if dark-coloured. Occasionally, the apothecia are more or less immersed in the brown layer, therefore, brown mycelium can be found up to the apothecial margin. Due to their intermingled growth and close contact, an interaction between the hyaline anchoring hyphae of *Orbiliomycetes* and the brown hyphae cannot be excluded.

The fungi in question are known as black yeasts, black fungi, meristematic fungi, or microcolonial fungi (= MCF) (De Hoog & Hermanides-Nijhof 1977; Butin 1991; Sterflinger et al. 1999; Selbmann et al. 2005; Sterflinger 2006; Ertz et al. 2014), and show relationships with *Dothideomycetes* but also *Eurotiomycetes* (*Herpotrichiellaceae*) or *Arthoniomycetes* (*Lichenostigmatales*). They occur on exposed, initially undecayed wood and bark, and on rock or other mineral substrate, where they form a thin surface layer, called 'biofilm'. Their presence indicates that the substrate was periodically desiccated and rehydrated, i. e., subjected to periodical rainfalls and direct insolation (ultraviolet radiation) over a period of a few years, during which these fungi provoke a distinct greyish to blackish stain to the substrate surface. Their hyphae grow only in the decayed outermost layer of plant substrate (< 1 mm deep), and here inside the lumina of the empty plant cells. Greying is also observed on exposed dead stems of perennial herbs and on dead attached coriaceous leaves. Also the black mould on coniferous resin is caused by dark brown mycelia of dematiaceous hyphomycetes.

The brown mycelia frequently form moniliform chains of rounded, smooth or sometimes encrusted cells of varying size, but cylindrical hyphae and cell aggregates also occur. Butin (1991) has shown by culture studies that at least 12 different species belonging to 11 genera occur on coniferous wood at altitudes of 1000–2000 m in the Alps, the most frequent being *Phaeosclera dematioides* Sigler et al. (*Dothideomycetes*). In pure culture the different species showed clear morphological characteristics, but when growing on natural substrate they formed very similar, scarcely differentiated structures. Within the tracheids they form a more hyphoid mycelium but above the wood surface more isolated, spherical, encrusted yeast-like cells which probably serve as dispersal elements.

Very similar black yeasts occur on stones (lithobiotic, saxicolous) and survive under the harsh conditions of long-lasting insolation and dryness, but without significant organic admixtures (Sterflinger et al. 1999, Sterflinger 2006). Repeated trials to detect apothecia of *Orbilia* on such blackened mineral substrate were unsuccessful. However, in rare cases apothecia were collected on bare soil (see p. 142), and DNA of a *Lecophagus* sp. was extracted from the microbial biofilm covering sandstone (GenBank FJ028718).

Black yeasts and other dematiaceous hyphomycetes usually grow in more or less intimate association with green algae (Fig. 120). Sometimes they form hollow spheres that include algae, so-called goniocysts. Apparently due to a higher desiccation tolerance, black yeasts also occur in arid regions where free-living algae are usually unable to survive. As with the associated algae (see below), we never observed haustoria of hyaline anchoring hyphae in these brown cells. Possibly, the brown hyphae protect the hyaline *Orbilia* mycelium to a certain degree from ultraviolet radiation.

On hygric substrates with constantly high local atmospheric humidity, black yeasts are replaced by dematiaceous hyphomycetes that produce dark brown, projecting setae or synnemata with terminal conidiogenesis. They belong to genera such as *Brachysporium*, *Haplographium*, *Cacumisporium*, *Graphium* etc., and are often found in association with desiccation-sensitive species of *Orbilia*.

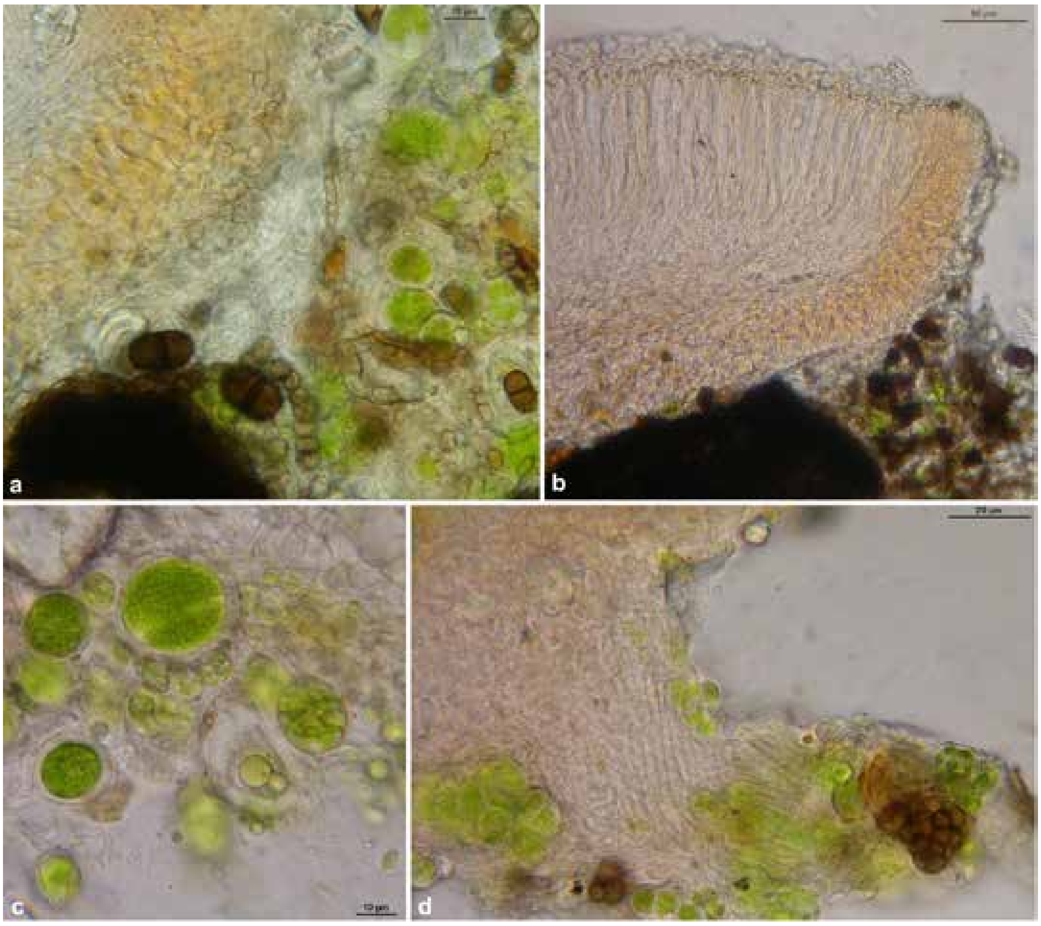

Figure 120: Median sections of apothecia formed on a biofilm composed of hyaline anchoring hyphae, coccoid green algae, brown cells of black yeasts forming chains or aggregates, brown conidia of *Diplodia*, and dark unidentified sporocarps. Note absence of brown cells on hygric substrate in **c**. — **a–b**. *Orbilia cercidicola* on xeric bark of *Cercis* (H.B. 9151e); **c**. *O. rosea* on hygric wood of *Quercus* (H.B. 9356); **d**. *O. clavuliformis* on xeric bark of *Malus* (H.B. 8212).

Associated algae. Biofilms on xeric, weather-exposed woody or herbaceous substrates often include a mixture of black yeasts and aerophytic algae, mainly *Chlorophyta* (Fig. 120), causing a characteristic, in external view greyish-olivaceous colour. Such a biofilm often covers large areas of a decorticated branch, while apothecia of *Orbiliomycetes* often occur only sparsely or in local groups on it. Also hygric branches and logs in not too shaded position are often covered by a thin to thick algal layer which may be inhabited by hygrobiotic *Orbiliomycetes* and usually lacks black yeasts. Here both coccoid and filamentous green or sometimes blue-green algae (*Cyanobacteria*) occur. If the substrate experienced occasional flooding, diatoms were also observed.

Aerophytic algae have mostly globose or ellipsoid cells which occur either singly or in small aggregates. Some are ensheathed by a thick gel layer. Others form multicellular filamentous elements. Characteristic genera are *Chlorella* (single globose cells), *Coccomyxa* (single ellipsoid cells), *Desmococcus* (aggregates of globose cells), and *Gloeocapsa* (aggregates in gel sheath). Algae with single ellipsoid cells have sometimes been misinterpreted by authors as ascospores of *Orbilia*.

The algae need a minimum intensity of light, but also a minimum amount of annual precipitation. Green algae are more or less absent in arid climates as well as on substrate lying on very shaded ground, and are sparse on those parts which are not easily wetted by rain. Algae were also not seen on substrate from tropical regions, even if collected at exposed position in open vegetation. For instance, algae could not or only very sparsely be observed in tropical northeastern Australia on standing dead stems of *Phragmites* (H.B. 8501) and *Bambusa* (H.B. 8497).

Because of the frequent presence of algae, *Orbiliomycetes* have sometimes been thought to be lichenized (Velenovský 1947: 102, *O. microclava*; Benny et al. 1978, *O. sarraziniana*). Also Haines & Egger (1982) observed algal cells in the basal apothecial tissue of several not further quoted species of *Orbilia*, but did not find any algae in their xerobiotic *O. piloboloides* (= *O. carpoboloides*), and also Kumar et al. (2012) did not observe presence of algae in *O. tenuispora*.

In our study, *O. carpoboloides* grew in some collections among abundant algal cells, while in others more or less completely without them. Quite a few species studied in this monograph were found to lack an association with algae, because they grew under extreme conditions of water supply, either in very arid or very humid habitats. Branches from arid deserts were often almost in total devoid of any algal cells, nevertheless a large number of *Orbilia* species occurred on them. On the other hand, areas with very thick layers of aerophytic algae in temperate climates are often devoid of *Orbilia* apothecia. Xerobiotic discomycetes from other relationships, such as *Durella connivens*, *Mollisia ligni*, or *Patellaria atrata*, may likewise form their apothecia in close association with abundant algae, therefore, they could as well be considered as optional lichens, but more probably they all simply share their habitat with aerophytic algae.

With the TEM, Benny et al. (1978: fig.s 21–23) observed haustoria in cells of a blue-green alga of the order *Chroococcales*. The haustoria were said to have emerged from the anchoring hyphae of *Orbilia sarraziniana* (as *O. luteorubella*). The observed alga was tentatively referred to the genus *Anacystis*, and the authors stressed the fact that a similar phycobiont is known from the lichen genus *Gonohymenia* (*Lichinales*). Besides the observation of a similar alga associated with another *Orbilia* identified as ‘probably *O. pulviscula* (Cooke) Seaver’, the authors saw some indication ‘that many, if not all, species of *Orbilia* are lichenized’.

Based on this report, an at least occasional connection of some species to algae has been considered in some books (Cannon et al. 1985, Hawksworth et al. 1996). Müller (1998) reported haustorial cells in *O. vinosa* and identified them based on their thick wall and included ellipsoidal bodies. However, his observation remains unclear as he did not observe fungal hyphae in contact with algal cells.

We have been so far unable to see haustoria with the LM in these and any other species of *Orbiliomycetes*. Pfister (1994) doubted the interpretation of Benny et al.'s TEM micrographs as penetration of an algal cell. There seems to be also an error in the scale of Benny et al.'s fig. 19, giving much wider anchoring hyphae than the treated species actually has (see under *O. sarraziniana*, p. 980).

In conclusion, we see no clear evidence for a lichenization of any of the many studied members of *Orbiliomycetes*. We confirm that most species may occasionally have at least some algal cells among their anchoring hyphae, but obviously none has evolved to a level comparable to lichens. We cannot, however, explain Benny et al.'s findings with the TEM. The mycelia obtained from ascospores of *Orbiliomycetes* are able to grow well on agar media, and they generally produce an anamorph and sometimes apothecia in pure culture without the presence of algae. The absence of *Orbiliomycetes* on purely mineral substrate supports the hypothesis that they are generally unable to obtain all their carbohydrates in symbiosis with algae as lichens do. Nevertheless, under the frequent natural condition of a rather final stage of substrate decay, it seems imaginable that *Orbiliomycetes* utilize some fixed carbon from the algae. In a much more obvious way they use pollen grains and invertebrates as a source of carbon and nitrogen (see p. 143 ff.).

Sherwood & Coppins (1980) drew attention to the apparent frequency of casual associations between lignicolous discomycetes and algae on weathered, scarcely decayed wood. The associated discomycetes thereby do not form a definite lichen thallus. The authors termed these associations 'potentially biotrophic', considering the possibility that the fungus obtains some of the fixed carbon from the algae if the fungal hyphae and algae come in contact. Wedin et al. (2004) observed optional lichenization in several species: a given species was currently placed in *Stictis* when the apothecia were non-lichenized, but in *Conotrema* when they were associated with a lichen thallus. Wedin et al.'s DNA-based study showed that such a species may have different nutritional modes: the fungus may start as a pure saprobiont on dead decorticated branches, but when the trunks become thicker it changes to a lichenized lifestyle on bark of the living trunks.

Associated mosses and liverworts. Various groups of bryophytes were noted as growing in close or remote association with *Orbiliomycetes* in the present study, and in very few cases the apothecia even grew on them (see p. 140). In central Europe, genera such as *Orthotrichum*, *Frullania*, or *Metzgeria* were often observed on xeric branches and trunks, mainly on bark, whereas on hygric wood or polypores the typical companions of *Orbiliomycetes* are genera such as *Hypnum* and *Lophocolea*.

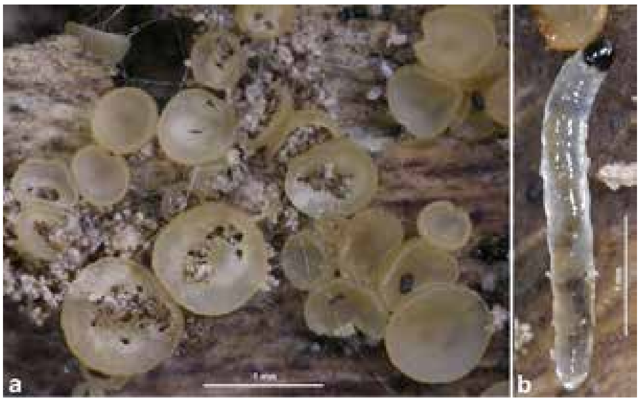

Figure 121: *Hyalorbilia inflatula* (H.B. 9041), apothecia (**a**) consumed by the fly larva in **b**.

Orbiliomycetes as a food source

Invertebrates that feed on apothecia. *Orbiliomycetes* are used as food source by various groups of invertebrate animals. On hygric substrates complete populations are consumed by snails and slugs. Also *Helotiales* are a preferred food source, whereas pyrenomycetes are protected by their thick-walled, often carbonaceous ascomata. Discomycetes on xeric substrate may be grazed especially by snails when the fungi are rehydrated during moist periods.

Among insects, damage to apothecia of *Orbiliomycetes* was noted by springtails, mites, millipedes, centipedes, and fly larvae. Such invertebrates consume apothecia even during dry periods and, therefore, also in the herbarium. In a moist chamber with *Hyalorbilia inflatula* a fly larva was observed eating cavities by starting at the apothecial base (Fig. 121).

Nematophagous *Orbiliomycetes* are thought to form trapping devices as a defense against nematodes which are adapted to fungal hyphae as food source (see p. 144–145). On the other hand, the consumption of apothecia by invertebrates might play a role in spore dispersal (endozoochory).

Fungal parasites of *Orbiliomycetes*. In 41 out of ~7200 here reported records of *Orbiliomycetes* the phenomenon of intrahymenial parasitism by the genus *Helicogonium* was observed (Figs 122–123). 35 of them were from European collections, three from North America, and three from China. In most cases the parasite was *H. orbiliarum* Baral & G. Marson. Members of *Helicogonium* produce only ascogenous hyphae and asci, rarely also phialidic anamorphs (Baral 1999). The asci are formed between the paraphyses and asci of their host species by suppressing more or less thoroughly the formation of host asci. Since the parasite often occupies the entire hymenium of the host, this kind of parasitism is easily misinterpreted as a single organism. However, if only some of the host asci are suppressed, two different types of asci occur intermingled (Figs 122: g; 123: a). Usually the wider and more projecting asci are those which belong to the parasite. Problematic is that asci of *Helicogonium* are always inamyloid like those of *Orbiliomycetes*, therefore, recognition of the parasitic relationship is easier with helotialean hosts which often have amyloid asci.

Three species of *Helicogonium* are so far known to occur in *Orbilia*: *H. orbiliarum* (from Europe, North America, China, Baral 1999: 47, Figs 122: a–e; 123), *H. hyphodisci* Baral & G. Marson (from China, Fig. 122: f), and *H. fusisporum* Baral & Kutorga (from Lithuania, Baral & Kutorga 2010, Fig. 122: g). A fourth could not be identified (from China, IVV: jgs-21). The eight ascospores of *H. orbiliarum* are globose to broadly ovoid and contain a few rather small LBs. They produce smaller ellipsoid ascoconidia which aggregate in clusters around the ascospores in the mature living asci prior to ejection and can easily be misinterpreted as warted ascospores (Fig. 122: b–c). In dead asci in which spore ejection was unsuccessful, the clusters got disintegrated (Fig. 122: e–f). The ascospores of *H. hyphodisci* are more elongate ellipsoid-clavate and produce allantoid (cashew-shaped) ascoconidia (Fig. 122: f). The unidentified species has elongate septate ascospores with two

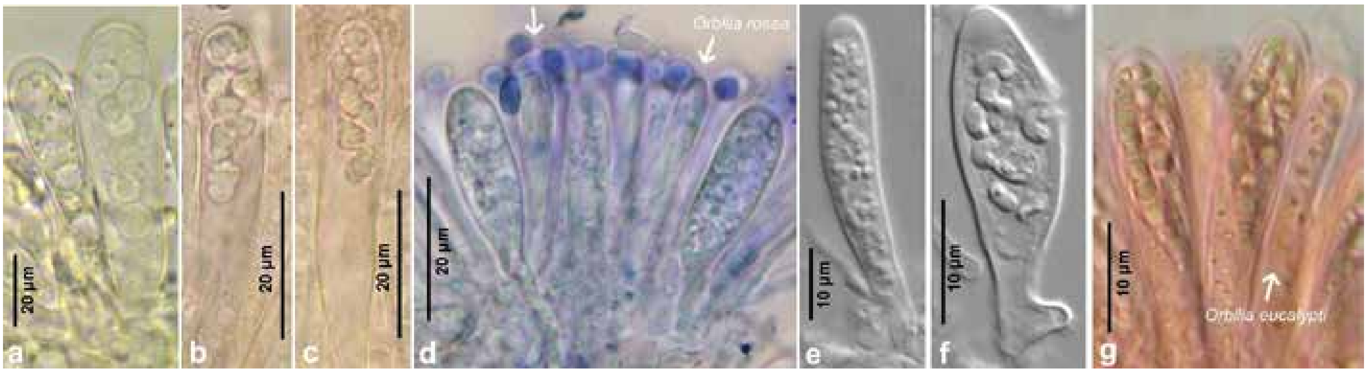

Figure 122. *Helicogonium* parasitic in hymenia of *Orbilia* spp. — **a–e**. *H. orbiliarum*, **a**. immature asci with eight subglobose ascospores (left ascus dead), **b–c**. mature living asci with dense clusters of small ellipsoid ascoconidia around ascospore, **d**. two immature living asci together with asci and paraphyses of *O. rosea* (in CRB), **e**. mature dead ascus with ascoconidia (ascospores almost invisible); **f**. *H. hyphodisci*, dead ascus with globose ascospores and allantoid ascoconidia; **g**. *H. fusisporum*, two mature asci and a host ascus of *O. eucalypti* (in KOH+CR). – **a**. P.P. 20080713-007-1 (phot. P. Perz), **b–c**. H.B. 8615a, **d**. E.R.D. 5925 (phot. E. Rubio), **e**. HMAS 75874 (phot. B. Liu 2006, as *O. euonymi*); **f**. H.B. 8978a (phot. H.Y. Su); **g**. H.B. 8533.

large LBs and elongate straight ascoconidia. The ascospores of *H. fusisporum* are comparatively large, fusoid, and also contain large LBs (Fig. 122: g), but no ascoconidia are formed on them within the asci. Only when studying dead asci with disintegrated clusters (Fig. 122: e–f), the ascoconidia may easily be confused with ascospores of multispored asci of *Orbilia*.

At least 14 species of *Orbilia* have so far been observed as host of *Helicogonium orbiliarum*: *Orbilia aristata* {1}, *O. aprilis* {1}, *O. aurantiorubra* {1}, *O. eucalypti* {14}, *O. euonymi* {2}, *O. frangulae* {1}, *O. luteorubella* {1}, *O. magnifica* {1}, *O. phragmotricha* {1}, *O. rosea* {1}, *O. sarraziniana* {3}, *O. tremulae* {1}, *O. vinosa* {7/2}, *O. xanthoguttulata* {1}. No other genus of *Orbiliomycetes* was so far found to have this intrahymenial parasite. *Helicogonium hyphodisci* in *O. laevimarginata* and *H. fusisporum* in *O. eucalypti* were each recorded only once. *H. orbiliarum* was at first thought to be adapted to the genus *Orbilia*, but we have seen it also in hymenia of different *Helotiales* (IVV: *Cyathicula* ?*tomentosa*, H.B. 5759; *Durella* ?*compressa*, H.B. 7077e; *Hyaloscypha minuta*/*intacta*, H.B. 6087; ?*Calloria* sp., H.B. 5482h). *Helicogonium hyphodisci* is otherwise only known from hymenia of *Hyphodiscus*.

No deformations to the host apothecia are provoked by any of these parasitic species. Therefore, infected apothecia cannot be recognized under the dissecting microscope. Very similar as in *Orbilia*, the asci of *Helicogonium* have long undulating stalks, which, however, vary in arising in some species from croziers and in very closely related species from simple septa. Croziers and simple septa occur even within *H. orbiliarum* in the present concept, when comparing different collections. The ascus apex is hemispherical to conical and always provided with a thin to thick apical thickening. SBs never occur in the living ascospores or conidia of *Helicogonium*.

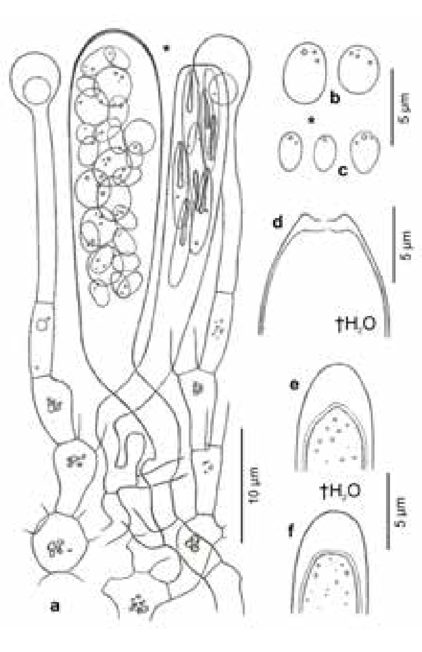

Figure 123. *Helicogonium orbiliarum* in hymenium of *Orbilia rosea* (H.B. 6366). — **a**. ascus of *H. orbiliarum* with eight subglobose ascospores and many smaller ellipsoid ascoconidia along with ascus and paraphyses of *O. rosea*, **b**. ascospores, **c**. ascoconidia, **d**. emptied ascus of *H. orbiliarum*, **e**: immature dead asci of *H. orbiliarum*.

In two Australian collections a ?chytridiomycete was found in hymenia of *Orbilia* sp. and *O. aviceps* (Fig. 124: a–e). The apparently same fungus was observed in *O. mali* in Europe (Montenegro, B. Perić pers. comm., Fig. 124: f). A similar species parasitic in hymenia of *Mollisia* was treated as a possible member of *Chytridiomycota* in Baral (1999: 11). The parasite in *Orbilia* deviates from that in *Mollisia* by sporangia with a glassy apical outgrowth with terminal globose inflation, and a subapical opening close to this outgrowth (but the outgrowth was not seen in the sample from Montenegro). The species might belong to the genus *Karlingiomyces* Sparrow, which is, however, reported to be saprotrophic (Blackwell et al. 2004). A flagellum was not observed on the sporangiospores, which could only indistinctly be seen inside the sporangia Fig. 124: a).

A few members of *Orbiliomycetes* may thrive as parasites on apothecia of *Orbilia*: *Hyalorbilia orbiliicola* forms apothecia on the apothecial margin of different desiccation-tolerant *Orbilia* species (Fig. 116: b). The hymenia of the host apothecia remain more or less immature, but the excipular and paraphysis cells are usually still viable when the apothecia of the *Hyalorbilia* develop. Frequently also the anamorph of *H. orbiliicola* (trinacrium angamosense-like) forms its conidia on the host apothecia, usually together with the teleomorph (see p. 425). A similar anamorph that deviates in more asymmetrical conidia (see p. 427) was repeatedly found to grow out of hymenia of different xerobiotic Australian species of *Orbilia*, but its presumed teleomorph was only seen in one of these records. Some other observations of parasitism by orbiliaceous anamorphs were made, for instance, asymmetrical dicranidion-like conidia formed on apothecia of *O. vinosa*, which were considered by us to belong to the closely associated apothecia of *H. hergiswiliana* (see p. 435).

A hyphomycetous intrahymenial mycoparasite, *Acremonium limoniforme* Baral, was observed in two distantly related desiccation-tolerant species of *Orbilia* (*O. cactacearum*, *O. macroasca*) in the semiarid southwest of Northern America (Baral 2019). The fungus is characterized

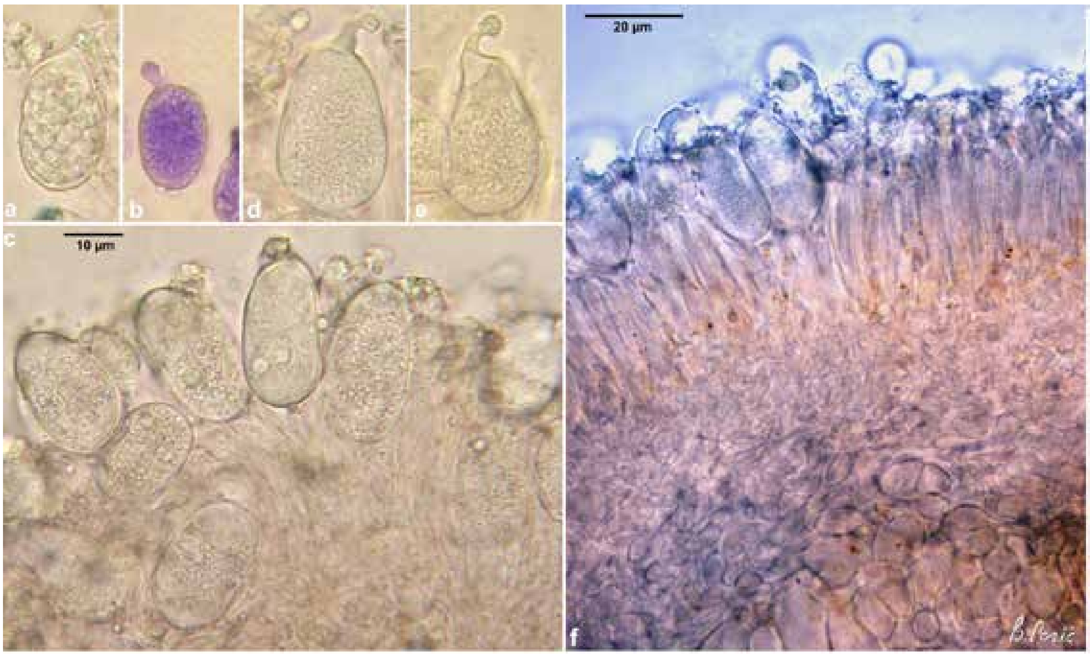

Figure 124: Sporangia of a ?chytridiomycete develop in hymenia of xerobiotic *Orbiliomycetes*: *Orbilia* sp. (**a–c**. on *Acacia*, H.B. 7204p, in CRB), *O. aviceps* (**d–e**. on *Banksia*, H.B. 8659b), *O. mali* (**f**. on *Punica*, B.P. Dgf/C7D-01-05-16b, phot. B. Perić).

by short hyaline conidiophores and non-septate, hyaline, medium-sized, limoniform conidia formed in hyaline, deeply invaginated sporodochia immersed in the hymenium of the host. Conidiogenesis seemed to be holoblastic in one of the two collections when viewed in the living state, but in the other collection the dead conidiophores showed a clearly enteroblastic (phialidic) conidiogenesis. Its phylogenetic relationship is unclear because no DNA data were available.

An unidentified species of *Niesslia* (*Niessliaceae*, *Hypocreales*) with minute dark superficial perithecia with short brown setae was 3 × found between 2009–2018 in North America growing abundantly on the hymenium of what appears to be *Hyalorbilia inflatula* (J. Karakehian, B. Liu, E. Crenson, J. Mack pers. comm., IVV: VIII.2009, VIII.2017, 23.VI.2018).

Dispersal and colonization of new substrate

Different strategies of substrate colonization can be observed within the *Orbiliomycetes*. They comprise dispersal by wind and water, but also by adherence to animals, and apparently by ingestion. Thereby, dispersal is mainly accomplished via conidia and ascospores, in some species also by detachable trapping organs, perhaps also by hyphal fragments and by chlamydospores.

Dispersal by wind and water. Dispersal by air currents is more efficient at high levels above the ground. Apothecia growing close to the ground are faced with problems of still air surrounding the substrate, whereas apothecia at higher levels are exposed to turbulent air. Sherwood (1981: 32) hypothesized that ascomycetes on exposed weathered woody substrate do not need highly developed discharge mechanisms such as amyloid apical rings, which are typical of those species adapted to the moist ground. In contrast to the *Helotiales*, we cannot see any difference in ascus morphology and spore discharge mechanisms in the *Orbiliomycetes* between these two ecological types, with the exception that asci with thick-walled apices occur exclusively in xerobiotic taxa, though only in about a third of them. It can, therefore, be assumed that asci of xerobiotic *Orbiliomycetes* are able to shoot their spore clusters as far as hygrobiotic ones, or perhaps even further when the ascus apices are thick-walled.

The frequent and exclusive occurrence of polyspory in xerobiotic species of *Orbilia* could be interpreted as an adaptation to wind dispersal, in order to increase the probability of colonization by a high number of spores. Yet, in the often small apothecia of these species the total number of spores is probably lower than in a desiccation-sensitive species with large apothecia. Another aspect could be that polyspory helps in establishing a heterocaryotic mycelium, since all spores of the spore cluster are still held together when splashing on the substrate. Especially if some of the spores do not survive long drought, polyspory might avoid single spore mycelia during substrate infection, but this would require homothally. Heterokaryosis as an advantage in xeric environment was considered by Sherwood (1981: 25). Although *Orbilia* spores often survive several years in the herbarium, they might not stay alive for such a long time when exposed to strong insolation. The consistent absence of a brown pigmentation in the spore wall in *Orbiliomycetes* suggests that the spores cannot compete in survival with brown-spored ascomycetes.

Unlike our results, Sherwood (1981: 26) found anamorphs to be absent in most xerobiotic discomycetes, and supposed that the xeric environment is characterized by low competition on substrates that are stable over a long timespan. She concluded that desiccation-tolerant fungi do not require rapid dispersal and colonization by means of asexual propagules. However, Sherwood was unaware of the predominant presence of *Orbiliomycetes* as well as their anamorphs on xeric substrate, and she might have overlooked the high competition that undoubtedly takes place during the rare events of humidity in xeric environments.

A large number of orbiliaceous anamorphs have staurosporous conidia*,* frequently with long and narrow, hyphoid extremities (curucispora/descalsia-like, dicranidion-like, dwayaangam-like, tridentaria-like, trinacrium-like). Others have unbranched multiseptate, vermispora- or anguillospora-like conidia. Almost all of them live in xeric habitats on dead exposed, mainly woody substrates and are dry during most of their lifetime. One of the advantages of such branched or C-shaped conidia might be a longer stay in the air during dispersal. Yet, stauro- and scolecoconidia have originally been reported mainly from aquatic habitats like foam or submerged leaves in streams (Ingold 1942, 1958; Miura 1974; Descals & Webster 1982; Sinclair et al. 1983). As a matter of fact, D. Magyar (pers. comm.) rarely found such conidia in air samples.

Experiments by Webster (1959) with variously shaped conidia of a number of rather distant species in a water-tunnel tested under five different water speeds showed strong differences in adhesion to an inserted collodion-coated glass rod that acted as a trap. Accordingly, tetraradiate conidia with long branches get attached with considerably greater efficiency than conidia with short branches, or unbranched conidia of various lengths. Tests on conidial sedimentation rates in motionless water yielded no correlation with conidial shape. Ingold (1966: 54) concluded that tetraradiate conidia represent an adaptation to transport in running water, their shape acting as a little anchor to get attached to submerged substrate. Therefore, later authors referred to such conidia as 'Ingoldian'.

A further property, mainly of staurosporous conidia, is that they easily get trapped by air bubbles and accumulate in foam or swim on the water surface. We have used this effect in order to collect conidia from xeric substrate in close vicinity of apothecia (see p. 6). A very similar effect was detected in ascospores of a few desiccation-tolerant *Orbilia* species which adhere solely with their apex to the surface of water drops or films (see Fig. 72) where they are transported by water currents.

Some of the filamentous (anguillospora-like) or staurosporous (curucispora-, descalsia-, trinacrium- or dwayaangam-like) conidia found in running water and currently referred to as Ingoldian more ore less strikingly resemble conidia of *Orbiliomycetes*. Yet, orbiliaceous conidia are usually not formed inside or close to waterbodies. For example, *O. junci* grows on dead dry parts of standing culms of *Juncus roemerianus* at the Atlantic sea shore in the east of Northern America. The normal tides thereby reach only the lower part of the culms, not the upper part where *O. junci* lives (Kohlmeyer et al. 1998). Because of the staurosporous, dwayaangam-like conidia of its anamorph, the habitat directly at the sea shore, and the occurrence of other *Dwayaangam* species in freshwater, the authors concluded that the anamorph of *O. junci* is an Ingoldian fungus adapted to water dispersal. However, at that time the conidia were only known from pure culture and their natural habitat unknown. Later, Kohlmeyer & Volkmann-Kohlmeyer (2001) detected conidia on the dead tips of the standing culms, and concluded that they can be wind- or water-dispersed to other senescent leaves. This is supported by our observation that the conidia of this species survive desiccation for at least a week.

Only a few species of *Orbiliomycetes* (e.g., *Lecophagus muscicola*, *Orbilia luteorubella*, *O. rectispora*, *O. rosea*, *O. sarraziniana*) actually live in wet, semiaquatic habitats. Two of them differ mainly in their anamorph, that of *O. luteorubella* being helicoon-like and that of *O. rosea anguillospora-like*. Apothecia of these two species are found at the banks of rivulets and lakes and are for most of the time exposed to dry air, into which the asci discharge their spores. The scolecosporous, worm-like conidia of *O. rosea* might show a slower sedimentation rate when floating in running water, whereas the likewise scolecosporous but strongly coiled, barrel-shaped conidia of *O. luteorubella* enable floating at the surface of stagnant water because of trapped air in their interior. Apparently, such conidia are adapted to water dispersal during high water levels.

But water comes temporarily also to dry substrates. During rainfalls, xeric substrate is covered by a water film and represents a short-time aquatic habitat with water running or dropping down from trees (Bandoni 1972, 1974). According to this author, conidia were held up on the surface tension film of the water. Several studies on stemflow from living trunks showed a rich amount of conidia of 'terrestrial Ingoldian' or 'terrestrial aquatic' fungi (see Descals & Moralejo 2001: 22), some of which are undoubtedly anamorphs of *Orbiliomycetes.* Ando & Tubaki (1984a, b) reported stauroconidia of *Curucispora ombrogena*, *Dicranidion fissile*, and *Dwayaangam yakuensis* from rainwater samples collected from aerial leaf-surfaces. Gönczöl & Révay (2003) found hyphomycetes communities with conidia of various *Trinacrium* and *Dwayaangam* species in water-filled treeholes of living broad-leaved trees. They also isolated eight different *Trinacrium* species and many other orbiliaceous anamorphs from rainwater stemflow from living trees (Gönczöl & Révay 2004, 2006 etc.). Using pressure-sensitive acrylic strips, Magyar (2008) observed various types of conidia, some of which being orbiliaceous (dwayaangam-, trinacrium-, vermispora-like), trapped by the surface of stem bark fissures during stemflow.

The origin of terrestrial conidia found in stemflow has been a matter of speculation, and especially their life cycle and desiccation tolerance was unknown. Descals & Moralejo (2001: 32) thought that the conditions on terrestrial plants may be generally too dry for the growth of Ingoldian hyphomycetes. Those taxa which spend most of their time under water may actually be sensitive to water loss. However, conidia of 'terrestrial aquatic' fungi observed in stemflow are undoubtedly formed on aerial parts of the trees, where also their mycelia and conidiophores are tolerant to desiccation.

Based on our observations of various orbiliaceous anamorphs on xeric substrate, frequently observed in association with apothecial populations, the conidia found in stemflow of living trees were formed on dead bark or wood of twigs and branches in the canopy of these trees. During rainfalls the conidia are transported downwards where they may attach to the rough, fissured bark surface or get trapped in treeholes, whereas others reach the soil, or drop directly into smaller or larger water courses, or get washed into floodings and temporary lakes. The seemingly unidirectional dispersal by dripping and running water appears at first disadvantageous, but it can be assumed that additional vectors such as arthropods and birds (see below) support a multidirectional distribution to the conidia. Magyar (2008) imagined the enormously large surface of fissured bark to act as a reservoir or 'spore bank' for further infections, allowing storage of a vast number of spores. Although some of the conidia might be transported there by air currents, Magyar concluded that 'the majority of free spores trapped inside the bark fissures was delivered by the rainwater from their colonies growing elsewhere on the host tree. Stauro- and scolecosporous taxa, especially, common in bark and stemflow rainwater but rare in the air samples, are thought to be bark-inhabiting hydrochorous species.'

Dispersal by animals. Hence, a further strategy implies the dispersal mediated by animals, either by invertebrates such as arthropods (copepods, beetles, mites, spiders, springtails) or smaller ones (nematodes, rotifers, tardigrades), or by vertebrates such as birds or mammals. Presence of *Orbiliomycetes* on the skin mucosome of larvae and adults of amphibia (*Salamandra*) in Massachusetts was demonstrated by Barnhart (2018) by molecular methods.

We suppose that spore clusters shot from asci are sticky and adhere to insects which transport them to other places (ectozoochory). Especially shortly after rainfalls when the asci are turgescent, animal activity is often high. We also assume that particularly those species with showy apothecia (e.g., *Orbilia*

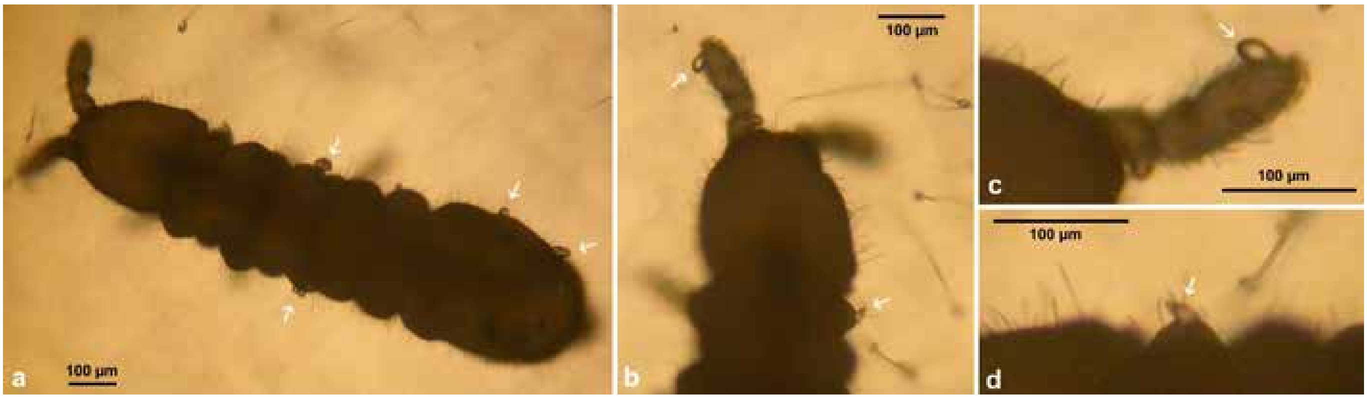

Figure 125: Springtail (*Collembola*) added to a pure culture of *O. menageshae*, with adhering conidia (H.B. 9275a).

fimbriata) attract flies and other insects (see p. 105, Function of pigments). For adherence to animal bodies, polyspory in *Orbilia* cannot be explained by a higher chance to hit the insect body, because the spores are ejected as a single entity.

Ectozoochory of conidia was, e. g., suggested by Pfister (1997: 16). It can easily be proved by adding small invertebrates to an agar culture. Conidia of many orbiliaceous species are covered by a thin gel sheath that stains lilac with CRB (Fig. 94: f–g). Only rarely the gel sheath is thick and visible without staining as in *D. polybrocha* (Pl. 12: i). The gel is adhesive to passing animals which undoubtedly serve as a vector for conidial transport. Particularly species with long, erect conidiophores, which are typical of moist habitats, possess conidia with a stainable gel film (Tab. 9). When adding a springtail to a culture of *O. menageshae*, the conidia adhered to the antennae, extremities, and the main body (Fig. 125). Then the springtail either detached the conidium from the conidiophore or, if the conidium is not mature enough, the animal escaped only with high effort. The stickiness of conidial gel seems to be comparable to that of adhesive trapping organs. Conidia formed on ± short conidiophores are likewise sometimes covered by gel. In addition, conidial shape might help in lodging to animals, especially to their legs, either by bending of phragmoconidia which are often hook-like towards the ends, or by different types of branching in the case of stauroconidia. However, in some species of *Hyalorbilia* the straight unbranched conidia seem to be devoid of such a gel as their surface did not stain in CRB (Tab. 9).

Also some trapping organs are detachable, particularly non-constricting rings (see Fig. 109: f), or they are directly formed on conidia. In both cases they are carried away by the prey. Also those aerial hyphae which coil upon touch might adhere to small invertebrates and get detached (see p. 105). Chlamydospores remain viable over a long timespan during which they are possibly translocated.

Ingestion of apothecia by snails without damage to the ascospores (endozoochory) was demonstrated in a single test with a door snail (*Cochlodina laminata* fide C. Allgaier): spores of *Orbilia aurantiorubra* looked vital in faeces of this snail which was kept in a moist chamber together with apothecia for some days. Also bdelloid rotifers were once seen under the microscope to engulf ascospores of an *Orbilia* of series *Hesperideae*, but with their trophi they were able to crush them, so in this case the animal did not contribute to the dispersal of the fungus. Our hypothesis that ascospores infect certain microscopic animals via ingestion (infection by ingestion) implies in the successful case also dispersal of the fungus.

Also larger animals such as arthropods, reptils, birds, and mammals might play a role in conidia and ascospore dispersal, either by adherence or by ingestion. Dispersal of *Orbilia arachnovinosa* and *O. pseudoaristata* (as Unidentified sp. 2170_1175 & 2170_622) by insects was shown in a study of Menkis et al. (2016) who obtained DNA from adults of the European elm bark beetle, *Scolytus multistriatus*, the vector of the Dutch elm disease, which were trapped by sticky inserts in delta traps. The beetles were not surface-sterilized prior to DNA extraction, so that it is unknown whether the propagules were out- or inside the insect body.

Desiccation tolerance

Fungi are generally devoid of structures that efficiently reduce evaporation of their internal cellular water when exposed to a low atmospheric humidity. However, they have other mechanisms to permit growth and survival in a periodically dry environment. Instead of retarding water loss, the protoplast of fungal cells of certain species is able to repeatedly withstand complete desiccation. This is often the case with propagules (meiospores and conidia), but in many fungal taxa also regarding the complete hyphal system and sporocarps of both anamorph and teleomorph.

Two main ecological groups can, therefore, be distinguished in fungi: those with **desiccation-tolerant** (= drought-tolerant) sporocarps, and those with **desiccation-sensitive** (= drought-intolerant) sporocarps. In the latter group usually only the propagules survive complete drying. Desiccation-sensitive taxa, which are also termed **hygrobionts**, grow on **hygric** substrate in continuously moist microhabitats which dry out only after prolonged periods of drought. In the worst case, this causes the death of the population, unless the mycelium shows a certain tolerance to desiccation. Desiccation-tolerant taxa, which are also termed **xerobionts**, live on **xeric** substrate which periodically dries out, therefore, their entire sporocarps survive drying. Cases in which the sporocarps are hygrobiotic but the mycelia xerobiotic are perhaps not uncommon: such fungi colonize wood of dead attached branches by their mycelia, but sporocarps are only formed on them after they fell down to the ground. For instance, *Chlorociboria aeruginascens* (*Helotiales*) causes a blue-green stain to xeric wood whereas apothecia are formed only on hygric wood on the ground. Conversely, mycelium of endophytes in living plant tissue might be intolerant to drying until the colonized plant parts die and desiccation-tolerant sporocarps are formed.

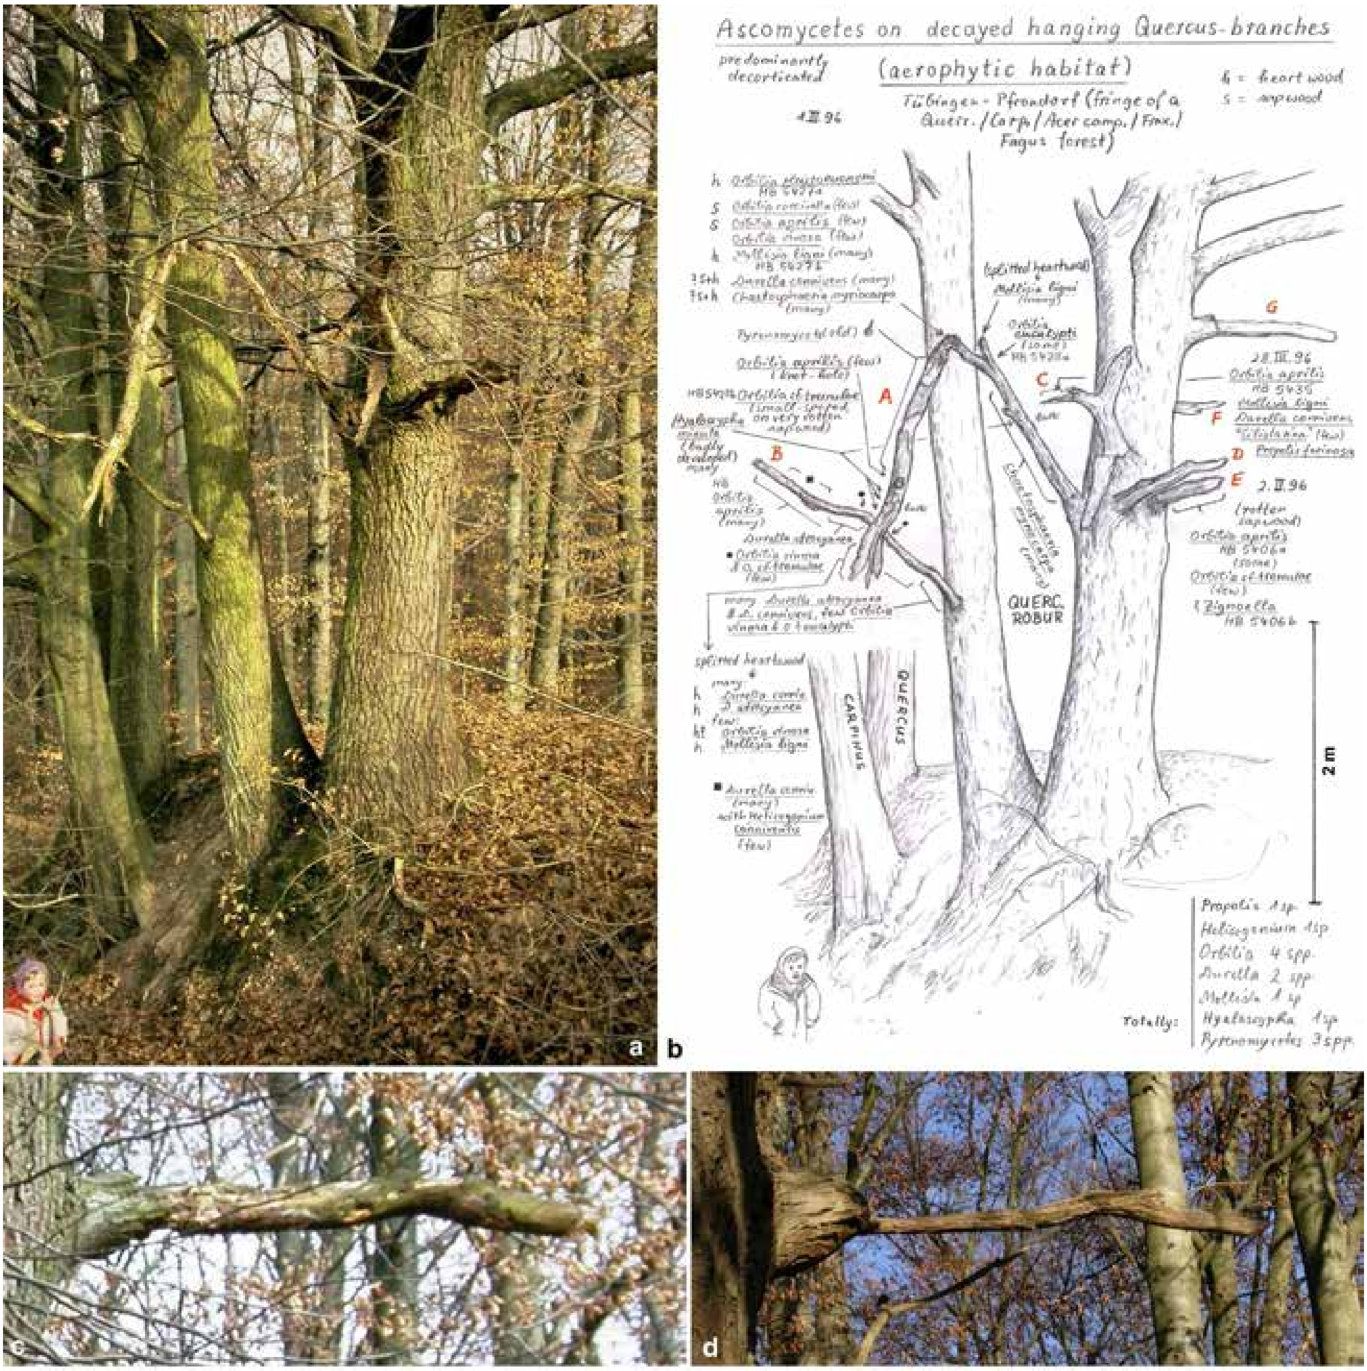

Figure 126. **a–b**: *Quercus robur* and *Carpinus betulus* at border of deciduous forest in Tübingen-Pfrondorf (southern Germany), 2.II. (H.B. 5406, **a** & **c**), 1.III. (H.B. 5423, 5427–28, **b**) & 28.III.1996 (H.B. 5435). A total of 12 species of ascomycetes (four orbiliaceous) were recorded on the attached, decayed and eroded, decorticated branches ~ 2–3 m above the ground. Branches D, F & G were not examined but monitored for their decay during the next years. **c–d**: Branch G was observed to persist for the following 14–18 years (until X.2013), during which the thickness of its decorticated part decreased from ca. 10–12 (**c**, 2.II.1996) to 3–4 cm (**d**, 14.XI.2010). During a control in X.2014 the branch had disappeared.

However, there is no sharp limit between the two groups. The strength of desiccation tolerance, i. e., the period of time the sporocarps survive complete dehydration in all their parts, strongly differs among the taxa. Some species, particularly members of *Hyalorbilia*, tolerate desiccation only for a few days or weeks, but others for several years. Moreover, considerable differences occur within a given species. For example, apothecia of *Orbilia tremulae* or *O. cejpii* usually did not noticeably withstand drying when growing on the moist ground, but they survived some weeks or months when occurring on attached xeric branches, although in such cases no differences could be observed in their ITS rDNA. Therefore, data given here on the proportion between xero- and hygrobionts are to be considered as approximate. Apothecia colonizing xeric substrate probably cover some of their water requirement from the plant tissue below. However, such water sources certainly play a subordinate role, since apothecia usually rapidly dry out during dry weather.

Parameters which determine the water relations in the substrate are the exposure against direct sunlight and rain and the humidity of the atmosphere. Three main habitat categories can tentatively be distinguished in this regard: **xeric** (periodically dry for a shorter or longer time), **mesic** (moist for a longer time but with dry intervals), **hygric** (continually moist while rarely drying out), and **semiaquatic** (continually moist but periodically flooded). Desiccation-sensitive species are unable to produce sporocarps on xeric, air-exposed substrate because the available water rather rapidly decreases after a moist period, depending on the thickness and absorptive capacity of the substrate. Vice versa, desiccation-tolerant species do not usually occur on continually moist substrate since they are unable to compete with fungi that are better adapted to hygric habitats, apparently because of a slower growth rate of their mycelia. A large amount of dead plant substrate on earth is subjected to repeated and in some areas very long-lasting dryness, and desiccation-tolerant species are adapted to colonize these enormous nutrient resources. The disadvantage of a delayed life cyle of each generation due to long periods of dormancy stands in opposition to the advantage of being protected from grazing by hygrobiotic animals, particularly from slugs, and from competition with fast-growing hygrobiotic fungi.

In the introduction to the biology of lichens, Nash (2008: 1.4) gave an excellent characterization of desiccation-tolerant, poikilohydric organisms, which widely applies also to non-lichenized ascomycetes. The unabridged paragraph seems worth reproducing here:

‘Most flowering plants and conifers have developed the capacity to maintain the water status of their leaves or needles at fairly constant levels and hence are referred to as homoiohydric organisms. In contrast, lichens are prominent members of poikilohydric organisms, whose water status varies passively with surrounding environmental conditions. Other poikilohydric organisms include mosses, some ferns and other primitive vascular plants. All of these organisms become desiccated relatively rapidly and, as a consequence, water availability is of prime importance for their survival and in explaining their patterns of occurrence.

One might assume that poikilohydric organisms are highly dependent on precipitation, primarily in the form of rain. Certainly this is true for many lichens, as can be seen for the lichen biomass relationship among interior desert sites. On the other hand, lichen biomass near the Pacific Ocean in the western part of the Sonoran Desert vastly exceeds values that would be predicted based on precipitation alone. This illustrates the ability of lichens to utilize other water sources, such as fog and dew. In addition, lichens have the remarkable ability to extract some moisture from unsaturated air under conditions of low temperatures and high humidities. This is essentially the reverse of transpirational water flow occurring through vascular plants and is due to the low osmotic values of lichen thalli. However, under intermediate to high temperatures and intermediate to low humidities, the water potential gradient from the lichen to the atmosphere is reversed and evaporation occurs.’

Hygrobiotic (desiccation-sensitive) fungi occur in zones of either medium to high annual precipitation (around 500–2000 mm), frequent fog, or low evaporation due to low temperatures. Rainfalls may occur either more or less equally distributed over the year (humid), or show a pluviseasonal change with long-lasting periods of drought either during winter (monsoon climate) or summer (mediterranean). Besides the amount and seasonality of precipitation and the microclimate, substrate humidity also depends on the average temperature of the region. Therefore, boreal zones need much less rain than subtropical zones. Particularly in the pluviseasonal zones, hygrobiotic species are usually only found during and shortly after the rainy season, whereas xerobiotic species can be collected all over the year.

Hygric substrate. Continually moist substrate enables hygrobiotic species to complete their whole life cycle without interruption provoked by dryness. When cultured on the natural substrate at room temperature in a moist chamber, the formation of fully mature apothecia of *Orbiliomycetes* was found to last about 2–5 weeks, as extrapolated by a hypothetical start from very small apothecial initials (see p. 40–41, Growth rate). The observed growth rate was distinctly lower in xerobiotic species, but due to their usually smaller size the full timespan to form mature apothecia is similar as in hygrobionts. However, this situation is artificial for a xerobiotic fungus which, under natural condition, periodically experiences dry periods and, therefore, much longer growth rates. Similarly, cold weather periods during winter interrupt or retard growth of cryotolerant hygrobionts. One of many examples for this is the genus *Sarcoscypha*, a lignicolous member of *Pezizales*, apothecia of which are formed during late autumn but become mature only in early spring.

Desiccation-sensitive species colonize rotten wood and bark, herbaceous plant parts or decayed sporocarps that lie more or less close to the moist forest floor, often at wet places or water courses, usually in shaded situation and protected from drying winds. Drying is often prevented by a cover of litter or by growing on the underside of branches and logs with close contact to the ground. Only rarely, hygrobiotic apothecia are found exposed to a dry atmosphere ~1–2 m above the ground, but then usually on deeply strongly rotten wood being soaked with water like a sponge (observed, e.g., in *Orbilia xanthostigma* and *O. orientalis*).

Xerobiotic (desiccation-tolerant) fungi occur in all climatic regions of the world where dead decayed plant substrate is exposed to alternate wetting and drying. Their highest diversity is in the subtropical to tropical, semihumid to arid zones, with occasional or seasonal precipitation ranging between around 100–800 mm per year. A distinctly lower number of xerobiotic species was found in temperate to subtropical humid to subhumid regions with continuous or seasonal rainfalls of ~800–1500 mm per year, and only a few such species were so far collected in tropical humid regions with rainfalls around 1500–2000 mm per year and only short-lasting periods of drought, or in arctic-alpine dwarf-shrub communities with a similar long-lasting humidity (see Tab. 33).

Xeric substrate. Desiccation-tolerant species live on all kinds of dead air-exposed plant parts up to the canopy of large trees. Xeric substrate comprises wood and bark of still-attached, or broken and hanging, usually dead twigs and branches, adhering dead leaves and fruits, also the dead outer bark of living trunks. It also includes more or less standing or hanging dead parts of herbaceous plants. Woody and herbaceous xeric substrate persists for a much longer time than hygric substrate. In humid areas, recently dead herbaceous substrate requires a minimum of two years until *Orbiliomycetes* develop. Woody substrate usually attains its optimum stage only when the bark starts to detach; the minimum timespan to attain optimum decay for colonization by *Orbiliomycetes* in humid regions might range at 3–5 years and in semiarid regions presumably at 10 years or more.

Typically, xeric substrate is exposed to direct sunlight for several hours on a sunny day. An old decorticated branch is poor in water content, and its surface dries out rapidly after a rainfall, at least in the course of a sunny day, in contrast to more shaded substrate in a dense forest. Due to the different degrees of tolerance to dryness, fungal communities also differ in their composition between xeric and mesic substrate.

Decorticated xeric wood usually looks more or less weathered and eroded when carrying ascomycetes. The rotten wood surface is typically covered by a biofilm of black yeasts which provoke a greyed surface (e. g., Figs 115: m, 119: b). Often free-living aerophytic algae are present in this biofilm (Fig. 120). Decorticated areas in an advanced decay, or detached hanging bark, also the presence of beetle galleries provide promising preconditions for desiccation-tolerant *Orbiliomycetes*. Only a few species were preferably or exclusively found at an initial stage of decay (e. g., *O. aradi* and resinicolous taxa).

Small ascomata on xeric substrate are unable to retard water loss from their cells for more than a few minutes or hours, depending on the size of the ascomata, the water-holding capacity of the substrate, i. e., the thickness of the substrate, the depth of its decay, and its hydrophily, and weather parameters such as temperature and wind. Therefore, the active growth period of small xerobiotic ascomycetes is usually restricted to periods of atmospheric moisture. The interruption of growth concerns all stages of the life cycle, including mycelial growth.

The natural hydration of xeric substrate is accomplished mainly by rain- and snowfalls, during the colder season or higher altitudes also by fog, or by dew during cold nights. Unpublished experiments in cold-temperate humid, colline central Europe (Tübingen, see Baral & Marson 2005) during the end of September 2010 showed that even an atmospheric humidity of almost saturated air (99 %) during the night rehydrates apothecia of *Orbilia aristata* and *Sclerencoelia fraxinicola* only to about half their full size, which is certainly not enough to enable spore discharge. Temperatures below +6–8 °C were necessary to attain a 95–100 % atmospheric humidity. In mountain ranges with oceanic influence, rehydration of xerobiotic fungi by fog and dew is probably more important than in lowland regions.

In subtropical semiarid areas the total lifetime of an apothecium can be estimated to last perhaps 5–10 years, showing active growth only during a few days or weeks per year. In temperate humid areas mature apothecia were found during summer to increase considerably in size within a period of 3–4 months, whereas during the entire winter time they showed hardly any growth (see p. 40–41). An experiment that demonstrates colonization of xeric substrate was done with a rope of plant fibres which, after exposure for about 3–4 years, carried various *Orbilia* spp. and other ascomycetes (see Baral & Marson 2005).

Desiccation tolerance within taxonomic groups, particularly discomycetes. Xerobiotic sporocarps occur in many groups of fungi, though in a strongly varying frequency. Many genera or higher taxonomic groups comprise both ecological types, whereas others are either more or less purely xero- or hygrobiotic. Within the discomycetes, these ecotypes may characterize groups at the ordinal or higher level. To the present knowledge, members of *Ostropomycetidae* and *Rhytismatales* are apparently exclusively desiccation-tolerant. Members of *Pezizales* are desiccation-sensitive in almost every case, including the genus *Octospora*, which occurs on mineral soil in a parasitic or symbiotic relationship with predominantly xerobiotic bryophytes, preferably during the cold and moist winter months. At least one species of the genus, *Octospora affinis*, is clearly xerobiotic: it grows on the rhizoids of *Orthotrichum* on bark of attached branches at ~ 0.5–3.5 m above the ground (Krieglsteiner 2006), and our tests showed that mature asci survive at least two weeks in the dry state. Another exception within the hygrobiotic *Pezizales* concerns the xerobiotic genus *Octosporella* with perithecioid ascomata occurring on bryophytes on xeric bark.

In *Leotiomycetes* both ecological types occur in rather equal frequency. Typical hygrobiotic genera comprise, for instance, *Sclerotinia*, *Ciboria*, *Hymenoscyphus*, *Ombrophila*, *Lachnum*, *Mollisia*, *Pyrenopeziza*, *Hyaloscypha*, *Calycina*, and *Calycellina*. However, some of these genera include also xerobiotic species (e. g., *Hymenoscyphus infarciens*, *Mollisia ligni*, *Hyaloscypha quercicola*). On the other hand, the heterogeneous genus *Claussenomyces* s.l. comprises mainly xero- (e. g., *C. jahnianus*, *C. atrovirens*) but also hygrobiotic species (e. g., *C. prasinulus*). Likewise, *Lachnellula* and *Capitotricha* mainly include xerobiotic taxa. Purely xerobiotic genera appear to be *Unguiculariopsis*, *Encoelia* in its old polyphyletic sense, *Tympanis*, and many others.

Desiccation tolerance within the *Orbiliomycetes*. Desiccation tolerance plays an extraordinary role within the *Orbiliomycetes* (see Tab. 5). In the present monograph, about 430 species (82 %) show a more or less pronounced desiccation tolerance of their entire apothecia, lasting about 1 month up to 4 years, ca. 94 species (18 %) were found to be more or less desiccation-sensitive, their tolerance lasting max. 1–2 weeks, and for about 10 % the available data were unsufficient.

Hygrobiotic (desiccation-sensitive) species are represented by about 65 % of *Hyalorbilia* spp., but only by ~ 18 % of *Orbilia* spp. Also the small genera *Pseudorbilia* and *Bryorbilia* belong in this group. Within *Orbilia* hygrobiotic taxa are almost exclusively found in section *Helicoon*, series *Orbilia*, series *Hyalinia*, series *Xanthoguttulatae*, and section *Arthrobotrys*. However, all these groups comprise also a number of xerobiotic taxa, e. g., *O. eucalypti*, *O. fabacearum*, *O. liliputiana* (series *Orbilia*); *O. pseudobrevistipitata*, *O. spirillospora* (series *Hyalinia*); *O. fusiformis*, *O. limoniformis* (section *Helicoon*); *O. anigozanthi*, *O. desertorum*, *O. fraxini*, *O. menageshae*, *O. rhamni* (section *Arthrobotrys*).

The cosmopolitan *O. xanthostigma* represents the most often collected hygrobiotic species of *Orbilia*. It grows on the upper and lateral side of old, mostly decorticated, water-soaked branches and logs lying on the forest floor, whereas its less frequent sibling *O. leucostigma* prefers the lower side. Further examples of frequently collected hygrobiotic species in the temperate humid northern hemisphere are *Hyalorbilia fagi*, *H. inflatula*, *H. polypori*, *Orbilia auricolor* (p.p.), *O. crenatomarginata*, *O. dryadum*, *O. epipora*, and *O. tremulae*. In the humid subtropics and tropics *H. arcuata*, *H. citrina*, and *H. japonica* are frequent along with *H. inflatula* and *O. xanthostigma*. All these species usually occur in shady forests away from surface water. Four further common hygrobiotic species of the temperate humid northern hemisphere (section *Helicoon*: *O. luteorubella*, *O. rosea*, *O. sarraziniana*; section *Arthrobotrys*: *O. rectispora*) occur on substrate close to the water level, being periodically flooded during abundant rainfalls or snowmelt by running (lentic) or stagnant (lotic) water of rivulets, ditches and marshes, or lakes. Mature apothecia are usually not found submerged by water, but a test showed that those of *O. luteorubella* completely survive several days underwater. The incidence of flooding is often recognizable on the collected substrate by aquatic organisms such as duckweed (*Lemna*), diatoms, eggs of *Cladocera*, filamentous green algae etc.

Hygrobiotic species of *Orbiliomycetes* have often comparatively large apothecia and, in contrast, small asci and ascospores. The apothecial colour is usually whitish to cream, pale yellowish or pale rosaceous-lilaceous. Only in a few species is it bright yellow, orange, or red. Also their mycelia in pure culture are generally more or less colourless. The exudate on the apothecia is often sparse, and only in slightly desiccation-tolerant species more abundant and sometimes distinctly yellowish (subtropical members of section *Helicoon*). The presence of VBs in the paraphyses is typical of many of them, and a few species are characterized by vacuolar pigments (e.g., *O. rubrovacuolata*).

Anamorphs of hygrobiotic species of section *Arthrobotrys* are characterized by long conidiophores, whereas in *Hyalorbilia* and in section *Helicoon* and series *Orbilia* they are comparatively short. The conidia are almost always unbranched (*Hyalorbilia*, sections *Arthrobotrys* and *Helicoon*), but in some species of series *Orbilia* they are branched. Many species of section *Arthrobotrys* are able to trap nematodes and other invertebrates, and since nematodes are rarely found on xeric substrate, it is logical that almost exclusively hygrobiotic species use them as prey.

Xerobiotic (desiccation-tolerant) species constitute with ~82% the majority of the large genus *Orbilia*, and with ~35% a smaller part of *Hyalorbilia*. They are also represented by the small, purely xerobiotic genera *Lilapila*, *Lecophagus*, and *Amphosoma* (see Tab. 56). Within *Orbilia*, many of the small to large subgroups are purely xerobiotic: sections *Lentiformes*, *Habrostictis*, *Aurantiorubrae* (with exception of series *Hyalinia* and *Xanthoguttulatae* p.p.), *Hemiorbilia*, and *Ovoideae*, and series *Microsomates* of section *Orbilia*.

There exists a distinct tendency of xerobiotic *Orbiliomycetes* and also other groups of discomycetes to have small apothecia and small excipular cells, but exceptions confirm the rule. In any case, xerobiotic species frequently possess rather large ascospores and/or larger asci which are often multispored, a phenomenon which seems to be related to spore dispersal in xeric habitats (see p. 152). The smaller-sized excipular cells might be a result of smaller apothecia, but certainly not a precondition for the ability to withstand desiccation. This is demonstrated by some desiccation-tolerant species with large apothecia and excipular cells, such as *O. anigozanthi* and *O. carpoboloides*. The fact that large asci are exclusively found in xerobiotic species further indicates that small cells are not required for a long-lasting desiccation tolerance.

Apothecial colour in xerobiotic species of *Orbiliomycetes* is very often orange or rose-red, rarely whitish, yellow, lilaceous, olivaceous-, or purplish-black (see Tab. 3), and also their mycelia in pure culture are usually pale orange to salmon-pink, exceptionally somewhat brownish. These pigments are thought to protect from ultraviolet radiation, but might also serve in attracting insects (see p. 105).

Anamorphs of desiccation-tolerant species possess more or less short conidiophores and often branched conidia (mainly trinacrium-, also dicranidion- and dwayaangam-like etc.), though many others produce unbranched conidia (vermispora-, brachyphoris-, and lecophagus-like). To the present knowledge, none of these anamorph-typified genera produce organs for trapping nematodes, with exception of *Lecophagus* which mainly preys on rotifers and tardigrades, i.e., invertebrates that are well-known for their high desiccation tolerance (see p. 238, 288).

High species diversity in semideserts. Although fungal growth depends on the presence of water, it was highly surprising to experience that there exist also a high number of different *Orbilia* species in dry regions. About 77 species are known at present to exclusively or occasionally occur in desertic, semiarid to arid areas of North America, and 94 species in those of Australia (Tab. 33). Almost all of them are newly described in the present study. The genus *Orbilia* is remarkable among the non-lichenized discomycetes in showing an adaptation to very long periods of drought similar as in lichenized fungi. This high number of xerobiotic species along with the total absence of hygrobionts in semiarid to arid regions indicates that the genus *Orbilia* is very successful under conditions of water shortage. Various other groups of non-lichenized discoid ascomycetes, mainly *Helotiales*, *Ostropomycetidae*, *Sordariomycetes*, and *Dothideomycetes*, occur in these areas of low humidity, though with a seemingly lower species diversity.

Neglect of xeric substrates. A current belief is that non-lichenized ascomycetes are unable to survive during long periods of drought and, therefore, predominantly occur on or close to the forest floor. A similar misjudgement regarding aquatic hyphomycetes occurring solely in streams and lakes was mentioned before. The resulting unbalanced collecting activities are responsible for an overrepresentation of hygrobiotic species in official herbaria, such as *Hyalorbilia inflatula*, *Orbilia auricolor*, *O. luteorubella*, *O. rosea*, *O. sarraziniana*, *O. tremulae*, and *O. xanthostigma*, whereas similarly common xerobiotic species are often only sparsely present (e.g., *O. vinosa*, *O. eucalypti*) or almost entirely absent (e.g., *O. aprilis*, *O. euonymi*).

Collecting xeric substrate was practised by some authors of the 19th and first half of 20th century, e.g., by Fuckel, Rehm, and Velenovský, who frequently reported desiccation-tolerant discomycetes on dry branches. Nevertheless, xeric substrate was and still is strongly neglected by many workers all over the world. As a result, most of the taxa, particularly inoperculate discomycetes, recognized until now have been collected on hygric substrate, and many ecological assessments almost completely neglect xerobiotic discomycetes.

The following examples illustrate this situation concerning orbiliaceous fungi. The five species of *Orbilia* described by Dennis's (1978) British Ascomycetes are all desiccation-intolerant. In Arnolds et al.'s (1984) checklist of the Netherlands macrofungi only two out of eight species are xerobionts. Spooner's (1987) work on Australasia (including Melanesia) presents six hygrobiotic orbiliaceous species (tentatively included is the type of *O. flexispora*) and two which are xerobiotic, viz. *Orbilia vinosa* and *O. ?carpoboloides* (type of *Habrostictis decipiens*). Korf (1992) listed in his preliminary treatment on Macaronesia besides eight ± hygrobiotic taxa only one (as *O. occulta*), which represents a mixture of two species which are clearly xerobiotic, *O. euphorbiae* and *O. pisciformis*. Only a few recent reports (Karasch et al. 2005, Priou 2005) draw attention to desiccation-tolerant *Orbiliomycetes*.

One of the reasons why the ecological group of xerobiotic discomycetes has so frequently been overlooked, even in temperate regions, is that collectors are usually not on expedition during rainy weather and, therefore, do not recognize dry shrunken apothecia on dead attached branches. Mycological forays are often in want of enough rain, so collectors are focused on fungi occurring at sparse localities where the substrate on the soil remained moist. The aesthetic appearance of fresh discomycetes in contrast to the less attractive dry apothecia is surely another reason to search mainly on the forest floor. Desiccation-tolerant fungi are indeed better recognized in the field after a rain, or during fog and dew in the morning, and it is another little-known fact that dry apothecia of some helotialean or ostropalean discomycetes on xeric substrate sometimes need to be submerged in water for quite a long time (about 5 min) in order to become completely hydrated and exposed.

A main reason for the lack of xerobiotic *Orbiliomycetes* in herbaria is that many species form scattered, minute apothecia ranging often only between 0.1 and 0.5 mm in the hydrated state. Often, they are strongly retracted or closed when dry and then almost invisible, even under a 20× hand lens. Therefore, promising substrate needs to be cautiously scanned in the laboratory under a dissecting microscope, preferably in the rehydrated state at a magnification of 10–20×, illuminated by a strong daylight lamp. In addition to the loss of essential characters in old herbarium material, all this explains why the great bulk of species diversity in *Orbiliomycetes* has so far been missed worldwide.

How long do cells remain viable in the dry state? The period of time a population remains viable in all of its parts, either when kept in the herbarium or during drought outside, depends on the aridity to which the species is adapted. In collections of xerobiotic species from temperate or montane-boreal regions, living asci can still be found some weeks or months after being sampled, and in species from deserts even after 1–3 or rarely 4 years. After 5 years deposit in the herbarium we have never found living asci, paraphyses or conidia of *Orbiliomycetes*. However, in *Orbilia austroobtusispora* and *O. pilifera* many cells of the ectal excipulum were still viable after 7.5 years. Ascospores often show the highest tolerance, the maximum observed in the present study being again *O. pilifera* with 7.5 years.

High desiccation tolerance of asci was also noted in the present study in some other classes of *Ascomycota*, e. g., in *Patellaria* '*andina*' (20–34 months), *Nitschkia broomeana* (17 months), or *Schizoxylon argentinum* (14 months). Members of *Lecanoromycetes*, however, were dead after about 9–12 months, either in all parts or at least regarding their asci, whenever examined during this study. Baral (1992: 378) gave a few examples of desiccation tolerance of asci and paraphyses, with a maximum of eight months in *Lecanora conizaeoides*, but at that time the high tolerance of many *Orbiliomycetes* was as yet unknown to him.

Ascospores of many ascomycetes are able to survive very long periods of drought, irrespective of being hyaline or brown. An extraordinary tolerance of hyaline ascospores was observed in *Patellaria atrata* and *P. andina*, being viable after 6–7.5 years, and also in *Sarcoscypha* spp. they survived 4–8 years (Baral ined.). Long time survival of spores was also addressed by Nguyen (2013), but his concern was to test basidiospores of ectomycorrhizal species deposited under moist condition in soil, resulting in viable spores after min. 6 years.

Ascospores and basal cells of the ectal and medullary excipulum are usually the most desiccation-tolerant parts of the teleomorph. But also the mycelium and the anamorph including their conidia may show a considerable desiccation tolerance. This is astonishing especially in those orbiliaceous species with staurosporous conidia which are currently brought in relationship with aquatic habitats. Such 'terrestrial Ingoldian' conidia are adapted to water transport on xeric substrate during rain and, therefore, need to be able to survive periods of drought. Likewise, conidia of *Lecophagus* exhibit a rather high desiccation tolerance because they are formed in habitats (e. g., periodically dry ponds, mossy soil, air-exposed bark) that are subjected to alternate drying and wetting. Trinacrium-like conidia in samples from mediterranean Europe were viable after 36 months (*O. hesperidea* H.B. 6468a, *O. pleiogambelii* H.B. 6482) or 32 months (*O. vinosa*, H.B. 9084a). Likewise, vermispora-like conidia from subtropical semiarid North America survived 30–32 months (*O. carnegieae*, H.B. 7764f), from tropical subhumid Australia 15 months (*O. euphorbiae*, H.B. 7295), and from mesomediterranean Europe 32 months (*O. aurantiorubra*, H.B. 9087a). As a rule, ascospores and conidia in specimens from ± temperate humid zones are less desiccation-tolerant. For example, ascospores and vermispora- or trinacrium-like conidia collected in Luxembourg were still viable after two (*O. aurantiorubra*, H.B. 6251) or three months (*O. vinosa*, H.B. 6201b), but possibly not after much longer periods.

In hygrobiotic species the propagules may often withstand desiccation for several weeks and even years although their apothecia usually die off within less than a day. Conidia survived 7–10 days (*O. xanthostigma*, *O. atlantis*), rarely 2–2.5 months (*O. auricolor*, *O. crenatomarginata*), ascospores about 2 (*O. xanthostigma*) or 3–4 weeks (*O. epipora*, *O. dryadum*), rarely 27 months (*O. crenatomarginata*) or over 3 years (*O. tremulae*). Also in semiaquatic species some ascospores were still viable after 2 weeks (*O. luteorubella*) or up to 10–21 months (*O. sarraziniana*).

Can viability of cells be maintained over a longer period of time? A few experiments were undertaken to maintain viability by periodical rehydration of pieces of xeric substrate with desiccation-tolerant apothecia. Two effects were observed: (1) immature apothecia may attain maturity when kept moist over a period of 1–2 weeks, and (2) vitality is maintained for a longer timespan compared to the continuous storage in the herbarium. In *O. velutina* and further ~10 associated *Orbilia* spp. from subtropical (semi)arid Australia we were thus able to study fully viable mature ascomata more than 4.5 years after sampling of the dry *Eucalyptus* branches (H.B. 9772). However, their ascertained tolerance without intermediate hydration was also in the range of 3.5 years. Under natural condition of rare periodical hydration one may assume that such highly desiccation-tolerant apothecia persist periods of more than 5 years from initial stages up to mature apothecia.

Ultrastructural or chemical basis of desiccation tolerance. When viewed under the light microscope, no morphological traits characterizing desiccation-tolerant cells can be recognized (Baral 1992: 379). Strong variance in cell wall thickness or vacuole size is observed in both tolerant and sensitive taxa. At an ultrastructural level, concentric bodies, which are globose structures of ~0.1–0.3 µm diam. with an electron-translucent core, were merely found in fungi being tolerant to periodical drying (mainly mycobionts of lichens, rarely non-lichenized fungi), and were thought to function against drought stress (Classen et al. 2000: 317).

Desiccation tolerance appears to originate from the chemical composition of the cytoplasm. The presence of polyols (polymeric alcohols) that serve in protecting macromolecules during desiccation might be important for the survival of cells. If the pool of polyols is depleted below a critical level, then recovery from desiccation is not possible (Bewley 1979: 203).

Terminology around dry fungal habitats. There is some controversy in terminology about the adaptation of fungi to water stress or the availability of water, which led to confusion in the past. Two very different adaptations occur. (1) As discussed above, a majority of fungi form their sporocarps in periodically dry microhabitats, involving complete desiccation of the protoplast of all its cells. This means that the fungus dries out when the conditions become dry and resumes growth when it gets rehydrated. The habitat of such fungi is characterized by an extreme variance in water supply, with the periods of drought often much longer than those of full hydration. (2) Various members of *Saccharomycetales* and *Eurotiales* show an osmotic adaptation, i. e., the fungus is able to grow on substrates (e. g., preserved food) with a high concentration of osmotically active solutes such as salts or sugars. In such habitats the water is constantly available over the time, but a higher concentration of solutes within the cells is necessary to facilitate absorption of water by the fungus.

We here adopt the term **desiccation-tolerant** (= poikilohydric or poikilohydrous, = poikiloxerophytic, = drought-tolerant, = xerobiotic) for case (1). It was introduced by Bewley (1979: 196) and is in current use for both fungi (especially lichens, see Kranner et al. 2008) and plants (especially bryophytes, see Oliver et al. 2005, Proctor et al. 2007, but also higher plants, see Alpert & Oliver 2002). For case (2) the term **xerotolerant** is in use for fungi being able to grow at a water activity below 0.94, which corresponds to an NaCl solution above 10 % (in comparison: seawater has 3–5 % NaCl) or a glycerol/saccharose solution above 30 %/45 %. The lowermost value at which such xerotolerant fungi can grow lies around 0.65–0.7 = ~ 30–40 % NaCl or ~ 60–65 % glycerol. The term **xerophilic** refers to species showing their optimum growth under such a high osmotic pressure (Brown 1978, Pitt 1975). These fungi are economically important as some of them cause huge risk of product loss. The term **drought-resistant** (drought-avoiding) is used for desiccation-sensitive perennial plants such as succulents, which are adapted to arid conditions by strong reduction of transpiration (evaporation) by a thick cuticle and a reduction of the assimilative surface, often coupled with water storage organs. Water storage is also a strategy of jelly fungi, but since they have no cuticle they can only somewhat postpone complete desiccation and will die off during long-lasting drought.

The term xerotolerant was misapplied by Baral & Marson (2001), Baral et al. (2009), and Unterseher et al. (2012) in the sense of desiccation tolerance. In the present study the term **xerobiotic** is used as an equivalent to desiccation-tolerant, although it has a wider meaning which includes drought-resistant plants (xerophytes). Desiccation tolerance is also circumscribed with the term **anhydrobiosis**, which is a subcategory of **cryptobiosis**. Cryptobiosis is defined as hidden life (suspended animation) caused by cessation of metabolism (see Clegg 2001), and also includes cryobiosis (frost), osmobiosis (high solute concentration), and anoxybiosis (lack of oxygen).

Phylogeny of desiccation tolerance. The formation of apothecia on attached, periodically dry substrate and the prerequisite for such an adaptation, the desiccation tolerance of the entire fungus, is probably an ancient, plesiomorphic characteristic within the *Orbiliomycetes* and has been retained in a vast number of taxa. This assumption results from another hyphothesis: ascus apical thickenings, which are exclusively found in desiccation-tolerant taxa, are probably plesiomorphic within the class (see p. 55).

Hygrobiotic species of *Helotiales* typically possess spores consistently oriented with their broader end towards the amyloid ascus apex, whereas many but not all xerobiotic *Helotiales* have lost the amyloid apical ring and sometimes show inverse orientation of the lowermost spores. The reason for this regression seems to be that spore discharge needs not be as efficient at levels of stronger air currents (see p. 63). Within the *Orbiliomycetes* the asci are inamyloid across the class, and inverse spore orientation occurs in most of the species, irrespective of their apothecia being desiccation-tolerant or not. It seems imaginable that those orbiliaceous species, which have switched to permanently moist habitats on the ground, were unable to newly invent amyloid wall structures. Perhaps therefore, they have maintained the peculiarity to form a compact spore cluster in which inverse orientation is not a disadvantage regarding effective ejection.

Geographic distribution

Considering the ambiguous taxa concepts in earlier times and the frequency of detecting novelties during our research, the knowledge about geographic distribution and climatic preferences of *Orbiliomycetes* is still highly fragmentary. The class as a whole is undoubtedly ubiquitary, being omnipresent in almost every climatic region of the world. *Orbiliomycetes* obviously play a dominant role on xeric substrate, with about 430 xerobiotic species known at present, but is also well represented on mesic and hygric substrate, especially when including the many nematode-destroying species without a known teleomorph. Truly aquatic members are unknown, however, while a few taxa are semiaquatic, i. e., temporarily flooded.

We have supplied distribution maps of most of those species with at least about 5–10 records. A high number of species were only rarely recorded, which might suggest that they are threatened or almost extinct. However, their seemingly rare occurrence is to the most part due to lack of exploration. The high number of existing species, the difficulty in detecting them, and their manifold taxonomic problems make research on distribution very time-consuming. Hence, most of the rarely reported taxa undoubtedly display a much wider occurrence and higher frequency than the present data suggests. Although suitable biotopes are being destroyed wherever humans settle or industry is established, it appears difficult with such minute organisms to demonstrate a real threat for any of the species.

Among the larger deserts of the world, only those of Australia and North America were systematically explored in the present study. In addition, detailed research was done by L. Quijada on semi- to hyperarid low- and highlands of the Canary Islands and by R. Tena and J.P. Priou and others on semiarid low- and highlands of Spain. Collections from desertic regions of Middle and South America, Asia, and mainland Africa were only occasionally available, but their similar vegetation types strongly suggest that they house a comparably high species diversity of *Orbiliomycetes*. Comprehensive studies have been done by us and others on the semihumid, (sub)mediterranean belt of southern Europe and southwestern Australia. Among the (sub)tropical ± humid regions mainly those from southern China and to a lesser extent those from Middle America have been explored by different workers.

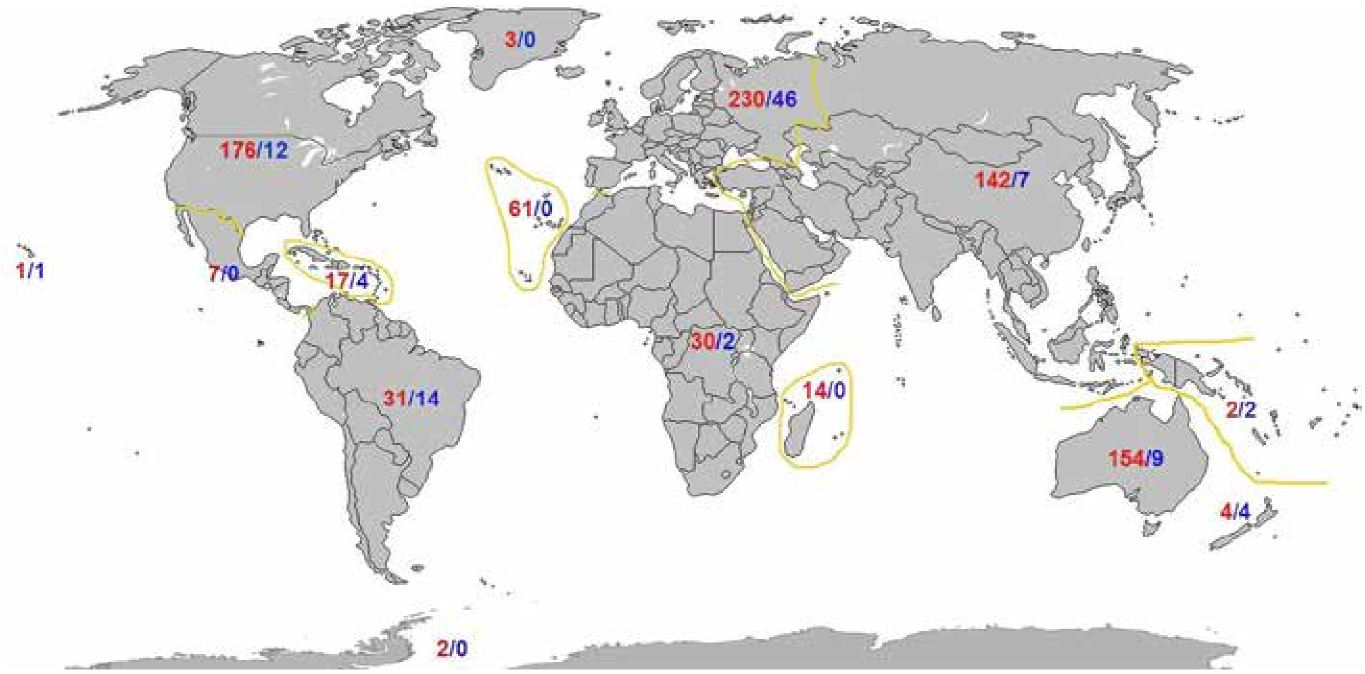

Figure 127: Approximate number of species with a known teleomorph accepted in this monograph (in red), in comparison to species recognized prior to 1989 (in blue), recorded in the different continents and archipelagos. Included are those species for which an apothecial state is known, but also a few so far purely anamorphic taxa which are treated with collection data in this study (see also p. 3, Fungal material and Appendix 2). The red numbers include also our provisional and unnamed taxa. See also Fig. 1.

Distribution and diversity in different continents and climatic regions. – **Local species diversity**. Most local treatments which include members of *Orbiliomycetes* contain rather low numbers of orbiliaceous species with known teleomorph. These numbers are generally far below of what can be expected to occur in any region with a minimum diversity of phanerogams. Vital characters have often not been used for identification in these works, therefore, some of the older reports include species which do not even belong to the class. Besides paucity of collecting, the main reason for the seemingly low species diversity is the neglect of semihumid to arid plant communities but also of xeric substrate in more or less humid regions.

In the following, the general distribution of *Orbiliomycetes* and the investigation rate of the different continents and countries is briefly treated. These considerations almost exclusively refer to collections of the teleomorph. Orbiliaceous anamorphs have variously been isolated and comprise numerous species without a know teleomorph, mainly from North America (e. g., Drechsler 1934–1950; Barron 1979–1991), Poland (Jarowaja 1968–1971), Russia (e. g., Mekhtieva 1967–1979; Soprunov 1951–1958), Japan (e. g., Matsushima 1975–2005), China (Yu et al. 2014), and Australia (e. g., Park et al. 2002).

Distribution patterns. A number of species were found to be cosmopolitan, i. e., they are known from all continents of the world. Examples are *Hyalorbilia inflatula* s.l., *Orbilia carpoboloides*, *O. corculispora*, *O. delphinus*, *O. eucalypti* s.l., *O. euonymi*, *O. lentiformis* s.l., *O. luteorubella*, *O. multiserpens*, or the *xanthostigma-leucostigma* complex. Many species are so far exclusively known from one continent, for instance, the European *O. aprilis*, *O. quaestiformis*, and *O. polyspora*. However, very similar taxa of these three species occur in Australia: *O. nothoaprilis*, *O. pleioquaestiformis* and *O. plurililacina*, respectively. But this situation may change when new collections become available. The very common *O. aprilis* was recently discovered in Northern America, but molecular data gained from one of the two samples indicates a cryptic sibling. *O. corculispora* was first detected by us in Australia, but later it was found to be rather widespread in mediterranean and atlantic Europe and to occur also in southern Africa and eastern Asia. However, their rDNA shows pronounced deviations among Australia, Asia, and Europe.

To the present knowledge, about 100 species have exclusively been recorded in Australia. However, to speak here of endemism would be premature, because many of them were rarely found and some have unclarified siblings in other continents. Among the six known species with black apothecia, three (*Amphosoma atroolivaceum*, *Orbilia patellarioides*, *O. olivacea*) were so far only recorded in Europe and the other three (*O. pileosoma*, *O. atrolentiformis*, *O. purshiae*) only in the Rocky Mountains and Colorado Plateau of North America, so one may assume that they are restricted to a continent. The genus *Lilapila* seems to be endemic to mountainous regions of central and southern Europe, but might well also occur in similar conifer forests of Northern America and Asia, being easily overlooked due to its dark apothecia growing on blackened resin.

Species diversity in different climatic zones. The total number of orbiliaceous species recorded during our research as well as the approximate proportion between xero- and hygrobionts differ among the different climatic zones. Tab. 33 provides an overview of the species diversity in four more intensely investigated regions of the world and also indicates the lack of collections in some of their climatic zones.

Apart from the European nemoral to boreal humid zone with around 170 species recognized at present, a surprisingly high species number was observed in desertic, semiarid to arid wood- and shrublands of the world, e. g., about 94 in Australia and 77 in North America. Due to the low annual precipitation and short periods of moisture, almost all species from desertic areas belong in the category xerobionts. However, the relatively low number of collections, ranging in comparison with the species numbers at 2.5 : 1 in North America and at 2.2 : 1 in Australia,

Table 33. Approximate number of xerobiotic and hygrobiotic species of *Orbiliomycetes* (before and after slash) and total number of records in 4 thoroughly explored regions in relation to 7 main climatic zones, * = zone requiring much more sampling, – = region lacking this climatic zone. Remarkable is the low number of known species in the (sub)tropical humid zone. Note the absence of hygrobiotic species in (semi)arid zones. Species numbers for North America and Australia are most likely far too low, particularly in semihumid to arid zones, when considering the roughly 10-fold higher record numbers in Europe.

Climatic zone	Europe		Macaronesia		North America		Australia	
	xerobiotic / hygrobiotic	records	xerobiotic / hygrobiotic	records	xerobiotic / hygrobiotic	records	xerobiotic / hygrobiotic	records
temperate to boreal humid	113/58	4546	–	–	68/25	246	6/8	15*
temperate subhumid	7/0	9*	–	–	59/0	132	–	–
(sub)mediterranean ± semihumid	70/15	663	25/2	47	1/0	2*	55/0	145
temperate semiarid to arid	–	–	–	–	53/0	125	–	–
(sub)tropical semiarid to arid	18/0	30*	23/0	88	41/0	94	94/0	208
(sub)tropical subhumid (savannah)	–	–	2/8	23	3/2	5*	37/0	55*
(sub)tropical humid	–	–	3/11	25	9/9	27*	15/8	28*

illustrate our experience that about every second or third collected population belongs to new species. In comparison to the much more intensely investigated European continent with a relation of over 26 : 1 for the nemoral to boreal humid zone, the actual diversity in desertic areas of North America and Australia is most likely much higher.

Also in semihumid (summer-dry), (sub)mediterranean, more or less subtropical sclerophyllous wood- and shrublands the number of xerobiotic taxa by far exceeds that of the hygrobionts which can only be found during the rainy winter season. In southern Europe about 70 xero- and 15 hygrobiotic species were recorded, and in southwestern Australia 55 xero- but no hygrobiotic species, no doubt because hygric substrate was neglected. The relation between collected populations and species lies in semihumid southern Europe at 7.8 : 1, in Australia at 2.5 : 1, and in Macaronesia at 1.8 : 1.

In savannah-like (winter-dry), monsoon-influenced, (sub) tropical subhumid regions the xerobionts play a considerable role. Hygrobionts have rarely been encountered because substrate on the ground was ignored in this field work. The species number in northern Australia was with 37 xeriobionts and no hygrobionts comparatively low, perhaps due to activity of termites, but the only 1.5× higher number of collected populations suggests a higher diversity in these zones.

Humid (winter-dry), monsoon-influenced evergreen broad-leaved forests in the subtropics display a high diversity of hygrobionts, but xeric substrate was largely neglected by collectors. Such forests have been intensely explored in the southeast of Asia (~65 hygrobionts and ~15 xerobionts), and to a much lesser extent in a regional area in northeastern Africa (subtropical afromontane Ethiopian highlands, nine spp., probably all slightly xerobiotic). Species diversity seems thus rather high in the humid subtropics. The actually existing species number is probably much above the current level, especially regarding xerobionts which were only occasionally encountered. It appears also that drought tolerance in this environment is comparatively low, often lasting only a few weeks.

In tropical rainforests the worldwide number of orbiliaceous species known at present ranges around 60, about 18 of which being xerobionts. The relation between collected populations and species lies here at 1.2–2.7 : 1. Most of the records come from regions with a wet and dry season. Yet, it seems probable that rainforests with their high plant diversity house many more species. Tropical humid areas are not easy to explore, especially with respect to vital taxonomy, therefore, many of the species from there are only known in the dead state. Because of the paucity of collectors in the humid tropics, only 23 species are so far known from northeastern Australia (~15 xerobiotic), 20 from America (~3 xerobiotic), and 14 from Africa (12 from Comoros, 2 from Senegal; ~5 xerobiotic). Orbiliaceous xerobionts might occur in the uppermost, periodically dry canopy, which is so far completely unexplored in regard to these fungi. Xerobiotic perennial basidiomycetes are frequent in the humid tropics on hanging branches and climbers, especially on open sites being exposed to sudden changes of humidity and temperature (Nunez 1996).

The very low species diversity observed in other ± humid, temperate to alpine-subarctic regions of the world is undoubtedly due to insufficient sampling. Up to now, only 6 xero- and 8 hygrobionts are known from cold- to warm-temperate southeastern Australia, 13 xerobionts from continental highlands of western Mongolia, 3 xerobionts from the subarctic tundra of Greenland (*O. canadensis*, *O. eucalypti*, *O. flagellispora*), and 11 xero- and 2 hygrobionts from (hemi) boreal Canada and Alaska. Much better explored is the humid zone of the Rocky Mountains and Colorado Plateau in the United States with 25 xerobionts, and that of Scandinavia and European Russia with about 22 xero- and 12 hygrobionts. Particularly rich is the knowledge about the orotemperate to orosubmediterranean Alps with at present about 56 xero- and 12 hygrobionts. The lack of hygrobionts in some of these regions is due to the neglect of hygric substrate.

Restriction to a climatic zone. Each climatic zone of a continent or geographical area exhibits its own species composition, because a majority of species show a more or less strong adaptation to climatic conditions, and because of the geographical isolation. For instance, more or less humid, cold-temperate to boreal forests in the region of the Rocky Mountains and Colorado Plateau strongly differ in their species diversity not only from semiarid shrublands at lower altitude in the same region, but also from cold-temperate to subtropical humid forests of eastern North America. As an example, *Orbilia spermoides* was so far only found in montane to subalpine conifer forests in mountain ranges of the Colorado Plateau and Chihuahuan Desert and in an orosubmediterranean conifer forest of the Southern French Alps, whereas the closely related *O. occulta* is only known at present from the Appalachian Mountains and its lowlands. Likewise, a number of species were only found in atlantic or sometimes also mediterranean areas of Europe (e.g., *Orbilia atlantis*, *O. rubrovacuolata*, *O. corculispora*, *Hyalorbilia ulicicola*), though some of them also occur in Macaronesia, Asia, and/or Australia.

Some species exhibit a rather wide ecological amplitude by occurring across very different climatic zones. For example, the distribution area of *O. vinosa* covers within Europe (oro) temperate, planar to subalpine and boreal, humid, continental to atlantic but also sub- and eumediterranean climates, and also *O. euonymi* shows a comparable lack of climatic preferences. A similar ubiquitous distribution is shown by *O. aprilis*, but this species appears to avoid both subalpine and boreal zones. Many further species appear to be similarly cosmopolitan, e. g., *O. flavida*, *O. trapeziformis*, and *O. obtusispora*.

Some species are more or less adapted to orotemperate or orosubmediterranean zones of the Alps, Carpathians, and mountain ranges of southern Europe. Most of them are confined to xeric coniferous wood and bark or particularly to resinous wounds, e. g., *Lilapila* spp. were observed at an altitude of 800–1820 m (45 ×), *O. patellarioides* at 860–1830 m (17 ×), *O. sphaerospora* at 890–1615 m (11 ×), and *Amphosoma resinicola* at 925–1780 m (10 ×). The latter was also observed in the boreal Rocky Mountains, whereas the distribution area of the closely related *A. atroolivaceum* extends down to submontane regions of central Europe (350–1780 m, 43 ×). A high amplitude similar to the latter species is observed in *O. flagellispora* (40 ×) which was found at colline up to subalpine, preferably orotemperate and orosubmediterranean, but also boreal areas of Europe, but single collections in arctic Greenland (250 m), boreal Canadian Rocky Mountains (1165 m), and subtropical semiarid Mexico (350 m, type) indicate a very wide distribution. *O. alpigena* (16 ×) on gymnosperm wood is so far only known from montane to subalpine central and southern Europe at 870–1760 m, whereas *O. montigena* (14 ×) on angiosperm wood shows a wider amplitude which ranges from colline to subalpine central and southern Europe (130–1585 m) but also hemiboreal northeastern Europe (150 m).

Semihumid, (sub)mediterranean areas with mild humid winters and hot and dry summers house a number of species which are more or less adapted to this climate. Some of them were so far only detected within Europe, e. g., *O. polyspora* and *O. myriosphaera*. Others were also recorded from northern Africa, Macaronesia, North America, or Australia (e. g., *O. bicknellensis*, *O. gambelii*, *O. pleiogambelii*, *O. hesperidea*, *O. microserpens*, *O. multiurosperma*, *O. pleiogambelii*, *O. serpentina*). A disjunct occurrence was noted for the rare *O. cercidicola*, which was repeatedly collected on *Cercis* at the type locality in the submediterranean maquis of southern France, but later also on *Ulmus* in the warm-continental subhumid Volga floodplain forests in southwestern Russia.

Three cosmopolitan species merit special attention. *O eucalypti* s.l. occurs in all ecozones of Europe, from thermomediterranean to subalpine and oroboreal, and from atlantic to subcontinental (the rareness in continental temperate zones is probably due to lack of data). Also in Macaronesia it occurs across all climatic zones. In Australia the species was frequently recorded by us in the subtropical semihumid southwest, whereas in North America it came to our attention only by a few samples from the cold-temperate humid Rocky Mountains and from the mild-maritime semihumid (types of *Dicranidion fragile* and *O. eucalypti*) and subtropical semiarid pacific west of California and Mexico. Also *O. corculispora* was found all around the globe, being recorded in western and eastern Australia, southeastern Asia, southeastern Africa, Macaronesia, and also in southern and western Europe. However, it shows a preference for an oceanic climate and extends from subtropical semiarid and semihumid (mediterranean) to mesotemperate humid. Likewise, the cosmopolitan *xanthostigma-leucostigma* complex occurs from tropical to subalpine-boreal zones all over the world, and its absence in semiarid to arid areas is due to a low tolerance of its apothecia to drought.

Rareness and endangerment, **suitable biotopes**. Natural plant communities with a high diversity of phanerogams and a low amount of human impact provide the basis for a rich diversity of *Orbiliomycetes* and other ascomycetes. Profitable biotopes lack severe forestry intervention during 20–30 years as a minimum, in order to preserve trees and shrubs at all age classes and with plenty of dead branches in all stages of decay, either attached or on the ground. Usually, fungal diversity is highest when a tract of forest land in a humid region remained untouched over some decades. In more arid regions this minimum period of time probably lasts longer. Such natural wilderness, even if small-sized, may be uncomfortable to enter because of thorn thickets requiring protective clothes.

Artificial plant communities in parks, hedgerows, botanical and private gardens etc. may also provide interesting collection sites. However, the current practice of gardeners and arborists to remove all dead parts of a plant is fatal to all saprobic fungi on both xeric and hygric substrate. Current nature protection activities preserve the agricultural landscape by regularly removing bushes and shrubs or cutting reed marshes, thereby completely eliminating the natural circuit of these plants that involves the formation of dead plant substrate. These activities aim at the protection of flowering herbs which represent the basis for insects and birds. Although open vegetation provides a biotope for many organisms, species diversity in a wilderness must not be lower but consists of a very different community of usually less spectacular species with a more hidden lifestyle.

Orbiliomycetes are threatened especially in poor countries with a dry climate, in which inhabitants depend on the sparsely occurring fire wood. A strongly predominant agriculture in humid lowlands often leaves only small remnants of forest as refugia for the native flora and funga and, therefore, threatens many of the more rare and adapted species. But also natural fires often destroy large areas of xeric vegetation in subhumid to arid regions, and the recolonization of such areas may take many decades until enough dead plant parts become available. Man-made fires, the conversion to farmland, and the increase of industry, human population, and tourism reduce the number of high quality biotopes.

Out of about 470 species treated in this monograph (by disregarding provisional species without a valid name), 118 were recorded only once, 63 twice, 48 three times, and only 126 more than ten times. It appears, therefore, that a high proportion of these 470 taxa are comparatively rare. However, a majority of the rarely collected taxa are newly described here based on recent collections, and their rareness might be due to a geographical restriction to a rarely visited area rather than a true rareness. Some old taxa reported about 80–200 years ago might be extinct, as they have never been recollected, but any conclusion about species extinction of such minute fungi remains hypothetical.

The following 15 species published before 1989 are only known with certainty from the type collection (year of collection in brackets): *Hyalorbilia anonyma* (1892), *H. andina* (1892), *Liladisca acicola* (~ 1866), *Orbilia acuum* (1927), *O.*

coccinella (~1825), *O. cookei* (1873), *O. cyparissias* (1933), *O. disseminata* (1892), *O. flexispora* (1964), *O. minutispora* (1924), *O. neglecta* (1897), *O. regalis* (~1878), *O. rubella* var. *minor* ≡ *O. rehmii* (1877–78), *O. saccharifera* (~1875), and *O. terrestris* (1978). *O. coccinella* might be restricted to the north of Scandinavia and, possibly therefore, it has been overlooked in later years. *O. terrestris* occurred in the Pamir Mountains and *O. neglecta* in Java, regions which are rarely visited by collectors. Five species derive from cold-temperate humid central Europe and three from warm-temperate humid eastern North America, therefore, they should not have escaped notice in recent years. But collectors of small ascomycetes are few, particularly regarding xeric substrate, on which at least four of them grew.

Geographic and climatic preferences, examples of plant communities

In the following, a historical review is given for each continent on the collecting activities in *Orbiliomycetes*, often with a discussion of the different climates and vegetation types in which they were found. Best explored are Europe and Macaronesia, in which emphasis has equally been placed on hygro- and xerobionts, followed by North America and Australia, where hygrobionts appear to be undercollected. Intensely explored is also eastern Asia, though mainly for hygrobionts. The mentioned species numbers for each country or region neglect most of the unillustrated or otherwise unverified literature reports as well as unexamined collections in official herbaria. These numbers include only a few of the purely anamorphic or DNA isolates because these were not the subject of the present study and would have been difficult to estimate for each region (see also Fig. 127 & Appendix 2).

1. Europe

By far the highest number of around 5300 collections were obtained in Europe, which can be considered as the best explored continent. This high number permits us to analyse the species diversity in the different climatic zones of the phytogeographically very diverse continent. Despite an approximately 3-fold overrepresentation of collections on xeric substrates, it can be assumed that the many diversely focused collectors provided a more or less balanced spectrum on species richness for each climatic zone.

In any case, species diversity was best explored in regions with a humid climate. Here the relation between collected populations and species ranges at 26.5 : 1, which illustrates the high rate of investigation in this continent. Apparently therefore, the number of recorded species of presently 171 is much higher than in the European mediterranean belt with 85 spp. and a relation of 7.8 : 1. As a consequence of the higher humidity, the number of xero- and hygrobiotic species lies in the humid areas in the relation of 2 : 1, compared to 4.7 : 1 in the mediterranean belt (Tab. 33).

A total of about 230 species have been recorded within Europe up to now (Fig. 127). To the most frequently recorded species (min. ~70 collections) belong the hygrobionts *H. inflatula*, *O. auricolor*, *O. crenatomarginata*, *O. rosea*, *O. sarraziniana*, and *O. xanthostigma* and the xerobionts *H. subfusispora*, *O. aprilis*, *O. aristata*, *O. aurantiorubra*, *O. carpoboloides*, *O. comma*, *O. eucalypti*, *O. euonymi*, *O. quaestiformis*, *O. trapeziformis*, *O. xanthoguttulata*, and *O. vinosa*.

When comparing the four main thermotypes (eumediterranean, submediterranean, temperate, boreal) and their subzones, the observed species numbers are rather similar in the four well-explored regions of Scandinavia, Germany/Switzerland/Austria, France, and Spain/Portugal, which all show a high variance of climatic zones. Differences between these four regions regarding a given thermotype might originate from insufficient sampling. In any case, the present data suggest that species numbers in the Iberian peninsula decrease from eumediterranean to temperate, but tend to higher numbers at higher altitudes, whereas orotemperate regions in central Europe showed less species than temperate regions, perhaps due to unbalanced sampling.

Most of the frequently collected species were found across more or less all thermotypes of Europe and that from atlantic to continental regions. Others showed a more or less pronounced restriction to a climatic zone. Three species are adapted to the mild, oceanic western part of Europe: *O. rubrovacuolata* is a (sub)atlantic species that occurs within Europe across four different thermotypes (St, Mt, Tt, Msm, see p. 15, Abbreviations). It is so far missing in the European eumediterranean belt, but was found in the mesomediterranean (Mt) zone of Macaronesia. Similarly, *O. atlantis* and *H. ulicicola* occur in three different thermotypes (St, Mt, Msm) in atlantic western Europe, but whereas *O. atlantis* is so far known from England and France, *H. ulicicola* was found in France and Spain and also occurs in the thermomediterranean (Tt) north and eumediterranean (Tm) southeast of Spain.

Some species showed a more or less strong adaptation to a thermotype. E. g., the meso- (Mt) to supratemperate (St) zone was preferred by *O. fraxini*, *O. luteorubella* (also Hb and Tb), and *O. orientalis* the orotemperate (Ot) and orosubmediterranean (Osm) zone by *O. arachnovinosa*, *O. subtrapeziformis*, and *O. delphinus* (the former two also oroboreal), and the eumediterranean zone by *O. desertorum* (Tm), *O. bicknellensis* (Tm, Mm), *O. rhamni* (Mm), whereas other also occur in more or less cooler regions: *O. microserpens* (Tm to Sm, also Ssm), *O. polyspora* (Mm, Sm, Msm, Ssm, rarely Osm), *O. pilifera* (Mm, Sm, Msm, also Ssm, Mt and St).

1a. Scandinavia, Balticum and northwestern Russia: Previous orbiliaceous reports from Scandinavia include those of Fries (1822: 146, 1849: 357) for southern Sweden, Sommerfelt (1826) for northern Norway, and Karsten (1861: 36–39, 1869: 106, 173–176) and Nylander (1869: 54–58) for southern Finland and northwestern Russia, with 6 hygrobiotic (*H. inflatula*, *O. epipora*, *O. leucostigma*, *O. luteorubella*, *O. tremulae*, *O. xanthostigma*) and 3 xerobiotic species (*O. coccinella*, *O. eucalypti*, *O. vinosa*) (names according to present reidentification). They mainly derive from the boreal zone, but probably also from the hemiboreal zone where Fries lived. Huhtinen (1992) described for a hemiboreal site in Finland *O. phragmotricha* (as *Orbiliaster paradoxus*).

This low number of ten species stands in contrast to unpublished sampling: particularly during three excursions to supratemperate Denmark and southern Sweden (2005–2007) and one to boreal Lapland (2010), various collectors (H.B., T. Læssøe, J.G.B. Nielsen, B. Spooner, W. Jaklitsch, P. Perz and others) strongly increased this number. Further recordings were made by O.E. Eriksson (Umeå, 2007, 2014), T. Dahl (Arendal,

Figure 128: **left**: Oroboreal humid *Betula pubescens* woodland with *Juniperus communis* and *Cornus suecica* at timberline, 870 m, Satsfjället, Saxnäs, Lapland, Sweden, 24.VII.2010, phot. H.O. Baral; attached branches of *B. pubescens* (*Orbilia eucalypti*, *O. arachnovinosa*, H.B. 9360) and *J. communis* (*O. cylindrospora*, H.B. 9398), fallen branches of *B. pubescens* (*Hyalorbilia polypori*, *H. inflatula*, *O. rosea*, H.B. 9361, 9362, 9410); **right**: ibid., *Picea abies* and *Betula pubescens* forest, 475–500 m, Lillälven waterfall, Bjurälven, 27.VII.2010, phot. H.O. Baral; attached branch of *B. pubescens* (*O. arachnovinosa*, H.B. 9375), fallen branches of *B. pubescens* (*Hyalorbilia inflatula*, *O. tremulae*, H.B. 9379).

2008–2012), S. Helleman (Norway, 2011–2012), T. Læssøe (Denmark, 2001, 2008–2020), G. Marson (Oslo, 2002), M. Pennanen (North Karelia, 2010–2013), K. Põldmaa (Finland, 1995), U. Söderholm (Tampere, 1994–1998) and others. From the Balticum, K. Põldmaa collected mainly on polypores between 1993–1997 (6 *Hyalorbilia* spp.). Samples from western Russia are especially those collected and studied by E. Popov between 2002–2012 (4 *Hyalorbilia* spp., 14 *Orbilia* spp.). A few older samples of hygrobionts from the Ural mountain range were reexamined here: from the oroboreal Ob river delta region east of the northern Ural (M. Saar and M. Murdvee, 1977, *O. cardui*, *O. sarraziniana*, *O. rosea*, *H. ?japonica*), the supraboreal middle Ural (A. Raitviir, 1973, *O. tremulae*, *O. leuco-/xanthostigma* s.l.), and the hemiboreal southern Ural (A. Raitviir, 1974, *O. crenatomarginata*, *O. sarraziniana*, *O. xanthostigma*).

A total of 48 species are now known from Scandinavia, about 60% of them being xerobiotic. The current number for Sweden is 29 (see Appendix 2). Because many of the taxa were undescribed, Eriksson's (2009: 117, 209) checklist contains only 12 species. When including, besides Scandinavia, the hemiboreal Balticum and boreal to supratemperate regions of northwestern Russia, the current species number is about 63. This high number is mainly due to numerous Russian collections of predominantly xerobiotic taxa, particularly by E. Popov. In Estonia only 6 *Hyalorbilia* spp. and 3 *Orbilia* spp. are known, almost all of them hygrobionts. The 7 *Orbilia* spp. from Latvia and Lithuania known to us are all but one molecular isolates from soil or coniferous wood (Menkis et al. 2006, 2012, 2015).

Within the boreal zone of Europe including the Ural mountain region, 12 hygro- and 22 xerobiotic taxa are known up to now. Among the four subdivisions of the boreal zone, only one species from the cryoroboreal subzone in Lapland came to our attention, the doubtful *O. inconspicua* on *Dryas* leaves, which also occurs in the cryorotemperate Alps and represents a mixture of two distantly related species. From the oroboreal subzone 15 species have been collected, all on woody substrates, mainly of *Betula* and *Salix*, with 9 hygrobionts (*H. inflatula*, *H. ?japonica*, *H. polypori*, *O. cardui*, *O. crenatomarginata*, *O. rosea*, *O. sarraziniana*, *O. tremulae*, *O. xanthostigma*) and 7 xerobionts (*O. arachnovinosa*, *O. aristata*, *O. canadensis*, *O. coccinella*, *O. cylindrospora*, *O. eucalypti*, *O. subtrapeziformis*). In the warmer supraboreal subzone only 3 hygro- and 3 xerobionts were found (including *O. flagellispora*, *O. tremulae*, and *O. vinosa*), which is probably a result of unbalanced collecting. In the thermoboreal subzone several species appeared that were absent in the cooler regions: a total of 7 hygro- (including *H. berberidis*, *O. auricolor*, *O. epipora*, and *O. luteorubella*) and 15 xerobionts were recorded (including *H. fusispora*, *H. juliae*, *O. aprilis*, *O. breviaristata*, *O. carpoboloides*, *O. comma*, *O. ebuli*, *O. filiformis*, *O. phragmotricha*, *O. plurivacuolata*, *O. quaestiformis*, *O. vitalbae*, and *O. xanthoguttulata*.).

In the hemiboreal zone, in comparison, 18 hygrobionts and 23 xerobionts are known at present. Some of these 41 species were absent in the boreal zone: among the hygrobionts these are, e.g. *H. fagi*, *H. polypori*, *H. tortuosa*, *O. crenatomarginata*, *O. mammillata*, and *O. oxyspora*, and among the xerobionts, e.g., *O. aurantiorubra*, *O. montigena*, *O. rubella*, and *O. siculispora*.

O. coccinella can be considered as a rarity of the boreal zone, being only known from the type collection in oroboreal Nordland. A restriction to the boreal zone can be assumed for *O. canadensis*, which was found in oroboreal Norway, subarctic Greenland, and boreal Canada. Various European species appear to prefer an orotemperate (altimontane to subalpine) and particularly orosubmediterranean climate, but only three

Figure 129: **left**: Supratemperate (cold-temperate) humid, colline *Aceri-Fraxinetum* with *Fagus*, *Alnus*, *Fraxinus*, *Acer*, *Allium ursinum*, *Anemone nemorosa* etc. on Knollenmergel, 410 m, Tiefenbach, Tübingen-Pfrondorf, Germany, collected between 1988–2012, phot. 27.V.2006, H.O. Baral; fallen branches and logs of *Acer pseudoplatanus* (*Orbilia leucostigma* H.B. 3543), *Alnus glutinosa* (*O. xanthostigma* H.B. 6745), *Tilia cordata* (*Hyalorbilia inflatula*, *O. eucalypti*, *O. crenatomarginata*, *O. dryadum*, H.B. 4726, 4727, 4738, 4894) and *Fagus sylvatica* (*O. sarraziniana*, H.B. 7000, 9707); **right**: orotemperate humid, subalpine spruce forest, 1550 m, Glaubenbielen, view to Alpoglerberg, Obwalden, Switzerland, 17.VIII.2006, phot. of them were so far encountered in the boreal zone as well: *O. arachnovinosa*, *O. cylindrospora*, and *O. subtrapeziformis*.

1b. **Great Britain and Ireland**: Berkeley (1860: 370), Berkeley & Broome (1865, 1866, 1873), and Cooke (1871) recognized for Great Britain a total of 6 orbiliaceous species (all as *Peziza*): *H. erythrostigma*, *O. auricolor*, *O. carpoboloides* (as *P. lasia*), *O. leucostigma*, *O. vinosa*, and *O. xanthostigma*. Phillips (1887: 327–335, as *Calloria*) and Massee (1895: 143–149) raised the number to 10 by adding *H. inflatula*, *O. coccinella*, *O. luteorubella*, and *O. rubella*. Yet, the identity of some of them remains doubtful.

Nine orbiliaceous species were reported by Dennis (1978: 187, 196), 16 by Clark (1980b), 14 by Ellis & Ellis (1985: 11, 248, 267), and 21 in the checklist of British ascomycetes (Cannon et al. 1985: 97, 104, 168) when counting those taxa which we consider orbiliaceous. Included are *O. comma* described by Graddon (1977) and *O. dryadum* (as *O.* cf. *acuum*) reported by Kirk & Spooner (1984: 573). Webster et al. (1998) added a further species, *O. oxyspora* (as *O. fimicoloides*). Descals isolated *Anguillospora rosea* (= *O. rosea*) between 1974–1981 in England, Wales and Scotland.

At present (2019), 48 orbiliaceous species are known from the Britannic islands, 11 in *Hyalorbilia* and 37 in *Orbilia*. About 30 of them grew on ± xeric substrate. A majority were recorded in England, but only 4 species in Scotland and 3 in Ireland. Seven species of *Hyalorbilia* and 18 of *Orbilia* were gathered by E. Batten and S. Francis between 2001–2006 in the coastal lowlands of Suffolk or rarely Norfolk in eastern England, a region with an oceanic humid climate which ranges at the border between supra- and mesotemperate. Rarities or unique collections from there were *H. rotifera*, *H. ulmi*, and *O. battenii*. Remarkable was the repeated detection of the mediterranean *O. corculispora* at supratemperate sites, though often with ± subglobose spores and only rarely with the typical curved ones. Further records from England were made between 2011–2019 by N. Aplin (South East England), J.P. Priou (Wales), B. Thompson (mainly West Midlands), C. Yeates (Yorkshire) and many others, and by one of us (H.B.) during two forays in South Yorkshire (2011) and Cambridgeshire (2017). The mild climate of England supports occurrence of atlantic species such as *O. atlantis* and *O. rubrovacuolata*. The most frequently recorded species were *O. eucalypti* and the previously overlooked *O. aprilis*. One of the rare records was *H. lunata* from meso- and supratemperate sites, though its core area appears to lie in the mediterranean laurel forest of Macaronesia.

1c. **Germany**: Fuckel (1870, 1871, 1874) reported 5 orbiliaceous species for Hessen: *Liladisca acicola* (as *Pezicula*), *O. carpoboloides* (as *Habrostictis rubra*), *O. sarraziniana* (as *Calloria vinosa*), *O. xanthostigma* (as *C. chrysocoma*), and *Orbilia* sp. (as *Pezizella rubella*). Rehm (1891: 453–460) reported about 10 orbiliaceous taxa for Germany (see p. 194). For Brandenburg Rehm (1894: 1224) added *O. flavidorosella* and Kirschstein (1938) *O. auricolor* (as *Orbiliella armeniaca*). About 8 of Rehm's 11 taxa are xerobionts. From Baden-Württemberg Ade (1924) described *O. ?flavida* (as *O. paradoxa*) and Baral (1989) *O. septispora*, from Bayern Svrček (1987) *O. ebuli*, and from Oberfranken (Bayern) Beyer (1994, 1997, 1998) *O. aristata* (as *O. occulta*), *O. auricolor*, *O. septispora*, *O. rectispora* (as *O. luzularum*), *O. vinosa*, and *O.* aff. *cardui* (as *O.* [cf.] *rubella*). Krieglsteiner (1999: 268–272, 2004: 654–657, 2007) reported a total of 17 *Orbilia* spp. (*O. clavuliformis* as *Orbilia* sp. 1, *O. aprilis* as *Orbilia* sp. 2), 2 *Hyalorbilia* spp. (*H. inflatula* and *H. subfusispora*, the latter as *O. vitalbae*), and *Lecophagus ellipsoideus* (as *Orbiliaceae* sp.) from Mainfränkische Platten (northwestern Bayern) and Rhön mt. (border to Hessen and Thüringen), representing 11 xero- and 9 hygrobionts.

During the present study, almost 100 species have been recorded within Germany (see Appendix 2): *Amphosoma atroolivaceum*, *Hyalorbilia* (18 spp.), *Lecophagus* (2 spp.), *Liladisca acicola*, *Orbilia* (75 spp.), and *Retiarius bovicornutus* (anamorphic). However, the 13 larger administrative units have very unequally been explored. Most collections were made in Baden-Württemberg (648, 74 spp.), followed by Bayern (252, 55 spp.), Sachsen (83, 23 spp.), and Thüringen (62, 25 spp.). The other nine federal states lie in the range of 7–38 collections and 6–17 species, the poorest explored being Schleswig-Holstein and Saarland. The paucity of collections

Figure 130: **left**: Temperate humid shrubland (*Salicetum*) on moist ground (Lower Jurassic, Terres rouges) with *Salix cinerea*, *S. aurita* × *caprea*, *Corylus avellana*, *Urtica dioica*, *Rosa canina*, *Rubus* etc., 305 m, Haus der Natur, Kockelscheier, Luxembourg, collected 1994–2010, phot. 13.X.2010, G. Marson; attached branches of *C. avellana* (with *Hyalorbilia helicospora*), *R. canina* (*O. vinosa*), *Salix* (*H. orbiliicola* on *O. aurantiorubra*, *O. eucalypti*, *O. ?tremulae*, H.B. 5964, 6244, 6281), *Ulmus* (*O. aristata*, *O. carpoboloides*, H.B. 6385), *Picea abies* (*O. euonymi*); **right**: ibid., thermophilous forest on slope in former ore mining area (Lower Jurassic, Terres rouges), 375 m, Brucherbierg, Kayl, collected between 1994–2014, phot. ?VII.2009, G. Marson; attached branches of *Cornus sanguinea* (*O. aristata*, *O. flagellispora*, *O. subaristata*, *O. vinosa*, H.B. 7005, 9163), *Quercus* (*O. obtusispora*, *O. ocellata*, *O. trapeziformis*, *O. vinosa*, H.B. 5079, 5104, 5111, 5112), *Rosa canina* (*O. vinosa*), *Salix caprea* (*O. aristata*, *O. vitalbae*, *O. xanthoguttulata*), *Clematis vitalba* (*O. euonymi*).

in these 9 states is obviously one reason for this disparity, another might be the widespread agriculture in some of them. Within the two southern states the large supratemperate zone of 100–700(–750 m altitude houses at present 75 spp. and the orotemperate zone (up to 1600 m) 29 spp. The low latter figure might be due to a more than 10× higher collection activity in the supratemperate zone and the comparative smallness of orotemperate areas in the two states.

Collections were made by D. Benkert (Brandenburg, 1967–1999), H.O. Baral (Baden-Württemberg, Oberpfalz etc., 1974–2018), L. Krieglsteiner (Bayern, Hessen etc., 1983–2007), N. Luschka (Bayerischer Wald, 1987–1990), W. Huth (Sachsen-Anhalt, 1987–2019), G. Marson (Baden-Württemberg etc., 1988–2005), T. Lohmeyer (Oberbayern, 1989–2014), W. Beyer (Oberfranken, 1992–2001), T. Richter (Mecklenburg, 1992–2019), A. Gminder (Baden-Württemberg, 1993–1999), E. Weber (mainly Tübingen, 1998–2017), P. Karasch (Oberbayern, 2001–2005), B. Mühler (Chemnitz, 2002–2015), S. Helleman (Thüringen, Niedersachsen etc., 2004–2016), B. Fellmann (München, 2005–2019), H. Bender (Mönchengladbach, 2007–2019), M. Bemmann (Heidelberg, 2009–2013), I. Wagner (Sonneberg, 2009–2018), and many others.

The most frequently collected species within Germany (> 20 samples) are *Hyalorbilia inflatula*, *H. juliae*, *H. subfusispora*, *Orbilia aprilis*, *O. aristata*, *O. aurantiorubra*, *O. auricolor*, *O. comma*, *O. crenatomarginata*, *O. eucalypti*, *O. leucostigma*, *O. sarraziniana*, *O. trapeziformis*, *O. vinosa*, and *O. xanthostigma*. Rarities are, e.g., *H. fomentarii* (also in Estonia), *H. oreadum* (also in Slovakia), *O. clavuliaristata* (also in eastern USA), *O. rosella* (also in Czechia), and *O. fissilis* and *O. zhongdianensis* (also in eastern Asia). *Liladisca acicola*, *O. flavovacuolata*, *O. jurana*, *O. rehmii*, and *O. solidaginis* are only known from the type collection.

1d. **Switzerland**, **Liechtenstein and Austria**: Höhnel (1907a) reported *O. xanthostigma* (as *O. botulispora*) for Austria, Rehm (1891: 453–457) *O. eucalypti* (as *O. coccinella*), '*O. luteorubella*' (?*H. inflatula* or *O. aprilis*), and *O. vinosa* for the Alps, and Breitenbach & Kränzlin (1981: figs 250–254, 261) about 8 orbiliaceous species for Switzerland: *O. auricolor* (as *O. curvatispora*), *O. eucalypti* and ?*O. tremulae* (as *O. coccinella*), *O. carpoboloides* & *O. comma* (as *Habrostictis rubra*), *O. crenatomarginata* (as *Hyalinia rosella*), *O. sarraziniana*, and *O. xanthostigma*. Records from Austria by Matočec et al. (2005: 324) include also *H. erythrostigma*, *H. inflatula*, and *O. luteorubella*, and those by Friebes (2011, 2017) and Friebes & Wendelin (2015) *O. abutilonis*, *O. crenatovinosa* (as *Orbilia* sp.), *O. leucostigma*, *O. pilifera*, *O. vinosa*, and *O. xanthoguttulata*.

Altogether 73 orbiliaceous species were encountered up to now in the three countries, 2 in *Lilapila*, 1 in *Amphosoma*, 12 in *Hyalorbilia*, and 59 in *Orbilia*. Of these 73 species, 20 occurred at least sometimes above 1350 m, and about 52 (71 %) are xerobiotic. When analysing the two main thermotypes separately, the orotemperate samples (> 800 m a.s.l.) included 39 spp. (4 in *Hyalorbilia*) and showed the same proportion of about 28 xerobionts (71 %) and 11 hygrobionts, whereas the supratemperate samples (< 800 m a.s.l.) included 54 spp. (11 in *Hyalorbilia*) and showed a slightly lower proportion of about 34 xerobionts (63 %) and 20 hygrobionts.

Collections from Switzerland were mainly made by H.O. Baral (1985–2018) and U. Graf (2006–2018), also by J. Breitenbach/T. Honermann/F. Kränzlin (1975–1980), P. Blank (1987–1991), E. Weber (2006, 2014), H. Aeberhard (2009–2014), E. Stöckli (2017–2018), B. Senn-Irlet (2017–2018) and others, from Liechtenstein solely by H.B. (1997), and from Austria mainly by W. Jaklitsch (1992–2003) and G. Friebes (2009–2019), also by F. v. Höhnel (1903–1916), W. Dämon (1990–1993), M. Mann

(2012–2018), R. Moosbeckhofer (2013–2018), A. Gallé (2013–2019), I. Wendelin (2014–2015) and others.

The most often collected species were in the supratemperate zone *H. inflatula*, *O. aurantiorubra*, *O. crenatomarginata*, *O. eucalypti*, *O. ficicola*, *O. sarraziniana*, *O. vinosa*, and *O. xanthostigma*, and in the orotemperate zone *Lilapila jurana*, *H. inflatula*, *O. alpigena*, *O. vinosa*, *O. rosea*, *O. subtrapeziformis* and others. Among the rare species is the type of *H. hergiswiliana* from Luzern, which was finally also found in Slovakia and Serbia. Remarkable is also the rare *O. jacaensis* from Pyrenees, discovered by B. Senn-Irlet in Graubünden. *O. crenatovinosa* was so far only found a few times in the orotemperate eastern Alps. *L. jurana* was at first only found in Swiss (and adjacent French) Jura, mainly by E. Stöckli, but was later detected by A. Polhorský in the Slovakian High Tatras.

1e. **Luxembourg**: During 1894–1902, the small country was investigated for *Orbiliomycetes* by J. Feltgen (and V. Noppeney), who recognized 9 species and 5 varieties (Feltgen 1899, 1901, 1903). A restudy of his specimens by one of us (H.B.) revealed 10 different orbiliaceous species (hygrobionts: *H. inflatula*, *O. auricolor*, *O. crenatomarginata*, *O. ?leporina*, *O. ?luteorubella*, *O. sarraziniana*, *O. xanthostigma*; xerobionts: *O. eucalypti*, *O. flavida*, *O. vinosa*), though with little correlation to Feltgen's species concept. G. Marson (1988–2019) and also H.O. Baral (1988–2001) thoroughly explored the country, but mainly regarding xerobionts. But hygrobionts have also been collected, especially on occasion of annual meetings held by the mycology group of Luxembourg between 1990 and 2000.

Luxembourg consists of two main natural regions: in the north the cooler, colline to submontane Oesling with its acidic soil (Devonian, in the south Buntsandstein), and in the south the warmer, colline Gutland, characterized by neutral to basic soil (Keuper and Lower Jurassic, the latter including iron-bearing rock = Terres rouges, = 'Minette') at the border to Middle Jurassic, Fig. 130 right). The climate is cold-temperate humid and subcontinental with some atlantic influence. Although the size of Gutland is only about 1.5 × that of Oesling, many more species of *Orbiliomycetes* were recorded in the former area. This could be due to the less favourable acidic soils in Oesling, but is perhaps only a result of the greater remoteness from G. Marson's home. Over 700 samples were studied, about 670 from Gutland and 40 from Oesling. The total species number was about 68 when disregarding unclarified genetic variants. All 68 occurred in Gutland, but only 25 in Oesling. The proportion between xero- and hygrobionts was 56 : 12 in Gutland and 20 : 5 in Oesling.

Remarkable rarities were, e.g., *Lecophagus ellipsoideus*, *Hyalorbilia latispora*, *H. rotifera*, *Orbilia fraxini*, and *O. poitevinica*, the latter otherwise only known from Marais Poitevin in western France.

1f. **Belgium and the Netherlands**: Arnolds et al. (1984: 309, 326) reported 9 orbiliaceous species for the Netherlands. The recent checklist for Flanders, Belgium (Declercq & Leysen 2017) gives 3 *Arthrobotrys*, 2 *Hyalorbilia*, and 17 *Orbilia* spp. Up to now, 10 *Hyalorbilia* spp. and 26 *Orbilia* spp. from almost 100 samples are recognized by us altogether in both countries (Belgium 9 hygro- and 11 xerobionts, Netherlands 15 hygro- and 15 xerobionts), most of them collected by B. Declercq (mainly Oost-Vlaanderen, 1993–2014) and S. Helleman (mainly Noord-Brabant, 2006–2015), some also by L. Rommelaars (mainly Noord-Brabant, 2002–2018) and others. The mild, overall supratemperate humid climate supports occurrence of atlantic species such as *O. rubrovacuolata*. Remarkable is the rare *O. xinjiangensis* which is otherwise only known from the type isolate in the continental Tian Shan Mts. in central Asia.

1g. **France**: In his 'Chamignons de France', Gillet (1881–83) reported about 9 orbiliaceous taxa of unclear identity in *Helotium*, *Lachnea*, and mainly *Mollisia*. From Bretagne Crouan & Crouan (1867) described 2 species: *O. carpoboloides* and *O. rubrovacuolata* (as *Peziza infixa*), and from southern France Saccardo (1883: pl. 1291) *O. luteorubella*, Rolland (1901) *O. hesperidea*, and Chenantais (1918) the unclear *Hyalinia ulicis*. From around Paris Boudier (1904–10: 265–270, pl. 459–467) reported 8 species: *O. aurantiorubra*, *O. auricolor* (as *O. cur-*

Baral; standing trunk of *Q. pubescens* (*H. fusispora*, H.B. 9156; 9 km eastwards at 1250 m, Col du Labouret, collected on attached *Pinus* and *Picea* branches: *Amphosoma atroolivaceum*, *A. resinicola*, *Lilapila* spp., *Orbilia alpigena, O. euonymi, O. flagellispora, O. patellarioides*, *O. subvinosa*, *O. vinosa*).

vatispora), *O. carpoboloides* (as *Habrostictis*), *O. crenatomarginata* (as *Hyalinia rosella* & *H. crystallina*), *O. eucalypti* (as *O. coccinella*), *O. rectispora* (as *Hyalinia*), *O. sarraziniana*, and *O. xanthostigma*. In his 'Discomycètes de France', Grelet (1948a: 49f.) added *O. leucostigma*, *O. luteorubella*, *O. polyspora*, and *O. vinosa*. Pacaud (2002: 88) reported 4 species for dépt. Vendée: *H. inflatula*, *O. auricolor* (as *O. curvatispora*), *O. eucalypti* (as *O. alnea*), and *O. xanthostigma* (as *O. delicatula*).

Over 1170 French orbiliaceous samples are treated in this study (excluding oversea provinces). The various administrative regions of France have very differently been investigated for *Orbiliomycetes*. To the well explored regions belong Bretagne (> 270 records, 57 spp.) mainly by J.P. Priou between 2000–2017, Provence-Alpes-Côte d'Azur (225 records, 57 spp.) and Rhône-Alpes (190 records, 69 spp.) mainly by G.M. and J.P. Priou between 1992–2017, and Poitou-Charente (147 records, 44 sp.) by various collectors (including H.B., J.P. Priou, P. Tanchaud, B. Capoen, M. Hairaud, S. Helleman, B. Coué etc.), especially during three meetings in dépt. Deux-Sèvres (2006, 2008, 2011). Better explored are also Alsace and Lorrain (mainly by J. Deny and H.B. 1990–2000) and Pays-de-la-Loire (mainly by J.P. Priou 2002–2016 and H.B. 2003). To the least explored regions belongs Corse, for which only one sample was available (*O. auricolor* on *Hedera*).

A total of 135 species were so far discovered in France, with 22% hygrobionts and 78% xerobionts: *Amphosoma* (3 spp.), *Hyalorbilia* (16 spp.), *Lecophagus* (3 spp.), *Lilapila* (4 spp.), *Orbilia* (109 spp.), *Pseudorbilia bipolaris*, and *Retiarius* ?*revayae* (anamorphic). Species so far exclusively known from France are *A.* aff. *resinicola*, *Lecophagus pini*, *L. subglobosus*, *Lilapila oculisporella* and *L. gallica*, *O. beatricis*, *O. cisti*, *O. cupressi*, *O. frullaniae*, *O. microlentiformis*, *O. myriolentiformis*, *O. olivacea*, *O. paracylindrospora*, *O. pseudocylindrospora*, *O. pyrenaica*, and *O. subdelphinus*. The North American *O. spermoides* was once also found in the Southern French Alps. *O. poitevinica* was named after its occurrence in Marais Poitevin

Figure 133: **left**: mesosubmediterranean semihumid shrubland (macchia) with *Quercus*, *Rosa*, *Pistacia*, *Acer*, *Ulex*, *Juniperus*, *Pinus*, 410 m, les Mouniers, Vallon-Pont-d'Arc, Ardèche, France, 8.X.2002, phot. G. Marson (#609); attached branches of *Ulex parviflorus* and *Quercus* (*Hyalorbilia subfusispora*, *Orbilia corculispora*, *O. montigena*, *O. vinosa*, H.B. 7317); **right**: supramediterranean semihumid *Juniperetum thuriferae*, 1040 m, Ermita de los Enebrales de Tamajón, Guadalajara, Spain, 14.V.1996, phot. H.O. Baral; attached twigs & branches of *Cistus ladanifer*, *Genista scorpius*, *Juniperus thurifera*, *Quercus rotundifolia*, *Rosa* (with *O. euonymi*, *O. gambelii*, *O. pleiogambelii*, *O. polyspora*, *O. rosicola*, *O. subaristata*, *O. subclavuliformis*, *O. subovoidea*, *O. trapeziformis*, *O. vinosa*, H.B. 5464, 5482, 5490, 5499, 5500, 5510, 5512, 5517).

in Poitou-Charantes, but a second sample was later made in Luxembourg. Remarkable is the presence of 4 different *Lilapila* spp. in mountainous regions of France.

Mainly J.P. Priou's collecting efforts raised the species number in Bretagne to now 51 (12 *Hyalorbilia* spp., 38 *Orbilia* spp., 1 *Pseudorbilia*). About 30 of them are xerobionts, and 6 of these xerobionts were presented by Priou (2005) as they had a published name at that time. 23 species (6 hygro- and 17 xerobionts) have been collected on *Ulex*, the most frequent being *H. ulicicola*, *O. corculispora* and *O. rubrovacuolata*. Remarkable rarities found in Bretagne are *Pseudorbilia bipolaris*, *H. herbicola*, *H. multiguttulata*, and *O. frangulae*. Because of the mild, atlantic climate various species from the mediterranean belt occur here, e. g., *O. corculispora*, *O. gambelii*, and *O. subovoidea*. Species with an exclusively atlantic distribution are *H. ulicicola*, *O. atlantis*, and *O. rubrovacuolata*.

In comparison to these lowland records at 1–320 m altitude, a similar number of 56 species was retrieved by comprehensive collecting in mountainous regions of the orotemperate to oro-submediterranean humid Southern French Alps (760–1950 m). 52 of these species are xerobionts, but the low number of hygrobionts is here due to a strong focus on xeric substrate. Some of the rarely collected species occurred here, and the region represents one of the main distribution areas of the genus *Lilapila*.

1h. **Iberian peninsula** (**Spain**, **Portugal**): 10 orbiliaceous species were treated by R. Galán in Pando & Hernández (2001: 121–126) in their 'Chorological basis of the mycological flora of Iberia': *Hyalorbilia inflatula* (as *Orbilia*), *O. auricolor*, *O. carpoboloides*, *O. eucalypti* s.l. (as *O. alnea*), *O. leucostigma*, *O. luteorubella*, *O. rubella*, *O. sarraziniana*, *O. vinosa*, and *O. xanthostigma* (as *O. delicatula*), and Rubio et al. (2005) added *O. crenatomarginata* (as *O. rosella*) and *O. eucalypti* s.l. under the name *O. coccinella* in their 'Provisional catalogue of macromycetes from Asturias'. In the present study, data from about 570 collections were available, comprising a total of 120 different species: 11 in *Hyalorbilia*, 106 in *Orbilia*, and 1 in each *Amphosoma*, *Bryorbilia*, and *Lecophagus*. Most of them (541 samples with 116 spp.) were made in Spain. Strongly underexplored are Portugal (28 samples with 5 *Hyalorbilia* spp. and 16 *Orbilia* spp.), but also Islas Baleares (4 samples with 4 spp.). Selected samples from the Natural Park of Somiedo in Asturias made in the 21th century were reported and illustrated in Rubio et al. (2010, 2015) and Rubio & Zapico (2018).

Our collections were made during a research visit in Alcalá de Henares in 1996 (H.B. & E.W., Madrid, Guadalajara), at the European Mycological Congress in Alcalá de Henares in 1999 (H.B. & G. M., Madrid, Guadalajara, Cuenca, Teruel, Castellón, Cataluña), and during two meetings in Somiedo in 2013 and 2017 and one in Jaca, Huesca in 2018 (H.B.). Various mainly Spanish collectors contributed with their collections and documentations, e. g., J. Linde & E. Rubio (Asturias, 2005–2019), J. Martin, I. Olariaga etc. (mainly País Vasco, 2012–2018), F.J. Balda (Navarra, 2013–2019), R. Tena (Teruel, 2010–2014), R. Blasco (Huesca, 2012–2019), J. Bometón (Cataluña, 2014–2017), F. Prieto (Madrid, Andalucía, 2001–2004), S. Tello (Andalucía, 2013–2017), and J.P. Priou (Portugal, 2006–2017).

The highest species number of 75 was observed in the eumediterranean zone, with 42 spp. in the supra- (Sm), 41 in the meso- (Mm), and 27 in the thermomediterranean subzone (Tm). An intermediate species number of 62 occurred in the submediterranean zone, with 33 spp. in the orosub- (Osm), 31 in the suprasub- (Ssm), and 21 in the mesosubmediterranean subzone (Msm). Only 54 spp. were found in the temperate zone, with 33 spp. in the oro- (Ot), 16 in the supra- (St), 17 in the meso- (Mt), and 18 in the thermotemperate subzone (Tt).

Many of the encountered species appear to be rare, and the following are exclusively known from the Iberian peninsula: *Bryorbilia arenicola* (Ssm), *O. asturiensis* (Ot), *O. crenatofalcata* (Sm, Ssm), *O. halimi* (Mm), *O. navicularis* (Sm), *O. octocorculispora* (Tm, Mm), *O. paramontigena* (Osm), *O. paravitalbae* (Tm, Mm, Osm), *O. pleioalbidorosea* (Sm, Osm), *O. pleistosphaera* (Sm), *O. rhamni* (Mm), *O. rosicola* (Sm), *O. somedana* (Ot), and *O. suberis* (Mm). Some other rare species have also been detected elsewhere: *O. jacaensis* (Ssm), described from Jaca at the base of the Pyrenees, was also found in the French Pyrenees and Swiss Alps (Ot), *O. angiosubvinosa* is known from different parts of Spain (Ot, Osm, Ssm) but apparently also occurs in North America (mild-maritime), and the insectivore *O. alba*, reported here from Asturias and Galicia (Tt), has variants in subtropical China and tropical South America.

1i. **Italy**: Saccardo (1883: pls 1289–1290, 1365) reported 3 orbiliaceous species from Italy (Südtirol): *O. eucalypti* (as *Calloria coccinella*), *Hyalorbilia* (?)*inflatula* (as *Calloria*), and *O. carpoboloides* (as *Habrostictis rubra*). Up to now, about 17 *Orbilia* spp. and two *Hyalorbilia* spp. are known from Italy, ~ 12 of them being xerobionts. They grew on woody angiosperms from orotemperate to mesomediterranean regions in the northern half of Italy, except for *O. auricolor* which was on dung in thermomediterranean Sicilia. More recent collections were, e. g., from Elba, by D. Triebel & G. Rambold in 1998, and Emilia-Romagna by J.P. Priou in 2004 and E. Camporesi in 2011. No collection from Sardinia was available.

1j. **Poland**, **Czechia**, **Slovakia**, **Hungary**: Schröter (1893: 120) reported for **Poland** 6 species for Silesia, viz. *O. aurantiorubra* (as *O. rubella*), *O.* ?*auricolor* (as *O. pannorum*), *O. carpoboloides* (as *O. lasia*), *O. eucalypti* (as *O. coccinella*), *O. vinosa*, and *O.* ?*xanthostigma* (as *O. chrysocoma*). Ginko (1986) added *O. auricolor* (as *O. curvatispora*) and *O.* ?*cejpii* (as *O. leucostigma*), and Chmiel's (2006) checklist of Poland includes also *O. luteorubella*, *O. sarraziniana*, and *O. xanthostigma*. Up to now, 10 *Hyalorbilia* spp. and 27 *Orbilia* spp. are known from Poland, besides *Amphosoma atroolivaceum*, 24 of them being xerobionts (63 %). Samples predominantly originate from Lower Silesia (Kłodzko county) where P. Perz collected between 2006–2013.

Velenovský (1934, 1940, 1947) reported for the former Czechoslovakia, mainly **Czechia**, 68 species and 12 varieties in *Orbilia*, and 1 in *Radotinea* (*R. caudata*). A restudy by Svrček (1954) accepted only 17 orbiliaceous species and 2 forms, and the present study about 41 species, the identities of which showing only moderate correlation with Velenovský's original concept. Six of them belong to *Hyalorbilia* and ~ 35 to *Orbilia*. Later Svrček (1977) added *O. polybrocha* (as *O. tenebricosa*). The relation between hygro- and xerobionts was about 55 : 45 %. During collecting in Czechia in 2008 and 2009 the first author (H.B.) found only *O. aprilis* and *O. vinosa*, but V. Halasů in 2019 *O. pseudoaristata*, which raises the species number of recorded species to 42. From **Slovakia** now 7 *Hyalorbilia* spp. and 24 *Orbilia* spp. are known, besides *Amphosoma atroolivaceum* and

Figure 134: Supratemperate humid forests with mediterranean influence at Fruška Gora mountain in suprasubmediterranean Vojvodina, Serbia; **left**: northern slope with steppe meadow vegetation (*Inulo-Chrysopogonetum grylli* with scattered small *Fraxinus ornus* trees) maintained by grazing, 235–270 m, Erdelj, 28.VIII.2012, phot. D. Savić; attached branches of *Colutea arborea*, *Fagus sylvatica*, *Quercus pubescens* (with *Hyalorbilia fusispora*, *H. juliae*, *Orbilia carpoboloides*); **right**: mountain top with *Aculeato-Querco-Carpinetum* (with *Ruscus aculeatus*), 420–510 m, Iriški venac, phot. 9.X.2007, D. Savić; attached twigs and branches of *Betula*, *Clematis*, *Larix*, *Picea*, *Populus*, *Prunus*, *Pseudotsuga*, *Quercus*, *Sorbus*, *Tamarix*, *Tilia*, *Ulmus* (with *H. orbiliicola*, *O. aprilis*, *O. aristata*, *O. carpoboloides*, *O. comma*, *O. clavuliformis*, *O. euonymi*, *O. ficicola*, *O. fraxini*, *O. montigena*, *O. nemaspora*, *O. subaristata*, *O. trapeziformis*, *O. vinosa*, *O. vitalbae*, *O. xanthoguttulata*), and on fallen substrate some hygrobiotic spp.

Lilapila jurana, most of them collected by A. Polhorský from the High Tatra Mts. and Danubian lowlands around Bratislava between 2016–2019.

The few collections from **Hungary** are all from the humid central north. Collections were made by L. Beenken in 1999 in the supratemperate Danube-Ipoly National Park at 200–285 m on *Quercus* and *Carpinus* xeric or hygric branches and logs (mainly on wood), by D. Magyar between 2007–2016 in the suprasubmediterranean Budapest urban area at 92–117 m on xeric trunk bark of mainly *Platanus*, rarely *Taxus*, and by A. Koszka in the supratemperate Vértes mt. at 266 m. Five xerobionts (*Lecophagus ellipsoideus*, *Hyalorbilia juliae*, *Orbilia aprilis*, *O. eucalypti*, *O. ficicola*) and two hygrobionts (*H. inflatula*, *O. xanthostigma*) were recorded. Four further xerobionts are only known from their anamorph (*Lecophagus vermicola*, *Mycoceros antennatissimus*, *Retiarius revayae*, *R. goenczoelii*).

Altogether about 75 orbiliaceous spp. have been recognized in the four countries up to now. 17 spp. came from the orotemperate zone of the Bohemian Forest, Sudetes mountains, and Carpathians (750–1800 m), and 68 spp. from the supratemperate to suprasubmediterranean hilly and lowland zone (25–700 m). Purely orotemperate species were *A. atroolivaceum*, *L. jurana*, *O. cylindrospora*, *O. filiformis*, and *O. subtrapeziformis*. The following species are so far only known from Czechia, all described by J. Velenovský: *O. acuum*, *O. cyparissias*, *O. leporina*, and *O. minutispora*. Remarkable is the occurrence of the predominantly mediterranean *O. gambelii* in the Danubian lowlands of southern Slovakia.

1k. Romania, Ukraine, Moldavia, Bulgaria, southwestern Russia: For **Romania** Pop (1994) listed a collection of *O. auricolor* (Cluj county). During our study three further species were recorded, *O. lentiformis*, *O. pleiolentiformis*, and *O. xanthostigma*. The former two species have been collected by R. Reuter in 1994 on the same xeric *Salix* branch in mesosubmediterranean humid southern lowlands at ~275 m, the latter by J.P. Priou in 2014 on a hygric *Salix* log in the supratemperate humid northern lowlands (280 m) at the foot of Carpathians.

Records from the supra- to orotemperate **Ukrainian** Carpathians were made by A. Pilát between 1929–1930 (*O. epipora*, *O. leucostigma*, *O. polybrocha*, *O. sarraziniana*, *O. xanthostigma*; names according to present study). Most of them were reported by Velenovský (1934), though under different names. Further species from this region were recorded in 2012 by A. Akulov (*Hyalorbilia fagi*, *H. inflatula*, *O. crenatomarginata*). From supratemperate humid, continental Ukrainian lowlands *O. xanthostigma* was collected by Z.K. Girzhitska (vid. E. Popov) in 1927 near Kyiv, and *O. aurantiorubra*, *O. carpoboloides*, *O. comma*, *O. crenatomarginata*, and *O. flavidorosella* between 2000–2012 around Kharkiv (Prylutskyi et al. 2017, Yatsiuk 2018, E. Popov pers. comm.).

In the west (Bryansk) and south (Rostov, Volgograd, Astrakhan) of **southwestern Russia** with a supra- to mesotemperate or suprasubmediterranean, humid to subhumid, continental climate, E. Popov collected 9 xerobiotic *Orbilia* spp. between 2002–2012. Among them is *O. cercidicola* on *Ulmus* which was otherwise only observed in mesomediterranean southern France on *Cercis*. The Volga floodplain represents the only site within Europe which is classified here by a subhumid ombrotype. Regarding the humid Caucasus region see under Asia (p. 177). No records are known to us from Moldavia and Bulgaria.

1l. Slovenia, Croatia, Bosnia and Herzegovina, Serbia, Montenegro: Previous reports include *O. xanthostigma* (as *O. delicatula*) from Montenegro (Matočec & Focht 2000, apothecia yellow, N. Matočec pers. comm.) and *O. polyspora* from Croatia

(Tkalčec et al. 2008). Up to now, no records from Slovenia or Bosnia and Herzegovina are known to us.

Collections in **Croatia** were mainly made by N. Matočec, H.O. Baral and E. Weber between 1998–2000. 24 *Orbilia* spp. and one *Hyalorbilia* (*H. juliae*) are known at present. Most of them derive from Dalmatian islands, particularly Korčula, rarely Palagruža (*O. auricolor*) and Dugi Otok (*O.* ?*cotoneastri*). The low number of only 3 hygrobionts (12 %, the latter two and *O. xanthostigma*) is due to collecting mainly in summer on xeric substrate. The climate of the sites was mostly meso- to thermomediterranean semihumid at 1–450 m, mainly with *Quercus ilex* shrubland and maquis, rarely mesosubmediterranean (semi)humid at 635 m. Only one sample was from the supratemperate humid north of Croatia (*O. auricolor* on *Carex*). The substrates comprised a high diversity of mainly woody angiosperms, but also gymnosperms. The most often collected species were *O. vinosa*, *O. hesperidea*, *O. gambelii*, and *O. subaristata*. Rarities were *O. albovinosa* on *Lonicera* and the so far unique *O. dalmatica* on *Juniperus*.

From **Montenegro** so far 16 *Orbilia* spp. and 4 *Hyalorbilia* spp. were recorded, mainly by B. Perić in 2016 and D. Savić in 2019, 5 of them hygrobionts (*H. inflatula*, *H. ulicicola*, *O. auricolor*, *O. crenatomarginata*, *O.* ?*xanthostigma*). Most collections were from the mesosubmediterranean (semi) humid lowlands at 8–210 m, a minority from the supra- to orotemperate humid mountains (935–1725 m, e. g., *H. inflatula*, *O. crenatomarginata*, *O. subtrapeziformis*). Substrates were mainly woody angiosperms, also *Inonotus* (*H. ulicicola*) and *Orbilia* (*H. orbiliicola*). Rarities were *O.* ?*albovinosa* on *Euphorbia* and *O. mali* on *Punica*.

In northern **Serbia** (Vojvodina) D. Savić investigated Fruška Gora between 2013–2019 for ascomycetes, especially *Helotiales* and *Orbiliomycetes*. This mostly calcarean mountain range with an altitude of 200–540 m lies in the south of the Pannonian Plain in the very southeast of central Europe. The surrounding agricultural lowlands along the Danube river have a suprasubmediterranean (sub)humid, somewhat subcontinental climate and receive continuous but moderate rain throughout the year. The climate on the mountain is more supratemperate humid. Plant communities of Fruška Gora mainly belong to *Querco-Fagetea*, with *Aculeato-Querco-Carpinetum* as the most frequent forest type, but also beech and linden communities (*Tilio-Fagetum submontanum*) play an important role. Diversity is very rich (1500 plant species, ~50 being woody), providing great potential for ascomycete diversity. More or less omnipresent trees are *Quercus petraea*, *Q. cerris*, *Q. pubescens*, *Fagus sylvatica*, *Tilia tomentosa*, *T. platyphyllos*, *T. cordata*, *Fraxinus ornus*, *F. angustifolia*, *Acer campestre*, *A. platanoides*, *A. pseudoplatanus*, *A. tataricum*, *Carpinus betulus*, *Sorbus torminalis*, *Staphylea pinnata* etc.

No previous reports of orbiliaceous taxa from Serbia are known to us. A total of 10 *Hyalorbilia* spp. and 42 *Orbilia* spp. were discovered in Fruška Gora including surrounding lowlands. Most of them are widely distributed in Central Europe, but some are rarities (e. g., *H. hergiswiliana*, *H. multiguttulata*, *O. clavispora*, *O. ficicola*, *O.*?*fraxini*, *O. nemaspora*, *O. sinensis*). *O. nemaspora* even represents a first record for Europe. About 33 species are xerobionts and 19 hygrobionts. Substrates were mainly woody angiosperms, also conifers and herbaceous stems.

1m. **Albania**, **North Macedonia**, **Greece**: No records are known to us from Albania, and only one from North Macedonia made by M. Theiß in 2006 (*O. xanthostigma*). Various collections were made in **Greece** by S. Helleman in 2009 in Attika (Athens) and mainly Peloponnese, by V. Kummer in 2010 in Rhodos, and by T. Giannakis (vid. B. Wergen) in 2015 in Central Macedonia (Thessaloniki, *O. gambelii*). Most of these places can be classified as semihumid and either meso- (Mm, 335–525 m) or thermomediterranean (Tm, 1–190 m). A total of 12 species were encountered on bark and wood of *Quercus*, *Pistacia*, *Anagyris*, *Myrtus* etc. All of them are xerobionts, because searching was only done on xeric substrate. Frequently collected were *O. subaristata* and *O. gambelii* at 12–525 m (Mm, Tm). Several species were only found in the thermomediterranean zone (e. g., *O. bicknellensis*, *O. hesperidea*). The single record of *O. serpentina* is the only which grew in a more semiarid region at 65 m (Tm). *O. myriosphaera* occurred at 1 m (Sm) and 855 m (Ssm), and *O. vinosa* at 30–185 m (Tm) and 565 m (Sm), the latter very probably occurring in Greece also at higher altitude (Ssm, Osm).

2. Africa (including islands near Madagascar)

Earlier records from the mainland of Africa comprise merely two species published in the 19th century, *Orbilia euphorbiae* (Ethiopia, Hennings 1891) and *O. serpentina* (Tunisia, Patouillard 1892a), and six further species which exist as unpublished herbarium specimens collected between 1920–1965 (see below). No previous record was known to us from the region of Madagascar. Also in the present study, collections were only sporadically available, therefore, a majority of African *Orbiliomycetes* diversity remain to be investigated.

For mainland Africa 30 orbiliaceous species are accepted by us up to now. The collection sites belong to the subtropical or rarely warm-temperate zone and comprise the northwestern ± coastal area (Maghreb), the afromontane Ethiopian highland and adjacent countries, the ± coastal region of southeastern and southern Africa, the Namib desert and savannah highland in southwestern Africa, and the coastal western Africa (Senegal). No collection was studied from tropical rainforests, but the occurrence of *O. blumenaviensis* in such a forest is proved by the type collection of its anamorph, *Arthrobotrys vermicola*, isolated from near Kampala (Uganda). For (sub)tropical sites on two islands near Madagascar 14 species are accepted.

Some of the recorded species might be endemic to mainland Africa (*Amphosoma natalense*, *O. aethiopica*, *O. caudimaeandrina*, *O. lobeliae*, *O. menageshae*, *O. myrioflexa*, *O. namibica*, *O. senegalensis*). Yet, considering the paucity of records compared to the rich species diversity observed in Macaronesia, there is little doubt that several hundreds of orbiliaceous species exist in mainland Africa with its diverse vegetation zones. The following arrangement of the different regions (phytochoria of mainland Africa according to White 1983, in Demissew 1988) gives an overview of the collection sites and recorded species.

2a. **Algeria**, **Morocco**, **Tunisia** (**Maghreb**) (mediterranean regional centre and transition to Sahara of northern Africa): The 7 orbiliaceous species known at present occurred in subtropical semihumid (eumediterranean) sites on mostly xeric bark and wood of angiosperms. All of them have been collected by French mycologists: Patouillard (1892a, b, *O. serpentina* on twig of *Artemisia herba-alba*), R. Maire (1920 in sched., *O. albovinosa* on *Lonicera etrusca*; *O.* ?*milinana* on *Ulmus*

Figure 135: Mesotemperate humid (winter-dry) evergreen afromontane forest with the tree-like (pachycaulous) herbs *Lobelia giberroa* (**left**) and *Solanecio gigas* (**below right**), 2520 m, Menagesha State Forest in subtropical Oromia region east of Addis Ababa, Ethiopia, 22.XII.2009 & 26.III.2010, phot. U. Lindemann; mesic stems and branches of *Solanecio*, *Lobelia*, indet. angiosperms (with *Hyalorbilia* ?*herbicola*, *H.* ?*brevistipitata*, *Orbilia aethiopica*, *O.* ?*caudata*, *O. euphorbiae*, *O. jugulospora*, *O. lobeliae*, *O. menageshae*, H.B. 9239–40, 9246, 9275–76, 9309–10, 9318).

campestris; *O. vinosa* on *Cistus crispus*), R. Bertault (1965 in sched.: *O. eucalypti* on *Acacia mollissima*), and G. Malençon (1934 in sched., *O. lentiformis* on *Thymelaea lythroides*; 1963 in sched., *O. auricolor* on *Acacia saligna*).

2b. **Eritrea**, **Ethiopia**, **Kenya** (Sudanian regional centre of eastern Africa): Only one orbiliaceous species was so far known from eastern Africa: the xerobiotic *O. euphorbiae* was described by Hennings (1891) on branches of *Euphorbia polyacantha* in the subtropical arid steppe of a high plateau in Eritrea.

Recent records from Ethiopia and Kenya were available from subtropical humid (winter-dry) afromontane evergreen forests with rainfalls in spring and mainly summer and a long dry period during autumn and winter (Fig. 135). Collections were mainly made by U. Lindemann (pers. comm.) from the Menagesha State Forest, an old volcanic area in the western Ethiopian highlands (Demissew 1988). Two tall trees, *Podocarpus gracilior* and *Juniperus procera*, constitute the forest. The collection site lies at 2500–2520 m a.s.l., and collections were made between 2009–2010 on fallen corticated branches of indet. angiosperms and on herbaceous stems of *Lobelia giberroa* and *Solanecio gigas* lying on the dry ground. The recorded eight species were either hygrobionts (*H.* ?*brevistipitata*, *H.* aff. *herbicola*) or showed a slight (*O. aethiopica*, *O. menageshae* s.l.) or more pronounced desiccation tolerance (*O.* aff. *caudata*, *O. euphorbiae*, *O. jugulospora*, *O. lobeliae*). Further collections of *O. menageshae* s.l. were made on *Yushania alpina* stems in a bamboo forest in southwestern Ethiopia (A. Gminder, 2014) and on a herbaceous *Euphorbia* stem in a highland forest of Kenya (O. Eriksson, vid. I. Olariaga, 1968).

2c. **Islands near Madagascar**: Samples belonging to 14 species were available from the islands of Mayotte (Comoros archipelago) northwest of Madagascar (M. Pélissier, vid. J.P. Priou, 2012–2014) and Réunion (Mascarene Islands) east of Madagascar (R. Reuter, 2011). They undoubtedly represent little more than an accidental spot check. From the tropical humid (winter-dry) Île de Mayotte the following 11, mainly hygrobiotic species were recorded at low altitude (90–440 m) on fallen hygric corticated to decorticated branches and logs of *Adansonia digitata* (*O. euphorbiae*), *Mangifera indica* (*O. vermiformis*), *Albizia lebbeck* (*O. blumenaviensis*, *Hyalorbilia* cf. *juliae*), indet. angiosperms (*H. citrina*, *H. ?japonica*, *O. ?fissilis*, *O. ?juruensis*, *O. nemaspora O. ?rosea*, *O. ?yuanensis*), and on stem of the bamboo *Dendrocalamus giganteus* (*O. nemaspora*). From La Réunion three xerobiotic species were observed at a subtropical humid (winter-dry) site at high altitude (2040 m) on an attached xeric corticated branch of *Acacia heterophylla* (*O.* cf. *aristata*, *O. eucalypti*, *O. vinosa*).

2d. **South Africa** (Kalahari-Highveld regional transition zone, eastern and southern part): seven species have been collected in the subtropical (winter-dry) savannah of southeastern Africa (D. Triebel & G. Rambold, 1990; V. Kummer, 2000 & 2006): in the subhumid Drakensberg Mts. and KwaZulu-Natal on a hygric angiosperm branch (*H. japonica*) and on xeric branches of ?*Vachellia* (*O. corculispora*) and ?*Pterocarpus* (*Amphosoma natalense*), and from the humid, more coastal Kranskloof Nature Reserve on fallen fruit of *Xylotheca kraussiana* (*O. auricolor*, *O. tenuissima*) and Oribi Gorge Nature Reserve on hygric indet. angiosperm wood (*O. xanthostigma*). A further species was observed in the warm-temperate humid Cape Mountains (Garden Route of southern Africa) on hygric indet. angiosperm bark (*O. jinguangsiensis*).

2e. **Namibia** (Kalahari-Highveld regional transition zone, western part): In 1995, R. Reuter collected in the warm-temperate arid highland savannah near Rehoboth an attached xeric branch of ?*Vachellia*, on which five different, highly desiccation-tolerant multispored *Orbilia* species occurred, three of them only known from this branch up to now: *O. caudimaeandrina*, *O. namibica*, *O. maeandrina*, *O. myrioflexa*, and *O. pluristomachia*. In the subtropical hyperarid Sossusvlei of the Namib desert, a piece of wood was taken by G. Parisot in 2007 from a decorticated branch of *Vachellia erioloba*, the famous upright tree corpses that died over 500 years ago from groundwater loss. On this piece of wood occurred *O. acaciae*, a species known before only from Australia and later from Macaronesia.

2f. **Senegal** (Guinea-Congolia/Sudania regional transition zone of western Africa): two drought-tolerant species have been collected by R. Reuter in 2000 and 2016 in tropical humid (winter-dry) open woodlands at low altitude on attached xeric branches of ?*Vachellia* (*O.* aff. *filiformis*, on wood) and *Citrus* (*O. senegalensis*, on bark).

3. Macaronesia

Korf (1992) reported 8 species of *Orbilia* s.l. (including *Hyalorbilia*) from the three archipelagos, but a restudy showed that he merged different species under one, so that he treated in fact min. 10 or 11 species. In their list of fungi of Canarian forests, Izquierdo et al. (2004: 29) reported 7 orbiliaceous species and Beltrán-Tejera et al. (2008: 183, 187) 3 for the National Forest Park of Garajonay in Gomera. Karasch et al. (2005) added 3 species on xeric branches of *Chamaecytisus proliferus* in La Palma. Later research, particularly in the islands of Tenerife and Madeira, mainly by L. Quijada & E. Beltrán-Tejera and J.P. Priou, raised the number of species to min. 61 for all Macaronesian archipelagos (54 from Canary Islands, 12 from Madeira, 1 from Azores), but none from Cape Verde. Of these 61 species, 28 are newly described in the present study, whereas most of the earlier published species have already been presented in Quijada et al. (2012, 2014a, b, 2016) and Quijada & Baral (2017, 2018). All 8 so far endemic *Orbilia* spp. (*O. adenocarpi*, *O. amarilla*, *O. asomatica*, *O. beltraniae*, *O. liliputiana*, *O. pisciformis*, *O. pseudeuphorbiae*, *O. succulenticola*) grew on plants endemic to this archipelago (*Adenocarpus viscosus Euphorbia canariensis*, *E. lamarckii*) but three of them occasionally or predominantly also on *E. balsamifera* which occurs as well in mainland Africa and the Arabian Peninsula.

3a. **Canary Islands**: The climate of the Canary Islands is very diverse due to the height of its volcanic mountains and the prevailing northeasterly trade winds that supply a humid climate to the northern slopes. It is classified as eumediterranean throughout, with different thermo- and ombrotypes ranging from inframediterranean hyper- to semiarid at the very lowlands, over thermo- to mesomediterranean in the region of the semihumid

Figure 136: Desert shrubs in Tenerife; **left**: inframediterranean arid tabaibal dulce (*Ceropegio fuscae-Euphorbietum balsamiferae*, adjacent to *Launaeo arborescentis-Schizogynetum sericeae*) with *Euphorbia canariensis* in foreground and *E. balsamifera*, *Plocama pendula*, *Kleinia neriifolia*, *Schizogyne sericea*, *Launaea arborescens* and *Cenchrus ciliaris* on the sides, 50 m, Montaña Centinela & Barranco la Vera, Abades, collected between 2009–2010, phot. 24.XI.2008, L. Quijada, lying xeric branches of *Euphorbia balsamifera* (*Orbilia pseudeuphorbiae*, *O. succulenticola*), *E. canariensis* (*O. acaciae*, *O. asomatica*, *O. pisciformis*, *O. pseudeuphorbiae*, *O. succulenticola*, H.B. 9153, TFC Mic. 22150 etc.), *E. lamarckii* (*O. pseudeuphorbiae*, TFC Mic. 22430), *Lavandula canariensis* (*O. pleioungulata*, TFC Mic. 22766); **right**: supramediterranean semihumid summit broom scrub (*Spartocytisetum supranubii*) with dead *Adenocarpus viscosus* in foreground, flanked by *Pterocephalus lasiospermus* and *Cytisus supranubius*, 2100–2160 m, Las Cañadas south of Teide, collected in 1978 and 2008–2012, phot. 27.XII.2009, L. Quijada; xeric twigs and branches of *Adenocarpus viscosus* (*O. adenocarpi*, *O. eucalypti*, *O. gambelii*, *O. macrodelphinus*, *O. microsoma*, *O. pleiogambelii*, H.B. 2280 etc., TFC Mic. 18428 etc.), *Carlina xeranthemoides* (*O. gambelii*, *O. ocellata*, TFC Mic. 23751, H.B. 9224), *Cytisus supranubius* (*O. euonymi*, *O. flavidorosella*, *O. subtrapeziformis*, H.B. 9225, TFC Mic. 24156 etc.).

Figure 137: Forests in Tenerife; **left**: mesomediterranean (sub)humid evergreen ridge-crest forest with *Erica platycodon*, *Laurus novocanariensis*, *Myrica faya*, *Viburnum rigidum*, *Pteridium aquilinum* etc., 860 m, Descansaderos de Tierra, Anaga, collected in 2012, phot. 27.V.2011, L. Quijada; lying log of *L. novocanariensis* (with *Orbilia xanthostigma*, TFC Mic. 23393; in 1976 at another place *O. dryadum* on *Myrica faya*, CUP-MM-434); **right**: mesomediterranean semihumid *Sideritido solutae-Pinetum canariensis* forest, Vilaflor, phot. 16.IV.1989, E. Weber; collected on xeric branches in pine forests close to these sites by L. Quijada at 1200–1600 m in 2012–2013 (*Aeonium arboreum*, *Chamaecytisus proliferus*, *Cistus* spp., *Pinus canariensis*, *Siderites soluta* (with *O. corculispora*, *O. flavida*, *O. ?paravitalbae*, *O. patellarioides*, *O. subaristata*, *O. vinosa*, TFC Mic. 23352–61, 23635–40, 23937, 23951) and by F. Bontemps at 1400 m in 1996 (*Acacia ?saligna*, *O. serpentina*, H.B. 5659).

(‘dry’) sclerophyllous shrublands or pine forests on the more southern slopes and the ± moist, (sub)humid cloud forests on the northern slopes, up to supra- (and oro-)mediterranean semihumid at the top. Rain falls during the winter months, with five dry months in summer.

Collections were available from Gomera, Gran Canaria, La Palma, and particularly Tenerife, the latter being thoroughly investigated by L. Quijada and E. Beltrán-Tejera between 2001–2015. Within Tenerife the recorded species show a remarkable adaptation to the humidity zones (Tab. 34). The highest number of species was observed in the semihumid zone (26 spp.), followed by the semiarid zone with 18 spp. (15 spp. in the lower and 10 spp. in the upper subzone), whereas in each of the remaining zones (hyperarid, arid, subhumid, humid) the number was 10 spp.

Table 34: Selected species of *Orbiliomycetes* collected in the Canary Islands (mainly Tenerife), sorted according to humidity (ombrotype) of the sites. The right column gives the observed thermotypes: Im = inframediterranean, Tm = thermomediterranean, Mm = mesomediterranean (i = lower, s = upper), Sm = supramediterranean. Numbers indicate the number of collections (only species with min. 3 collections are included). Ombro- and thermotypes according to Del-Arco et al. (2006); desiccation tolerance (x = xerobiotic, h = hygrobiotic).

Species	hyperarid	arid	lower semiarid	upper semiarid	semihumid	subhumid	humid	Thermotype	Desiccation tolerance
O. pseudeuphorbiae	7	11	5	–	–	–	–	Im23	x
O. acaciae	2	1	2	–	–	–	–	Im5	x
O. asomatica	2	1	2	–	–	–	–	Im5	x
O. pisciformis	2	5	5	–	1	–	–	Im13	x
O. pleioungulata	1	3	8	–	–	–	–	Im12	x
O. succulenticola	–	3	4	4	1?	–	–	Im11 Mms1?	x
O. pleiomicrosoma	–	1	2	1	1	–	–	Im3, Tm2	x
O. obtusispora	–	–	2	2	–	–	–	Im4	x
O. beltraniae	1	–	3	3	1	–	–	Im7	x
O. scolecospora	–	1	2	1	–	–	–	Im4	x
O. subaristata	–	–	1	1	1	–	–	Im2, Tm1	x
O. eucalypti	1	10	12	3	7	4	2	Im26, Tm2, Mmi6, Mms4, Sm1	x
O. hesperidea	–	–	1	1	1	–	–	Im3	x

O. vinosa	–	–	4	–	4	1	–	Im5, Tm3, Mms1	x
O. adenocarpi	–	–	–	–	10	–	–	Mms4, Sm6	x
O. corculispora	–	–	–	–	3	–	–	Tm2, Mmi1	x
H. lunata	–	–	–	–	1	5	5	Tm7, Mmi4	h
H. tortuosa	–	–	–	–	–	2	2	Tm2, Mmi2	h
O. dryadum	–	–	–	–	–	6	4	Tm1, Mmi8	h
O. xanthostigma	–	–	–	–	–	~17	~29	Tm~40, Mmi~8	h
H. polypori	–	–	–	–	–	1	6	Tm6, Mmi1	h

According to Tab. 34, most of the drought-tolerant species occurred in varying frequency either in the hyperarid to lower semiarid zone or more in the lower and upper semiarid zone, or only in the semihumid ± south-facing slopes and summit zone. Solely *O. eucalypti* was found across all humidity zones, though especially in the arid to subhumid zones.

The inframediterranean lowlands (up to ~300–400 m altitude in the north and ~400–600 m in the south) comprises two main types of **succulent xerophytic scrublands** (tabaibal-cardonal, Fig. 136 left): (1) cardonal (*Periploco laevigatae-Euphorbietum canariensis*) in the semiarid (rarely semihumid or arid) north dominated by *Euphorbia canariensis*, and (2) tabaibal dulce (*Ceropegio fuscae-Euphorbietum balsamiferae*) in the (hyper)arid south (rarely north) dominated by *E. balsamifera*. Most records were on *Euphorbia* spp. and the number of observed species was 12 in the cardonal and 16 in the tabaibal dulce (a total of 21 spp., all belonging to *Orbilia* except for *Hyalorbilia fusispora*). Some of the more frequently collected species preferred the tabaibal (*O. acaciae*, *O. pseudeuphorbiae*), others the cardonal (*O. beltraniae*, *O. obtusispora*, *O. scolecospora*, and *O. succulenticola*). *O. pleioungulata* occurred more frequently in the cardonal, and *O. pisciformis* in both communities at equal frequency.

The thermo- and mesomediterranean (sub)humid **cloud forest** zone on the north-exposed upper slopes ranges at ~650–1900 m (Fig. 137 left). It houses *Orbiliomycetes* which never or only exceptionally appeared in drier zones. The vegetation types include remnants of the laurel (*Lauro novocanariensis-Perseetum indicae*) and ridge-crest forest (*Ilici canariensis-Ericetum platycodonis*), the more degraded fayal-brezal (*Myrico fayae-Ericetum arboreae*), and the natural and planted Canary pine forest (*Sideritido solutae-Pinetum canariensis*). Up to now (2019) 7 *Hyalorbilia* spp. and 7 *Orbilia* spp. were here recorded (Tab. S6). However, most collections were made on hygric branches and logs on the ground. Actually, most of these species show very little tolerance to drought, except for *O. eucalypti* (?collected on the ground) and *O. vibrioides* (on xeric branches). This low number of xerobiotic species in the cloud forests appears to be due to the neglect of attached branches (see under Madeira). Among the 14 species, *H. lunata* occurred also once in the dry Arbutus woodland (*Visneo mocanerae-Arbutetum canariensis*), and *O. eucalypti* across all climatic types (Tab. 34).

Only three species were so far collected in the **juniper shrubland** between xerophytic scrubland and cloud or pine forest, the thermomediterranean semiarid *Junipero canariensis-Oleo cerasiformis*, facies with *Pinus canariensis* at one site of the western slopes of Tenerife (*O. asomatica* on *Euphorbia lamarckii*, *O. pleioungulata* and *O. subaristata* on *Juniperus phoenicea* var. *turbinata*).

In the mesomediterranean semihumid **pine forest** (*Sideritido solutae-Pinetum canariensis*) on the west-, south- and east-exposed slopes (Fig. 137 right), which ranges at ~1200–2200 m, so far 11 species were recorded (*O. adenocarpi*, *O. corculispora*, *O. eucalypti*, *O. flavida*, *O. flavidorosella*, *O. patellarioides*, *O.* ?*paravitalbae*, *O. serpentina*, *O. subaristata*, *O.* ?*succulenticola*, *O. vinosa*). Some of them were only once found, so their ecological amplitude in the Canary Islands is unknown. Two (*O. eucalypti*, *O. vinosa*) occurred at equal frequency also in the succulent xerophytic scrubland, *O. eucalypti* also in the summit broom scrub and cloud forest.

The meso- to supramediterranean semihumid **caldera de las Cañadas**, around the Teide volcano is a high plateau of ~2000–2500 m altitude surrounded by a high rim (Fig. 136 right). The vegetation is mainly provided by the low summit broom scrub (*Spartocytisetum supranubii*), being treeless because of the low temperature due to the surrounding crater wall. A total of 10 orbiliaceous species were recorded, mainly on *Cytisus supranubius* and *Adenocarpus viscosus*, all being xerobiotic (see legend of Fig. 136). Most of them were only once found, even regarding the entire archipelago, but do also occur in Europe or North America. Outstanding is *O. adenocarpi* which was the only more frequently recorded species here, with overall 10 collections. It occurred only on *Adenocarpus viscosus* and only in this zone and once in the uppermost pine zone. Although the *Spartocytisetum supranubii* is endemic to Tenerife (del-Arco et al. 2016), *A. viscosus* (codeso de Cumbre) and *Cytisus supranubius* (retama) also occur at the top of La Palma, being endemic to the two islands.

3b. **Madeira**. The climate of Madeira is classified as submediterranean, semihumid to humid, except for the thermomediterranean semihumid southern lowlands. A total of 12 species are known at present. Korf (1992) reported *O. epipora* (= *H. inflatula* as reidentified by Quijada et al. 2014a) and *O. luteorubella* which requires reexamination. R. Reuter collected in 1997 *O.* ?*subulivinosa* and *O. vibrioides*, and K. Gilbert & B. Wergen in 2018 *O. cejpii*. A majority of records with overall 11 species were sampled and studied by J.P. Priou in 2009 and 2015, with emphasis on attached xeric twigs and branches. Most of the collections originate from the north-exposed (sub)humid cloud forests: the mesosubmediterranean laurel (*Lauro novocanariensis-Perseetum indicae*) and suprasubmediterranean ridge-crest forest (*Ilici canariensis-Ericetum platycodonis*). Here 3 *Hyalorbilia* spp. and 7 *Orbilia* spp. were recorded (5 xero- and 5 hygrobiotic species). Only one (*O. clavuliaristata*) came from the thermosubmediterranean semihumid lower zone.

3c. **Azores**. The islands of Azores comprise a temperate to submediterranean and only exceptionally eumediterranean climate. Only two samples are known which originate from thermotemperate semihumid areas of São Miguel and Flores, being reported by Korf (1992) under the name *O. inflatula* and reexamined by Quijada et al. (2014a, as *Hyalorbilia* spp.). One resembles European *H. ulicicola* and the other North American *H. texensis*.

4. Asia

Most Asian countries are badly explored until now, except for a few, in which either the xerobionts (China, Japan) or the hygrobionts (Mongolia, Turkey) were inadequately collected. Species diversity of Asia is at present 128, with about 22 *Hyalorbilia* spp., *Lecophagus muscicola*, 106 *Orbilia* spp., and *Pseudorbilia bipolaris*. This high number is mainly due to records from China. Despite this high number, the total diversity within Asia is probably two or three times higher. For the Ural region see p. 165, under boreal Europe (1a).

4a. **Central Asia**: Samples from the central Asian high- and lowlands were available for Tian Shan Mts. (Tajikistan) and especially Altay and Sayan Mts. and adjacent regions (Altay, Mongolia, Xinjiang, Tuva, Irkutsk). A total of 24 species were recorded until now, 3 in *Hyalorbilia* and 21 in *Orbilia*, about 12 of them being xerobionts.

During an excursion to cold-continental (sub)humid highland forests of western (Mongolian Altay Mts., 2200–2900 m a.s.l.) and northern (Yablonovy Mts., 1240–1600 m a.s.l.) parts of **Mongolia** in 2005, P. Karasch collected 13 xerobiotic *Orbilia* spp. on woody substrates. Two are only known from there (*O. basiflexa*, *O. mongolica*), the others were also recorded from Europe and North-America. Each species was only 1–2 × found, whereas *O. delphinus* was found at six localities. From the region of Tian Shan in **China** derives the type of *O. xinjiangensis* by X.Z. Liu in 2003, and from Chinese part of the Altay mountain range the hygrobiotic *O. juruensis* by Z.F. Yu in 2007 and *O. dryadum* by B. Liu in 2003.

A. Raitviir and others collected *Orbiliomycetes* at several sites between 1968–1980: *O. ?cardui* from the Tian Shan mountain range in **Kyrgyzstan** at the altimontane, cold-continental humid Lake Sary-Chelek; the type of *O. terrestris* from the Pamir-Alay mountain range in **Tajikistan** at the northwestern edge of Himalaya in a warm-continental semihumid (mediterranean) valley; *O. xanthostigma*, *O. sarraziniana*, *O. dryadum*, and the here described *H. sibirica* in humid angiosperm forests of the Sayan Mts. and Yenisey river in the **Tuva (Russia)**. E. Parmasto collected in 1975 in the eastern Sayan Mts. south of lake Baykal (**Irkutsk**, **Russia**) *H. ?fagi*, *O. tremulae*, and *O. xanthostigma*. In the cold-continental (sub) humid Altay mountains (**Altay**, **Russia**) E. Popov collected in 2008 4 xerobionts (*O. lentiformis*, *O. phragmotricha*, *O. arachnovinosa*, *O. aristata*) and 4 hygrobionts (*H. inflatula*, *O. epipora*, *O. fissilis*, *O. xanthostigma*).

4b. **Caucasus and Turkey**: In the **Caucasus** region, unpublished orbiliaceous samples were taken at several occasions between 1968–1977, particularly by B. Kullman in 1974, also by M. Murdvee, E. Parmasto, V. Puusepp, A. Raitviir and others. They are preserved at TAAM and were reexamined in the present study, resulting in 12 accepted, always hygrobiotic species. Further 3 samples collected in 1925, 2009, and 2012, 2 of them xerobiotic, were forwarded to us by E. Popov, resulting in overall 15 species. Due to the neglect of xeric substrate the actual diversity of orbiliaceous fungi in the Caucasus region remains largely unexplored.

A majority of collections derive from the **Russian** north-exposed slopes of the northwestern Caucasus (**Adygea**, **Krasnodar**, **Karachayevo-Cherkesiya**), and volcanic Beshtau Mt. (**Stavropol**), particularly from the orotemperate humid zone at 1000–1800 m, with forests composed of *Abies nordmanniana*, *Alnus*, *Carpinus*, *Fagus orientalis*, *Picea orientalis*, *Populus tremula*, *Pyrus caucasica*, and *Quercus*, but also from the supratemperate zone at 600–800 m, with *Carpinus*, *Fagus orientalis*, and *Ulmus*. Collections from the southeastern Caucasus were made at 700–900 m in the suprasubmediterranean humid south-exposed slopes of northwestern **Azerbaijan**, with *Carpinus*, *Corylus avellana*, *Fraxinus*, *Robinia pseudoacacia*, *Tilia platyphyllos*, and *Ulmus* as hosts. Further collections came from a marshy delta at 5 m in the mesotemperate (mt) humid Kolkheti National Park of western **Georgia** (near Poti at the Black Sea between Caucasus and Pontic Mts.), with the hosts *Platanus orientalis* and *Eucalyptus globulus*.

The following species were recorded (thermotype in parenthesis): hygrobionts include *Hyalorbilia caucasica* (Mt), *H. fagi* (Ssm, Mt), *H. inflatula* (St), *H. ?japonica* (Ssm), *H. polypori* (Ot), *Orbilia auricolor* (St or Ot), *O. epipora* (Ssm), *O. ?rosea* (St), *O. sarraziniana* (St, Ssm), *O. scolecospora* (Ssm), *O. sinensis* (Ssm), *O. tremulae* (Ot), and *O. xanthostigma* (Ot, Ssm, Mt); xerobionts include *O. aprilis* (Ot) and *O. subtrapeziformis* (Ot). Most frequently collected was *O. xanthostigma* (9 ×, but information on hymenial colour was absent in 5 samples), followed by *H. fagi* (4 ×) and *H. polypori* (3 ×). The rare *H. caucasica* is only known from the type collection, but not easily distinguished from *H. ulicicola*. Since several species were collected only once, their ecological amplitude in the Caucasus region remains unknown.

Akata & Doğan (2015) published for the first time orbiliaceous (hygrobiotic) species from **Turkey**, collected in the Pontic Mts. of the eastern Black Sea region: *O. auricolor* (as *O. curvatispora*), *O. sarraziniana*, and *O. xanthostigma*. In 2014 Y. Uzun collected *O. carpoboloides* on a xeric trunk of *Ulmus* in the same region, and A. Kaya and Y. Uzun *O. subaristata* on xeric twigs of *Pinus brutia* near Gaziantep (Y. Uzun pers. comm.).

In 2002–2003, T. Askun (unpubl.) collected xerobiotic *Orbilia* spp. around Balıkesir in the Marmara region (northwestern Turkey). The area lies at the border between the mediterranean and pontic floristic region and is tentatively classified here as supramediterranean. The altitude was 135–485 m and the geology calcareous. Both broad-leaved and mixed conifer forests were investigated, the broad-leaved trees comprising *Acer*, *Carpinus*, *Celtis*, *Fagus orientalis*, *Fraxinus*, *Mespilus germanica*, *Paliurus spina*, *Platanus orientalis*, *Populus*, *Quercus ilex*, *Salix alba*, and the conifers *Abies*, *Cedrus*, *Cupressus sempervirens*, *Juniperus*, *Picea orientalis*, *Pinus brutia*, *and P. nigra*. Collections were made on attached branches, predominantly of *Pinus brutia*, followed by *Quercus ilex* and many of the other genera. A total of 10 *Orbilia* spp. were encountered. The most frequent species were *O. euonymi* (7 ×) and *O. subaristata* (7 ×); the remaining included *O. eucalypti*, *O. flavida*, *O. gambelii*, *O. ovalis* (only anamorph), *O. pleiomicrosoma*, *O. subovoidea*, *O. subvinosa* (only anamorph), and *O. vinosa*.

4c. **Southern Asia**: Tewari & Pant (1966) reported *O. sarraziniana* from Uttar Pradesh (northern **India**) as first record of an identified *Orbilia* from India (unillustrated). Thind & Sharma (1980) added for India *O. auricolor* s.auct., *O. curvatispora*, *O. luteorubella,* and *O. xanthostigma*, and Thind et al. (1983) *O. rubrococcinea*, but all these reports are of doubtful identity, except for *O. curvatispora* (= *O. auricolor*) which was reexamined here. Unidentified up to now remained Batra & Batra's (1963) orbiliaceous collections from India (see p. 199).

Ahmad's (1978) unillustrated report of 3 hygrobionts for **Pakistan** includes *H. ?inflatula* (as *O. auricolor*), *O. ?auricolor* (as *O. curvatispora*), and ?*O. dryadum* (as *O. leucostigma*). Two xerobiotic species were examined in the present study (*O.* aff. *caudata*, *O.* cf. *trapeziformis*). From tropical humid (winter-dry) **Thailand** Ekanayaka et al. (2018) recorded *H. erythrostigma*, *H. arcuata* (as *H.* cf. *inflatula*), *O. caudata*, *O.* aff. *renispora* (as *O. leucostigma*), and the dubious *O. stipitata* (p.p. = *O. nemaspora*), and during the present study J.P. Priou in 2012 *H. tortuosa* and C. Peller in 1996 *O. milinana*.

Figure 138: Subtropical humid evergreen broad-leaved forests in Yunnan, southern China; **left**: with *Castanopsis orthacantha*, *Cinnamomum*, *Cyclobalanopsis*, *Lithocarpus variolosus*, *Rhododendron*, 2560 m, Jizushan, Dali, collected in 20.X.2008, phot. 18.VIII.2005, Y. Zhang; lying branches of indet. angiosperms (2300 m: *Orbilia ?battenii*, *O. cejpii*, *O. eucalypti*, *O. fissilis*, jz-34, 36, 41, 46; 2700 m: *Hyalorbilia japonica*, *H. macrohelicospora*, *H. multiguttulata*, *H. ulicicola*, *O. binchuanensis*, *O. ?cardui*, *O. latispora*, *O. laevimarginata*, jz-1, 3–7); **right**: with indet. *Taxodiaceae*, 1700 m, base of mountain Laifengshan, Baoshan, collected in VIII.2004, phot. 14.VIII.2005, Y. Zhang; hygric branches of indet. ?gymnosperms (*H. arcuata*, *O. hoana*, *O. tenuispora*, tc-22–23, 51).

From **Vietnam** N. Petit collected in 1995 *H. tortuosa* and *O. ?subfabacearum*. The type of *O. fici* (= *O. blumenaviensis*) comes from **Singapore**, and *O. pseudobrevistipitata* was collected by P. Wagner in 1995 from **Philippines**. From tropical humid **Indonesia** Penzig & Saccardo (1902) described *O. neglecta* and *O. sinuosa* (?= *H. inflatula*/*H. japonica*), and Rifai & Cooke (1966) the anamorph of *O. javanica*.

4d. **Eastern Asia**: The regions of eastern Russia, China, Korea and Japan are subjected to a humid, more or less continental, monsoon-dominated, winter-dry climate that ranges from the subarctic to tropical belt. Best explored is China, followed by Japan and Russia, whereas no collection of a teleomorph from Korea is known to us. A majority of the recorded species can more or less be classified as hygrobionts. The few xerobiotic taxa were mostly encountered by accident on fallen substrate, not by systematic search. In conclusion, the occurrence of xerobiotic *Orbiliomycetes* in eastern Asia remains largely unexplored. Due to the restriction to sampling in moist habitats, collecting was preferably done from June to November, following the rainy period which lasts from April-May to September-October.

The cold-continental to boreal **Russian Far East** (mainly **Primorje** and **Sachalin**) was treated by Raitviir (1991: 356–362) with at least 10 orbiliaceous species: *H. inflatula*, *O. auricolor*, *O. cardui*, *O. crenatomarginata* (as *Hyalinia crystallina*), *O. ?epipora*, *O. eucalypti* (as *O. microclava*), *O. luteorubella* (including *O. ?rosea*), *O. orientalis*, *O. ?sarraziniana*, and *O. xanthostigma* (as *O. delicatula*, ?including *O. leucostigma*). Only *O. orientalis* (type) was reexamined in the present study. We also saw photos of *O. ?umbilicata* from cold-continental Primorje (2005, E. Popov), and studied a sample of *O. crenatomarginata* from extremely continental and rather dry, boreal **Sakha** (Yakutia, 1968, H. Remm).

Until the end of the 20th century, **China** was poorly explored for *Orbiliomycetes*. The first report by Teng (1939: 167, see also Teng 1996) listed only one species, *O. sinuosa* (?= *H. inflatula*). More recent reports include *O. auricolor* (Zhuang & Korf 1989, as *O. curvatispora*; Wu 1998), *O.* aff. *umbilicata* (as *O. xanthostigma*, Zhuang 1997), *O. xanthostigma* (as *O. delicatula*) and *H. inflatula* (Wu 1998). Many further, often new orbiliaceous species were reported in the 21th century by Guo et al. (2014a, 2014b), Li et al. (2009), Liu et al. (2005a, b, 2007a, b), Mo et al. (2005b), Qiao et al. (2012, 2015), Qin et al. (2011), Su et al. (2011c), Wu et al. (2007), Yu et al. (2006, 2007a, b, 2009a, b, 2011), Zhang et al. (2006, 2007, 2009b, 2015, 2016, 2020a), Zhuang & Hyde (2011). For the region of Tibet, Liu et al. (2006b) reported *H. inflatula* and 9 *Orbilia* spp. (including *O. bomiensis* and *O. milinana*). In his comprehensive unpublished monograph on the *Orbiliaceae* of China, Liu (2006) reported over 350 samples made by him and X.Z. Liu mainly between 2002–2005, some also between 1994–1999 and earlier, including 8 *Hyalorbilia* spp. and 20 *Orbilia* spp.

Besides these reports on taxa with a known teleomorph, many papers on taxa without a known teleomorph appeared since 1994. The total number of species with known teleomorph lies up to now at almost 100 when including Taiwan. Species diversity was much higher in the warm-temperate to tropical southern parts (roughly south of 34° latitude) in comparison with the cooler, oro- to supratemperate northern parts of China (or high altitudes in more southern and western China), i. e., about 90 % of all recorded species occurred in the warmer regions and only about 28 % in the cooler zones. Among those species from cooler zones which were not recorded in the warmer parts of the country are *O. bomiensis*, *O. cejpii*, *O. epipora*, *O. nemaspora*, *O. quercus*, *O. tremulae*, *O. xinjiangensis*, and *O. zhongdianensis*.

A majority of collections came from subtropical, monsoon-influenced, often purely broad-leaved, evergreen highland forests in southern China, being composed of, e. g., *Castanopsis orthacantha*, *Cinnamomum glanduliferum*, *Lithocarpus variolosus*, *Magnolia campbellii*, *Quercus* (*Cyclobalanopsis*) *glauca*, *Rhododendron delavayi*, and *Schima* '*argentea*', based on data from two frequently visited areas in Binchuan county (Dali, Yunnan), Jinguangsi virgin forest (Golden Light Temple, ~2500 m) and Jizushan (Chicken-foot Mountain, ~2700 m, Fig. 138), or mixed with conifers, e. g., a *Quercus schottkyana* (= *Cyclobalanopsis glaucoides*) and *Pinus armandii* dominated forest in the Longquan (Dalongkou) National Forest Park in Yimen county (Yuxi, Yunnan, ~1700–1800 m). Fragments of many of these collections made between 2003–2010 were sent to us for study, and the results were published in various papers (see above references).

From orotemperate to cold-temperate ± humid northeastern China (Heilongjiang, Jilin, Beijing) derive about 5 *Hyalorbilia* and 10 *Orbilia* spp. Most of them are hygrobionts, except for *O. jugulospora* and *H. juliae* and perhaps *O. cejpii*. From cold-continental western China (Xinjiang, Tibet) are *H. inflatula* and 8 *Orbilia* spp., with *O. bomiensis* and *O. milinana* and possibly *O. xinjiangensis* being xerobiotic, and from orotemperate central and southern China 4 *Hyalorbilia* spp. and 4 *Orbilia* spp., with *H. juliae* and possibly *O. zhongdianensis* being xerobiotic. In sum there are about 8 *Hyalorbilia* and 20 *Orbilia* spp. from these cooler, deciduous or conifer forest regions. Several of these species are rarities, whereas the most frequently collected ones were *H. inflatula* and *O. xanthostigma* (Liu 2006).

From warm-temperate humid regions of China derive about 6 *Hyalorbilia* and 26 *Orbilia* spp., from subtropical regions (particularly humid highlands) *Pseudorbilia bipolaris*, 13 *Hyalorbilia* spp., and 50 *Orbilia* spp., and from tropical humid regions *H. polypori* and 15 *Orbilia* spp. In sum there are min. 17 *Hyalorbilia* and 66 *Orbilia* spp. from the warm-temperate and evergreen forest regions. Many of them appear to be rarities as they were only collected at one site, but some are known from different regions, such as *H. arcuata*, *H. japonica*, *O. dorsalis*, *O. hoana*, *O. laevimarginata*, or *O. tenuispora*. Here, too, *H. inflatula* was by far the most often collected species (Liu 2006), whereas *O. xanthostigma* was only sometimes encountered in the (sub)tropics and only once in Yunnan (Liu 2006). In addition, numerous anamorph-typified taxa, mainly without known teleomorph, were recorded as soil isolates particularly from these warmer regions.

From **Japan**, earlier reports include those of *Orbilia* ?*epipora* (as *H. inflatula*), *O. sarraziniana*, and *O. luteorubella* by Otani (1990). 33 collections by T. Hosoya (1990–1997) and W. Gams (1997) were revised in the present study, with 3 *Hyalorbilia* and 16 *Orbilia* spp., the most often collected taxa being *O. xanthostigma* and *H. japonica*. Rarities were, e. g., *O.* ?*battenii*, *O.* ?*renispora*, *O. spirospora*, and *O. umbilicata*. More or less all of these species are hygrobionts. Most collections were from temperate areas in Honshu and Hokkaido, but 3 from the warm-temperate (*O.* ?*cejpii*, *O. tenuispora*, *O.* ?*umbilicata*) and 2 from the subtropical zone (*H. citrina*, *O. spirospora*). Among the anamorphic taxa, Morikawa et al. (1993) isolated *Lecophagus muscicola* in the subtropical zone of Honshu.

5. Australasia and Melanesia

Previous **Australian** reports comprise totally 9 teleomorphic orbiliaceous species. Spooner (1987) accepted 8 spp. growing on wood and bark of *Eucalyptus*, *Melaleuca*, *Xanthorrhoea*, and unidentified plants collected from 9 different locations at 15–270 m altitude: 7 around Melbourne (Victoria) in warm-temperate humid southeastern Australia (*Orbilia xantho-* or *leucostigma*, 1914, collector unknown; *Hyalorbilia inflatula*, *O. auricolor*, *O.* ?*dryadum*, *O. flexispora*, *O. scolecospora*, '*O. vinosa*', 1962–64, G. or K. Beaton), and 2 near Brisbane (Queensland) in subtropical humid (winter-dry) eastern Australia (*O.* ?*carpoboloides*, undated, F.M. Bailey; *H. inflatula*, 1981, B.C. Sutton). No collection data were available for 2 samples reported by Bell (2005), cultured on Australian dung (*H. inflatula*, *O.* ?*cejpii*). A sample from tropical humid Solomon Islands referred by Spooner (1987) to *O. juruensis* (Fig. 163) requires reexamination.

Previous records from **New Zealand**, mainly by P.R. Johnston between 1989–2008 and J.A. Cooper between 2010–2012, comprise only 4 species when not differentiating cryptic, morphologically indistinguishable taxa of the *xanthostigma-leucostigma* complex, based on a total of 35 selected collections from 29 sites, some of which being revised in the present study: *H.* ?*ulicicola* (1 ×) *O. cunninghamii* (16 ×), *O.* ?*luteorubella* (2 ×), *O. xanthostigma* (16 ×). Included is the type of *O. cunninghamii* described by Sydow (1924). The 29 sites belong to low or medium altitudes (2–745 m) across the entire length of the country from the cold-temperate very south to the subtropical north, all with a humid (slightly summer-dry) oceanic climate.

Anamorphic records from Australasia include a forest litter isolate of *O. oxyspora* from **Papua New Guinea** (Matsushima 1971) and 19 predacious species of series *Arthrobotrys*, *Dactylellina*, and *Gamsylella* isolated from soil, moss, wood and dung in Western **Australia** (Park et al. 2002).

The low number of species known before 1996 is a result of the former neglect of xeric substrates. As a matter of fact, only one of those older records, the type of *O. decipiens* (?= *O. carpoboloides*) described by W. Phillips (in Cooke 1887), represents a xerobiotic species, and no such species is known so far from New Zealand. In contrast to this, the numerous Australian records presented here are almost exclusively from xeric substrates. They raised the number of species with a known teleomorph for Australasia to 154, which suggests that also in New Zealand many xerobiotic species remain to be discovered.

Within **Australia**, teleomorphs of *Orbiliomycetes* were studied in the present monograph from a total of ~460 individual populations, when counting each species recorded within each collection. About 3–10 orbiliaceous species were observed per site on a given host species, though sometimes only 1 or rarely up to 14. Collections derive from almost 100 sites at 2–1073 m altitude from all around Australia. Many of them represent woodlands and forests in a region less then ca. 100 km from the coastline, but numerous others are more or less desertic shrublands in the so-called 'outback' which in the west extends to the seaside. Except for two humid sites from which collections were sent to us by E. Batten (Tasmania, *H. polypori*, 1996) and T.R. Lohmeyer (Victoria, *O. xanthostigma*, 2008) and older samples mentioned above, all these sites were investigated by one of us (G.M.) during four collecting trips in 1998, 2001, 2006, and 2007.

A majority of collections derive from subtropical semihumid (summer-dry), mediterranean forests and open woodlands in the southwest (32 sites) and (sub)tropical (semi)arid shrublands in the west and centre of Australia (36 sites). Other sites are in monsoon-influenced (winter-dry) tropical savannahs in the northwest and north, in rain forests in the tropical humid

Table 35. Major vegetation groups in Australia evaluated for all reported collection sites, with indication of the number of populations/species, thermo- and ombrotype, biogeographic region (ecoregion), and collected substrate.

Vegetation group	Pop./spp.	Thermotype	Ombrotype	Ecoregion	Collected substrate
acacia forests and woodlands	11/9	subtropical	semiarid to arid	Carnarvon, Murchison	*Acacia* sp., *Psydrax latifolia*, *Vachellia farnesiana*
acacia open woodland	22/19	subtropical	semiarid	Gascoyne, rarely Murchison	*Acacia* spp., *A. cyperophylla*, *Eucalyptus* sp.
acacia shrublands	128/71	subtropical to tropical	semiarid to arid, rarely semihumid	Avon Wheatbelt, Burt Plain, Carnarvon, Pilbara, Yalgoo, Desert Uplands, Great Sandy Desert, McDonnell Ranges, Finke, Geraldton Sandplains etc.	*Acacia aneura*, *A. coriacea*, *A. georginae*, *A. jennerae*, *Allocasuarina decaisneana*, *Atriplex nummularia*, *Brachychiton gregorii*, *Psydrax latifolia*
	2/2	tropical	savannah	Dampierland	*Adansonia gregorii*, indet. tree
casuarina forests and woodlands	4/4	subtropical	semihumid	Geraldton Sandplains	*Acacia* sp.
eucalypt low open forest (karri-tingle)	5/5	subtropical	semihumid	Jarrah Forest	*Chamaelaucium ciliatum*, *Banksia grandis*
eucalypt tall open forests (karri-tingle)	6/6	subtropical	semihumid	Warren	*Eucalyptus* sp., *E. jacksonii*
	3/3	warm-temp.	humid	South Eastern Highlands	*Nothofagus cunninghamii*, indet. trees
eucalypt open forests (jarrah-marri)	5/4	subtropical	semihumid	Jarrah Forest	*Banksia grandis*
	11/11	subtropical to cold-temp.	humid	Sydney Basin to Tasmanian Northern Slopes	*Eucalyptus* sp., *Melaleuca* sp., indet. trees
(banksia-) eucalypt woodlands	54/26	subtropical	semihumid	Swan Coastal Plain, Jarrah Forest	*Acacia* sp., *Anigozanthos manglesii*, *Arbutus andrachne*, *Banksia cuneata*, *B. grandis*, *B. menziesii*, *B. sessilis*, *Eucalyptus* sp., *Jacksonia* sp., *Melaleuca rhaphiophylla*, *Ptilotus polystachyus*
	53/40	warm-temperate to tropical	savannah, subhumid, humid	Dampierland, Brigalow Belt, Einasleigh Uplands, Stuart Plateau, Naracoorte Coastal Plain, NSW South Western Slopes, Darling Riverine Plains	*Acacia aneura*, *A. cheelii*, *Adansonia gregorii*, *Casuarina cunninghamiana*, *Eucalyptus* sp., *Geijera parviflora*, *Livistona nitida*, *Melaleuca* sp., *Pittosporum phillyreoides*, *Salix babylonica*, *Xanthorrhoea australis*
eucalypt open woodlands	54/34	subtropical	semihumid, semiarid	Jarrah Forest, Swan Coastal Plain, Geraldton Sandplains, Avon Wheatbelt, Mallee	*Acacia* sp., *Agonis flexuosa*, *Allocasuarina campestris*, *Banksia cuneata*, *Calothamnus* sp., *Eremaea* sp., *Eucalyptus* sp., *Hakea* sp., *Jacksonia* sp. *Macrozamia riedlei*, *Nuytsia floribunda*, *Verreauxia reinwardtii*, *Xanthorrhoea preissii*
	9/8		savannah, subhumid	Brigalow Belt South	*Casuarina cunninghamiana*, *Melaleuca* sp.
hummock grasslands	15/11	subtropical	semiarid to arid	Pilbara, Carnarvon, McDonnell Ranges	*Acacia* sp., *A. aneura*, *A. estrophiolata*, *Solanum lasiophyllum*
other forests and woodlands	19/11	subtropical	semihumid	Swan Coastal Plain	*Adenanthos sericeus*, *Anigozanthos manglesii*, *Eremaea pauciflora*, *Hibbertia aurea*
other shrublands	27/24	subtropical	semihumid, semiarid	Yalgoo, Geraldton Sandplains etc.	*Acacia* sp., *Dodonaea angustissima*, *Lamarchea hakeifolia*, *Nuytsia floribunda*
rain forests and vine thickets	23/17	tropical	humid	Wet Tropics and Einasleigh Uplands	*Acacia* sp., *Bambusa* sp., *Barringtonia racemosa*, *Cocos nucifera*, *Hibiscus tiliaceus*, *Licuala ramsayi*, *Phragmites australis*, indet. climber
tropical eucalypt woodlands/grasslands	2/1	tropical	savannah	Arnhem Plateau, Daly Basin	*Acacia* sp.
tussock grasslands	6/6	subtropical to tropical	arid	Pilbara	*Acacia* sp., *Ipomoea costata*

northeast, and in woodlands and forests in the subtropical to warm-temperate (sub)humid east and southeast of Australia (39 sites). Collected substrates were mainly wood and bark of angiosperms, such as *Acacia*, *Adansonia*, *Allocasuarina*, *Atriplex*, *Banksia*, *Dodonaea*, *Eremaea*, *Eucalyptus*, *Jacksonia*, *Lamarchea*, *Melaleuca* and *Nuytsia*, but also herbaceous stems, particularly *Anigozanthos* and *Phragmites*, and the somewhat woody *Solanum lasiophyllum*, stems of bamboo, and petioles of *Cocos*, *Livistona*, and *Macrozamia* (Tab. 35).

Among the overall ~154 species, for which a teleomorph was recorded in Australia, at least 9 belong to *Hyalorbilia* and 146 to *Orbilia* as circumscribed here. Based on the evaluated humidity zones, the following species numbers were obtained. When starting clockwise in the southwest of Australia, 55 spp. occurred in the mediterranean zone, 73 spp. in the semiarid zone (68 in the subtropical and 10 in the tropical belt), 43 spp. in the arid zone (38 in the subtropical and 6 in the tropical belt), 24 spp. in the savannah (12 in the subtropical and 12 in the tropical belt), 18 spp. in the humid tropical zone, 17 spp. in the subhumid subtropical zone, 12 spp. in the humid subtropical zone, and 13 spp. in the humid warm-temperate zone. In summary, 37 spp. occurred in humid and 37 in subhumid (savannah-like) zones, whereas 55 were found in semihumid and 94 in semiarid to arid zones (see also Tab. 33). Among the 9 *Hyalorbilia* spp., 5 occurred in the humid (*H. arcuata*, *H. citrina*, *H. inflatula*, *H.* cf. *orbiliicola*, *H. polypori*), 1 in the semihumid (*H. juliae*), 2 in the subhumid (*H.* aff. *erythrostigma*, *H.* aff. *orbiliicola*), 2 in the semiarid (*H.* aff. *orbiliicola*, *H. pleioerythrostigma*), and 1 in the arid zone (*H.* aff. *orbiliicola*). Only about 13 of the 154 species can be classified as more or less hygrobiotic.

The majority of Australian species, mainly of series *Hemiorbilia* and *Habrostictis*, appear to prefer (semi)arid (sub)tropical regions. However, many of them were also often recorded in the semihumid zone (*O. australiensis*, *O.*

Figure 139: Subtropical semihumid forests and woodlands in Jarrah Forest ecoregion, southwestern Australia; **left**: eucalypt open forest (jarrah-marri), 307 m, Beelu National Park, Kalamunda, 13.XII.2001, phot. G. Marson (#547); 28 km NW from there (#546, 2001 & 2006): attached branches of *Banksia grandis* (with *O. aviceps*, *O. curvatinavajoana*, *O. eucalypti*, *O. microserpens*, H.B. 7322, 8659); **right**: Eucalypt woodland, 272 m, Udumung Nature Reserve, Wannamal, 3.–4.IX.2006, phot. G. Marson (#952–953); attached twigs and branches of *Acacia* sp. and *Eucalyptus* sp., xeric petioles of *Macrozamia riedlei* (with *Orbilia albidorosea*, *O. australiensis*, *O. austroocculta*, *O. austroregalis*, *O. coronohesperidea*, *O. eucalypti*, *O. kingsiana*, *O. myrioobliqua*, *O. nothovinosa*, *O. pleiocrescens*, H.B. 8391, 8582, 8604, 8662).

Figure 140: Subtropical semihumid Eucalypt woodlands in Swan Coastal Plain ecoregion, southwestern Australia; **left**: banksia-eucalypt woodland, 48 m, Kings Park in Perth, 7.IX.2006 & 14.XI.2007, phot. G. Marson (#965–957); lying xeric stems of *Anigozanthos manglesii* (kangaroo paw, with *Orbilia anigozanthi*, *O. kingsiana*, *O. ?nothoaprilis*, H.B. 8303, 8831), attached branch of *Banksia grandis* (with *O. astrovinosa*); **right**: eucalypt woodland dominated by *Jacksonia* sp., 37 m, Walyunga National Park, Perth, Swan Coastal Plain ecoregion, 23.XI.2001, phot. G. Marson (#501); attached branches of *Jacksonia* (both sites together with 14 *Orbilia* spp., e. g. *O. albidorosea*, *O. austroocculta*, *O. austroregalis*, *O. kingsiana*, *O. myrioaustraliensis*, *O. myriofusiclava*, *O. myrioobliqua*, H.B. 7284).

Figure 141: Subtropical shrublands in Geraldton Sandplains, western Australia; **left**: semihumid shrubland, 278 m, Northampton, 9.XII.2001, phot. G. Marson (#539); attached branches of *Nuytsia floribunda* (yellow-flowered, with *O. brachychitonis*) and *Acacia* sp. (with *O. commarosa*, *O. eucalypti*, *O. myriofusiclava*, H.B. 7237); **right**: semiarid wood- and shrubland, 292 m, Moora, 25.X.2007, phot. G. Marson (#1110); attached twigs of *Calothamnus* sp. (with *Orbilia australiensis*, *O. hesperidea*, *O. myrioobliqua*, H.B. 8966). Collecting in these semiarid shrublands requires protection against insects.

Figure 142. Subtropical semiarid acacia and other wood- and shrublands in western Australia; **left**: with *Acacia*, *Lamarchea*, *Dodonaea*, *Callitris* (northern mallee), 190 m, Nerren Nerren, Yalgoo ecoregion, 8.XI.2007, phot. G. Marson (#1129); attached branches of *Dodonaea viscosa* subsp. *angustissima*, *Acacia* sp., and *Lamarchea hakeifolia* (with *Hyalorbilia pleioerythrostigma*, *Orbilia fimbriata*, *O. gemma*, *O. lamarcheae*, *O. myriolilacina*, *O. pseudoflagellispora* and further 13 *Orbilia* spp., H.B. 8838, 9020, 9050); **right**: acacia shrubland (mulga), 67 m, Overlander Roadhouse, Carnarvon ecoregion, 7.XII.2001 & 6.XI.2007 (#533); attached branches of *Acacia* sp. (with *O. myriella*, *O. myrioauris*, *O. myriofusiclava*, *O. myrionanosoma*, *O. myriopseudoregalis*, *O. pleistoobliqua* and further 6 *Orbilia* spp., H.B. 7215, 8727).

pleioaustraliensis, *O. myrioobliqua* etc.). *O. myrioobliqua* belongs to a morphologically extraordinary group of 8 species with 32–128-spored asci within series *Vibrioides* which are so far only known from semihumid to arid western Australia. A number of species might be endemic to the mediterranean southwest, such as *O. anigozanthi*, *O. austroocculta*, *O. astrovinosa*, *O. aviaristata*, *O. aviceps*, *O. curvatinavajoana*, *O. nanosperma*, and *O. triangulispora*, but the low number of records is probably the reason for this restriction. The most often collected species in Australia, *O. eucalypti*, was so far exclusively found in the mediterranean zone. Other species, e. g. *O. myrioobliqua* and *O. myriofusiclava*, occur here but also in the semiarid zone, and various further ones, such as *O. pleioaustraliensis*, *O. multiserpens*, *O. myriella*, *O. pleioaustraliensis*, *O. pleioserpens*, and *O. pluristomachia*, were mainly found in the semiarid but also in the semi- to subhumid or arid zone.

A **subtropical semihumid** climate, reminiscent of the European mediterranean belt, characterizes the southwest of Australia and a large not investigated area around Adelaide in the southeast. Different main vegetation groups can be distinguished within this summer-dry region: in the very south of the hilly Darling Range it is the dense eucalypt tall open forest (karri-tingle) in the Warren ecoregion (Fig. 139 left), with a height of ~20–60 m and the highest humidity, with *Eucalyptus diversicolor* (karri) and *E. jacksonii* (red tingle) as typical species. Collections were made on *Eucalyptus* at 60–300 m a.s.l. and include *Orbilia aviaristata*, *O. lilacina*, *O. nanosperma*, *O. pseudoflagellispora*, and *O. subalbovinosa*, and in a eucalypt low open forest on *Banksia* and *Chamelaucium* at 75 m also *O. aviceps*, *O. triangulispora* and others. To the north follows the eucalypt open forest (jarrah-marri), characterized by *E. marginata* (jarrah) and *Corymbia calophylla* (marri), with records of *O. aviceps*, *O. curvatinavajoana*, *O. eucalypti*, and *O. microserpens* on *Banksia grandis* at 70–370 m a.s.l.

Around the Darling Range occur remaining fragments of the banksia-eucalypt woodlands, with a height of ~10–20 m, mainly composed of *Banksia grandis*, *B. menziesii*, *Eucalyptus marginata* and other eucalypt and acacia species (Fig. 139 right, 140 left) or *Jacksonia* (Fig. 140 right), besides casuarina and other forests and woodlands with various trees and shrubs, for instance *Nuytsia* (Fig. 141 left). Numerous species have been recorded here on these and various other substrates at 10–200 m a.s.l., including *O. anigozanthi*, *O. curvativitalbae*, *O. eucalypti*, *O. kingsiana*, *O. multicurvula*, *O. myriofusiclava*, *O. myrioobliqua*, and *O. nothovinosa*.

The region of **subtropical to tropical semiarid to arid** western and central Australia is represented by the Pilbara desert and the large centre of Australia which includes the McDonnell Ranges. The summer-dry region comprises two main types: (1) eucalypt open woodlands (mallee), in semiarid areas the dominant vegetation with multistemmed, ~10–20 m tall eucalypts, e. g., northern (Figs 141 right, 142 left) and southern mallee shrubland and heath (Nevill & McQuoid 1999), and (2) acacia shrublands (mulga) in semiarid and arid areas, dominated by

Figure 143: Tropical woodlands and forests in Northern Australia; **left**: subhumid Eucalypt open woodland (savannah) with tussock grass understory, 20 m, Fitzroy river, Dampierland ecoregion (Kimberley Plateau), 1.XI.2007, phot. G. Marson (#519); attached branch of *Adansonia gregorii* (baobab, with *Orbilia brachychitonis*, *O. carminorosea*, *O. euphorbiae*, H.B. 8777); **right**: humid rainforest and vine thicket, 15 m, Cape Tribulation, Wet Tropics ecoregion, 30.VIII.2006, phot. G. Marson (#936); originally vertical branch of *Hibiscus tiliaceus* (with *O. spirillospora*, *O. ?subfabacearum*, H.B. 8487).

Acacia aneura (Fig. 142 right), with multistemmed, up to ~5–10 m tall shrubs occurring in various ecoregions of the outback. Collections were made on *Atriplex*, *Allocasuarina*, *Acacia*, *Brachychiton*, *Dodonaea*, *Lamarchea* etc. at 5–700 m a.s.l. and include *O. australiensis*, *O. pleioserpens*, *O. multiserpens*, *O. myriomuscula*, *O. myrioobliqua*, *O. pleioaustraliensis*, *O. pluristomachia* and many others, a total of 94 *Orbilia* spp. The unexpected occurrence of rather dense and high acacia forests and woodlands as well as tussock grasslands in the semiarid to arid Pilbara desert is explained by a restriction to dry river flats.

The monsoon-influenced region of **tropical subhumid** northwestern and northern Australia (Fig. 143 left) in the Kimberley Plateau and Arnhem Plateau shows a savannah-like vegetation with dry but very mild winters. Typical are the scattered water-storing baobab trees (*Adansonia gregorii*) and *Acacia* spp., and a widespread tussock grass understory that grows during summer but is straw-coloured during winter. Collected substrates at 10–300 m a.s.l. include *Acacia aneura*, *Adansonia gregorii*, *Eucalyptus* sp. etc., with *Orbilia arachnopus*, *O. brachychitonis*, *O. carminorosea*, *O. euphorbiae*, *O. hesperidea*, and *O. paracaudata*.

Continuous and heavy summer rainfalls occur in the rainforests and vine thickets of **tropical humid** northeastern Australia at the northern end of the Great Dividing Range (monsoon-dominated evergreen forest, Fig. 143 right), though with a dry period during several months. Despite the high annual precipitation, drought-tolerant species occur in the dry season here. Collected substrates at 5–400 m a.s.l. include *Acacia* sp., *Bambusa*, *Cocos nucifera*, *Hibiscus tiliaceus*, and *Licuala ramsayi* in the Wet Tropics ecoregion, and *Barringtonia racemosa* and *Phragmites australis* in the more savannah-like Einasleigh Uplands, with 18 orbiliaceous species (4 in *Hyalorbilia*), e.g., *H. arcuata*, *O. bambusina*, *O. neocomma*, *O. nothoaprilis*, and *O. spirillospora*.

Records from **subtropical subhumid** (north)eastern Australia (winter-dry, monsoon-dominated savannah-like vegetation) derive from eucalypt (open) woodlands in the northern part of the Great Dividing Range at 100–300 m a.s.l., mainly in the large Brigalow Belt South ecoregion. Collected substrates were *Casuarina cunninghamiana*, *Eucalyptus* sp., *Geijera parviflora*, *Livistona nitida*, *Melaleuca* sp., and *Pittosporum phillyreoides*, on which more than 20 xerobiotic *Orbilia* spp. were observed, e.g., *O. angustoaristata*, *O. corculispora*, *O. geijerae*, *O. nothovinosa*, and *O. palmicola*. The holotype of *O. decipiens* (?= *O. carpoboloides*) from the coastal region of Brisbane also belongs to this climatic zone.

Collections from **warm-temperate (sub)humid** southeastern Australia (not or only slightly winter-dry forests and woodlands) in the southern part of the Great Dividing Range include 15 xerobiotic *Orbilia* spp. (e.g., *O. arachnopus*, *O. multinanosoma*, *O. myrioeuonymi*) which derive from eucalypt woodlands at two sites in the Central Tablelands west of the mountain range at 500–550 m a.s.l. and from eucalypt open forests at two sites in the Blue Mountains at 850–1050 m. Despite the high altitude the climate is warm-temperate there. Collections of hygrobiotic species from south and east of the southern Snow Mountains and Tasmania include eucalypt tall open forests at 100–600 m a.s.l. (*H. inflatula*, *O. dryadum*, *O. xanthostigma*), but also eucalypt open forests and eucalypt woodlands at 20–250 m (*H. polypori*, *O. flexispora*, *O. scolecospora*). Collected substrates include *Eucalyptus* sp., *Melaleuca* sp., *Salix babylonica*, and *Xanthorrhoea australis*.

6. North America

6a. **Northern America** (**including Greenland**): Previous reports of orbiliaceous teleomorphs include mainly those from eastern Northern America: from **Pennsylvania** (Schweinitz 1832, *Orbilia xanthostigma*, as *Peziza rufula*), **New Jersey** (Cooke 1875a, *O. cookei*, as *P. exigua*; Cooke & Ellis 1878, *O. regalis*; Rehm 1885, *O. occulta*), **Ohio** (Bachman 1909: 57, *H. inflatula*, as *O. auricolor*; *O. ?cejpii*, as *O. coccinella*; *O. ?dryadum*, as *O. xanthostigma*; '*O. vinosa*'), **Virginia** (Berkeley 1875, *O. carpoboloides*, as *P. fibriseda*), **Kentucky** (Rehm 1883, *O. carpoboloides*, as *Calloria rubrococcinea*), and **Alabama** (Berkeley (1875, *O. saccharifera*), **exceptionally** from the west, i.e., from **California** (Phillips & Harkness 1884, *O. eucalypti*). From the northwest are records from **Alaska** (Korf in Kobayasi et al. 1967, *O. ?eucalypti*, as *O. coccinella*?; *Orbilia* sp.), and from the northeast from **Québec** and **Ontario** (Haines & Egger 1982, *O. carpoboloides*, as *O. piloboloides*). Seaver (1951) included a few more or less unclear orbiliaceous species, such as *O. luteorubella* and *O. rubella*, but merged some of the above under *O. cruenta*.

About 120 records, mainly teleomorphic, made after 1990 by others than us in the northwest and particularly north- to southeast of Northern America came to our notice, either by receiving documents and/or molecular data or through personal studies by one of us (H.B.): from **Alaska** (D.H. Pfister & B. Liu in 2011, *O. ocellata*), **British Columbia** (O. & A. Ceska in 2013–2017, 7 spp.; C. Peller 1996, *O. canadensis*), **Ottawa** (J. Mack in 2013–2015, 2 spp.), **Quebec** (J. Cimon in 2009–2013, 3 spp.), **Greenland** (A. Raitviir in 2000, 3 spp.), **Prince Edward Island** (A. Carter in 2018–2019, 4 spp., two of them anamorphic), **Nova Scotia** (C. Peller 1996, 3 spp.), **Massachusetts**, **Maine** and **New York** (D.H. Pfister in 1994–96, Pfister 1997, B. Liu in 2011, D. Haelewaters, L. Quijada, A.C. Dirks, L.A. Kappler etc. in 2013–17, Haelewaters et al. 2018, E. Crenson in 2017–2019, ~25 spp.), **North Carolina** and **Tennessee** (Kohlmeyer et al. 1998, *O. junci*, W. Jaklitsch in 2003, 4 spp.), **Georgia** (Shao et al. 2018, 6 spp.), and **Florida** (1998, L. Ferron, 2 spp.; 2017, B. Kaminsky & D. Borland, R. Healy, 4 spp.).

All these records together represent about 50 different species (when omitting cryptic, morphologically indistinguishable taxa), all of which being from more or less humid (rarely semihumid, California) areas. They were mainly on woody gymno- and mainly angiosperms, rarely on herbaceous mono- and dicot stems. Despite the humid climate about 27 of these 50 species are xerobiotic.

A total of about 124 orbiliaceous purely xerobiotic species (including unnamed ones) were discovered during seven collecting trips in 1991, 1994, 1995, 1996, 1997, 2000, and 2003 by one of us (G.M.). A total of 127 collection sites were visited from which orbiliaceous species are reported here. Except for four sites from the Prairies of **Texas**, all are located in the western parts of Northern America in the region of the Canadian and mainly US-American Rocky Mountains, Colorado Plateau, and the deserts of Mojave, Sonora, and Chihuahua. Among these 127 sites, 46 lie in **Arizona** and 42 in **Utah**, but only 7 in **Colorado**, 6 in **British Columbia**, 4–5 in **New Mexico**, **Idaho**, and **Nevada**, and 1–3 in **California**, **Wyoming**, and **Montana**. The 127 sites embrace climatic zones with very diverse temperature and moisture parameters, ranging from hot arid deserts with different kinds of shrublands and succulent steppes

Table 36. Major vegetation groups tentatively evaluated for all collection sites in western United States, with indication of the number of recorded populations and species of *Orbiliomycetes*, thermo- and ombrotype of sites, biogeographic region, and collected substrate. ctmp = cold-temperate, wtmp = warm-temperate, wcont = warm-continental, subtr = subtropical; hum = humi, shum = subhumid, sar = semiarid, ar = arid; MRoMt = Middle Rocky Mountains, SRoMt = Southern Rocky Mountains, GrBas = Great Basin, ColumPl = Columbia Plateau, WyoBas = Wyoming Basin, ColPl = Colorado Plateau, MojDes = Mojave Desert, SonDes = Sonoran Desert, ChihDes = Chihuahuan Desert.

Vegetation group	Populations/ species	Thermo-type	Ombrotype	Ecoregion	Collected substrate

up to cold-temperate or boreal humid conifer forests, according to the high variance in altitude and latitude in this mountainous western part of the continent.

The seven collecting trips yielded 460 here registered orbiliaceous records (populations), which increase the total species number for Northern America to around 162 (176 when including unnamed taxa). About 75 of these 162 species were so far exclusively observed in this continent,

Figure 144: **left**: Subtropical semiarid Sonoran paloverde-mixed cacti desert scrub, with *Carnegiea gigantea*, *Cylindropuntia versicolor*, *Fouquieria splendens*, *Larrea tridentata*, *Olneya tesota*, *Opuntia engelmannii* etc., 745 m, near Visitor Center, Saguaro National Park, Tucson, Arizona, 30.V.2003, phot. G. Marson (#716, H.B. 8085); xeric branches *Olneya tesota* (*O. ?barrowensis*, *O. maeandrina*, *O. multigambelii*, *O. multicreosoteris*, *O. myrioolneyae*, *O. myriourosperma*). **right**: Warm-continental semiarid sagebrush desert scrub with *Artemisia tridentata* and *A. filifolia*, 1813 m, near Hatch Rock, La Sal Mts. in background, Canyonlands National Park, Colorado Plateau, Utah, 16.VI.2000, phot. G. Marson (#263, H.B. 6736); collected nearby in dry riverbed, xeric branches of *Ericameria nauseosa* (*O. delphinus*, *O. dixiensis*, *O. lentiformis*, *O. mesaverdiana*, *O. multimaeandrina*, *O. plurilentiformis*, *O. phanosoma*, *O. multitrapezoidea*, *O. myriophanosoma*, *O. ocellata*).

Figure 145: Warm-continental semiarid shrubland with *Pinus*, *Juniperus*, *Artemisia* etc. in the pinyon-juniper woodland, 1590 m, Devils Garden, Arches National Park, Utah, 8.VI.2003, phot. G. Marson (H.B. 8051); xeric branches of *Fraxinus anomala* (*O. multimaeandrina*, *O.* aff. *paloverdensis*).

of which most are ± xerobiotic, except for *O. renispora* and *O. xanthoflexa* which represent the only seemingly endemic hygrobionts in Northern America.

Species diversity among the different climatic zones was found to be rather equal, although the proportion between xero- and hygrobionts strongly differs, being around 69 : 26 (= 2.65 : 1) in the temperate humid zones, 62 : 2 (= 31 : 1) in the subhumid zones, and 65 : 0 in the semiarid to arid zones (Tab. 33). The relation between population and species numbers indicate that on average about every second or third encountered population belonged to a different species. However, some of the species have been found much more often than others, the most frequent in the west of United States being *O. maeandrina* (25 ×), *O. delphinus* (22 ×), *O. lentiformis* (19 ×), *O. bicknellensis* (15 ×), *O. calyptrata* (13 ×), *O. multimaeandrina* (13 ×), *O. ocellata* (13 ×), *O. macrodelphinus* (12 ×), and *O. flexisoma* (10 ×).

Various species showed a restriction to a given climatic zone, based on the available data. For instance, *O. cactacearum* (5 ×), *O. cryptogena* (6 ×), *O. multigambelii* (9 ×), *O. myriourosperma* (5 ×), *O. pleiomesaverdiana* (5 ×), *O. pluristomachia* (7 ×), *O. sonorensis* (9 ×) and several others occurred only in different arid to semiarid grass- and shrublands at altitudes around 600–1700 m, *O. bicknellensis* (15 ×) and *O. calyptrata* (13 ×) in addition also in semiarid to subhumid shrub- and woodlands at altitudes around 1500–2000 m. The following species preferred humid forests at about 1800–2800 m: *O. aristata* (3 ×), *O. clavipisca* (3 ×), *O. coniferarum* (4 ×), *O. euonymi* (7 ×), *O. delphinus* (22 ×), *O. gambelii* (8 ×), *O. magnifica* (5 ×), and *O. vinosa* (3 ×). Others, particularly the more frequently collected ones, showed little adaptation, e. g., *O. lentiformis* (22 ×) and *O. maeandrina* (25 ×) occurred from the subtropical (semi)arid deserts up to the boreal humid conifer forests.

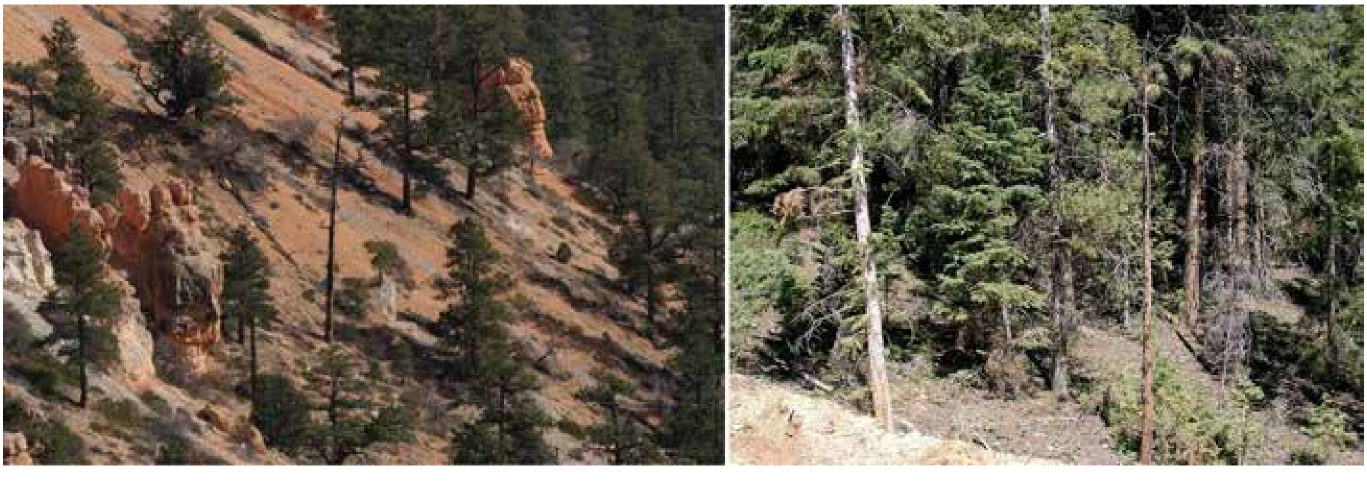

Figure 146: Cold-temperate (sub)humid Rocky Mountain montane conifer forests in Bryce Canyon, Utah; **left**: ponderosa pine forest with *Pinus ponderosa* and *P. edulis*, 2300 m, Navajo trail SE of Sunset Point, 25.VIII.1994 & 20.VI.2000, phot. G. Marson (H.B. 5164, 6744); xeric branches of *Cercocarpus ledifolius* (*O. pleionavajoana*) and *Acer* sp. (*Orbilia cupularis*, *O. microsoma*, *O. multimaeandrina*, *O. navajoana*). **right**: Douglas fir mixed forest with *Abies concolor*, *Pseudotsuga menziesii*, and *Pinus* sp., 2500 m, near Trough Spring, 13.VI.2003, phot. Four belts have been recognized in the region of the Rocky Mountains and Colorado Plateau following the classification in Elmore & Janish (1976). They correspond to or comprise different plant comunities and differ from each other by ascending moisture and descending temperature. However, these belts and plant comunities are not sharply separated from each other because various, often characteristic plants occur across several of these belts, and mainly the predominance of a plant serves as a key character (GAP-reference).

The pinyon-juniper belt (1200–2100 m) is represented by the pinyon-juniper woodland, the pine-oak belt (1900–2800 m) corresponds to the ponderosa pine forest, the montane fir-aspen belt (2600–3100 m) to the Douglas fir mixed conifer forest, and the spruce-fir belt (3100–3800 m) to the Engelmann spruce forest and other subalpine conifer forests. The given altitudinal levels refer to the Colorado Plateau (see C. Hart Merriam). They depend on the geographical latitude and the exposition of the area: from the south to the north of the Rocky Mountains the elevation boundaries between these communities and between the corresponding climatic zones decrease, e. g. between the cold-temperate and boreal zone from about 2500–2700 m in the south to 1200–2000 m in the north of the United States (according to climate zones map); at the same altitudinal level, the cool north slopes and dry south slopes differ in vegetation density and composition, e. g., a pinyon-juniper woodland may occur on a south-exposed slope of a mountain and a ponderosa pine forest on its northern slope.

The treeless **semideserts** are characterized by a semiarid to arid ombrotype and occur particularly on dry plains and mesas, either at the base of these belts or also at higher altitude. Different types of sclerophyllous chaparral scrublands and desert scrubs but also grasslands grow in these regions. Depending on the geographical latitude and altitude, their thermotype is subtropical, warm-temperate, warm-continental, or cold-temperate. Semideserts are mainly located in the landscapes of the Colorado Plateau, Great Basin, Mojave Desert (including Death Valley), Sonoran Desert, and Chihuahuan Desert (Mexican highland). Climatic and geological conditions determine the plants by which these semideserts are dominated, such as *Arctostaphylos patula* (greenleaf manzanita), *Artemisia tridentata* (big sagebrush, Fig. 144 right), *Atriplex* spp. (saltbush), *Coleogyne ramosissima* (blackbrush), *Krascheninnikovia lanata* (winterfat), *Larrea tridentata* (creosote bush), *Sarcobatus vermiculatus* (greasewood) etc. However, some of these 'monocultures' are man-made, e. g., the expansion of grazing-resistant sagebrush was provoked by livestock grazing since the late 1800s which also suppressed wildfires. In the Sonoran Desert different *Cactaceae*, such as *Cylindropuntia* spp. (cholla), *Fouquieria splendens* (ocotillo), and the large *Carnegiea gigantea* (saguaro), but also *Parkinsonia* spp. (paloverde) and *Olneya tesota* (ironwood) are characteristic (Fig. 144 left). The second highest number of orbiliaceous records and species comes from this vegetation complex (Tab. 36). At the end of the Ice Age, the area of the desert scrubs was dominated by pinyon-juniper woodland and grassland which later retreated to the foothills of the nearby mountains.

The **pinyon-juniper woodland** (Fig. 145) includes a cold- to warm-temperate or warm-continental, semiarid to subhumid climate and typically consists of *Pinus edulis* (Colorado pinyon pine) and *Juniperus osteosperma* (Utah juniper). The shrubs and small trees grow scattered and develop on well-drained, mainly non-acidic soils. Pinyon-juniper woodlands are widespread in the Great Basin, Colorado Plateau, and Rocky Mountains. Many areas show desertification of understory conditions since the late 1800s through livestock grazing by suppressing former fire regimes. The highest number of orbiliaceous records and species comes from this vegetation complex (Tab. 36). Frequently recorded species were, e. g., *Orbilia arizonensis, O. flexisoma*, *O. lentiformis*, *O. macrodelphinus*, *O. maeandrina*, *O. multimaeandrina*, and *O. purshiae*.

The montane **ponderosa pine forest** (Fig. 146 left) includes a cold-temperate (subhumid to) humid climate and is typically composed of *Pinus ponderosa* and *Quercus gambelii* (Gambel oak). The trees are tall, straight and evenly spaced, allowing sunlight to penetrate to the forest floor. Ponderosa pine forests occur on slopes and high plateaus of the mountain ranges in Arizona and Utah. Also here wildfires play a dominant role, and grazing has altered the vegetation. Frequently recorded species were, e. g., *Orbilia delphinus*, *O.gambelii*, and *O.microsoma*.

The montane **Douglas fir mixed forest** (Fig. 147 left) occurs under a cold-temperate to boreal humid climate and typically consists of *Pseudotsuga menziesii* (Douglas fir), *Abies concolor* (white fir), and *Picea pungens* (blue spruce). On poor soil and after wildfires this forest may be replaced by pure stands of *Populus tremuloides* (quaking aspen). Frequently recorded species were, e. g., *Orbilia coniferarum*, *O. delphinus*, *O. euonymi*, and *O. maeandrina*.

The **Engelmann spruce forest** (Fig. 147 right) includes a boreal humid climate and forms the uppermost forest belt, in correspondence to the subalpine zone of the European Alps. It is mainly composed of *Picea engelmannii* and *Abies concolor*, sometimes associated with *Populus tremuloides*. Like the Douglas fir mixed forest, Engelmann spruce forests occur across the entire Rocky Mountains and Colorado Plateau above a critical altitude. Despite a high annual humidity, intense wildfires may temporarily replace these conifer forests by pure aspen stands. In this vegetation type occurred, e. g., *O. lentiformis*, *O. macrodelphinus*, and *O. maeandrina*.

In the boreal humid climatic zone occurs in the upper montane to subalpine Rocky Mountains, especially in their northern part (Montana), the **lodgepole pine forest**, which is dominated by *Pinus contorta*, a species that also requires wildfires for germination. Only *O. atrolentiformis* and *O. pileosoma* from near the Yellowstone National Park were recorded in this vegetation type. No records were available from another subalpine forest, being restricted to the southeast of Northern America, the **bristlecone pine forest** represented by *Pinus longaeva*, *P. aristata*, or *P. flexilis*. It occurs above the spruce-fir forests adjacent to the alpine tundra and is known for its very old trees.

6b. **Middle America**. Only a few species have previously been reported from the Carribean islands and the mainland of Middle America, namely *Hyalorbilia citrina* from **Dominica** (Smith 1901) and *Orbilia ?auricolor*, *?O. epipora*, and *O. juruensis* from **Panama** and **Cuba** (Dennis 1954 & 1970). From **Lesser Antilles** (**Guadeloupe** and **Martinique**) Patouillard & Gaillard (1889) reported *O. lancicula* as common (see also Dennis 1954), which from its type from French Guiana is a *Hyalorbilia* (*?H. inflatula*).

Sporadical collecting after 1970 revealed some other orbiliaceous species (see Appendix 2). The investigated regions include the mainly subtropical semiarid northwest of **Mexico** (**Baja California**, 1990–96, R. Galán et al., 4 spp.) and the tropical humid mainland and Carribean region: **Costa Rica** (1992, G. Kost, *O. aureocrenulata*), east of **Mexico** (**Cancun**, 2004, M. Eckel, *O. cocois*; **Veracruz**, 2018, L. Quijada, *O. aureocrenulata*), **Puerto Rico** (1970, R.P. Korf, 3 spp.; 1996, D.H. Pfister et al., 12 spp.; 2018, L. Quijada, *O. jesu-laurae* [Quijada et al. 2020], *O. milinana*), **Dominica** (1970, R.P. Korf, 3 spp.), **Jamaica** (1971, R.P. Korf, 4 spp.), **Guadeloupe** and **Martinique** (2005–6, C. Lechat, 10 spp.). This results in a total number of 23 species known from Middle America (when neglecting unclear literature reports). Four of them were so far only recorded here (*H. puertoricensis*, *O. cocois*, *O. jesu-laurae*, *O. subuliformis*), and only about six of them are desiccation-tolerant.

7. South America

For the South American continent only sparse records exist in the literature. From the more northern, (sub)humid subtropical highlands and tropical lowlands the following species were known (Dennis 1954, 1970, Patouillard & Gaillard 1889, Rehm 1895, Jeng & Krug 1977, Rubner 1996): from **Ecuador** *Hyalorbilia andina* (as *Orbilia auricolor*), *H. anonyma*, *H. citrina* (type of *O. andina* var. *lateritia*), and *O. elegans* (apothecia obtained in culture); from **Trinidad** *Orbiliaster pilosus* (type), *Orbilia alba* (type), and *O. ?crenatomarginata* (type of *O. curvatispora* var. *minor*); from **French Guiana** *?Hyalorbilia* sp. (type of *O. lancicula*); from **Venezuela** *H. ?inflatula* (as *O. lancicula*), *O. gaillardii* (type), *O. ?oxyspora* (type of *O. fimicola*), *O. tenuissima*, *O. xanthostigma*, and *Orbilia* sp. (the latter two not further specified by Dennis 1970).

From more southern, tropical to cold-temperate (sub)humid regions the following species were known (Hennings 1902a, Höhnel 1907b, Montagne 1853, Romero 1994, Spegazzini 1889, 1909, Starbäck 1899): from **Paraguay** *O. tenuissima* (type); from **Brazil**: *H. citrina* (type of *O. crenulatolobata*), *O. blumenaviensis* (type), *O. brasiliensis* (type), *O. caudata* (type), *O. disseminata* (type), *O. juruensis* (type); from **Argentina** *H. inflatula*, *O. carpoboloides* (as *O. chordicola* and *Helotium marmolense*), *O. nemaspora* (as *Orbilia* sp.), *O. ?scolecospora*, *O. xanthostigma* (as *O. delicatula*)); from **Chile** *O. xanthostigma* (as *Helotium persoonii*).

More recent records include those from tropical humid **Venezuela** (1996, D.H. Pfister et al., *H. citrina*) and **French Guiana** (C. Lechat in 2007, *H. citrina*, *O. guyanensis*), subtropical (sub) humid highlands of **Colombia**, **Ecuador**, **Peru**, and **Bolivia** (W. Jaklitsch in 1994, *O. ?caulicola*, *O. colombiana*, *O. eucalypti*, *O. ?flavidorosella*; L. Beenken & C. Hahn in 1998, *H. erythrostigma*, *O. gaillardii*; J.P. Priou in 2005, *O. colombiana*, *O. puyae*), and tropical humid rain forests in southern **Brazil** (M. Mann in 2011, *H. citrina*, *O. aureocrenulata*).

The total number of species known from South America at present lies at 31. Endemic taxa of the continent could be *H. anonyma*, *O. brasiliensis*, *O. colombiana*, *O. disseminata*, *O. gaillardii*, *O. guyanensis*, and *O. puyae*.

HISTORY OF TELEOMORPH GENERA

Generic concepts in the literature. In the course of the past 200 years, taxonomic concepts of genera and species of orbiliaceous fungi have undergone severe changes due to a different emphasis on special characters of the teleomorph. Characters nowadays considered as taxonomically less reliable, such as ascospore shape and septation, paraphysis shape, and hair characteristics, or macroscopic features, had a prevalent impact on the generic concepts of previous authors. At the time of the first reports of this group of fungi (Persoon 1801, Albertini & Schweinitz 1805, Fries 1815, Schweinitz 1832), macroscopic features such as colour, translucency, shape, and consistency of the apothecia, including structure of the margin and presence of a stipe, were the basis for the recognition of species in discomycetes and their division into genera. The name *Orbilia* is derived from the more or less circular and smooth outline of the usually sessile apothecia, a rather unspectacular feature. A somewhat waxy or gelatinous consistency and a certain translucency is often attested as characteristic of the group. Because species delimitation in the early times has mainly been a matter of apothecial pigmentation, most names of the older taxa of *Orbilia* refer to apothecial colour.

With the works of Berkeley & Broome (1860–75), Nylander (1869), Karsten (1861–85), Fuckel (1870–74) and others, microscopic features of ascomycetes, such as size and shape of the ascospores and shape of the paraphyses, were found to be taxonomically valuable and, therefore, briefly mentioned in the diagnoses. Such features were also described in some orbiliaceous fungi, in which spore characteristics were found to provide good species markers, whereas paraphysis characteristics were used more at the generic level. Boudier (1885) introduced the truncate apex and bifurcate base of asci and Rehm (1891: 453) their negative iodine reaction as more or less consistent key characters of the group. Boudier considered the presence of teeth at the apothecial margin as a generic character to distinguish *Hyalinia* from *Orbilia*.

Crouan & Crouan (1867), Berkeley & Broome (1873), Patouillard (1892b), and Boudier (1904–10) were the first to provide detailed illustrations of orbiliaceous fungi. Their microdrawings attest to the good quality of the microscopes of that epoch. Patouillard was the first to observe spore bodies in the living ascospores. Yet, this valuable character was almost completely neglected during the next hundred years.

Particularly in those early times, the orbiliaceous fungi were not clearly recognized as a well-defined natural group distinct from macroscopically similar taxa of *Helotiales* or *Pezizales*. Indeed, confusion with various quite distant genera frequently happened. During the 19th and 20th century, orbiliaceous fungi have been placed in not less than 30 different teleomorph-typified genera (for the many anamorph-typified genera see p. 214 ff.). According to their type species, 15 out of these 30 genera are today considered to belong to the *Helotiales* (*Calloria*, *Dasyscyphus*, *Helotiopsis*, *Helotium*, *Hymenoscyphus*, *Laetinaevia*, *Mollisia*, *Mollisiella*, *Ocellaria*, *Patinella*, *Pezicula*, *Pezizella*, *Pithyella*, *Pseudohelotium*, *Trichopeziza*), two in the *Phacidiales* (*Phacidium*, *Tympanis*), three in the *Pezizales* (*Lachnea*, *Humaria*, *Peziza*), and three in the *Basidiomycota* (*Craterocolla*, *Lachnella*, *Hirneola*).

The remaining seven genera are today considered to be orbiliaceous from their type species. Four of them achieved general acceptance during the 20th century: species with a dentate apothecial margin of agglutinated, non-septate glassy hairs were segregated in the genus *Hyalinia* Boud. (1885, paraphyses uninflated), species with non-agglutinated, septate hairs in *Orbiliaster* Dennis (1954, paraphyses uninflated) or *Habrostictis* Fuckel (1870, paraphyses inflated and beaked, apothecia erumpent), and species with a smooth margin in *Orbilia* Fr. (1836, paraphyses capitate, apothecia superficial). Two further genera were placed in synonymy: *Cheilodonta* Boud. (1885) with *Habrostictis*, and *Orbiliella* Kirschst. (1938) with *Orbilia*, and a third (*Radotinea* Velen. 1934) was not further regarded. Boudier's (1885) generic concept based on paraphysis shape and presence of hairs was adopted by Nannfeldt (1932) and accepted with little alterations by many subsequent authors. Velenovský (1934, 1940, 1947) and Seaver (1951), however, followed the system of Phillips (1887), Rehm (1891), and Massee (1895) of a broad concept of *Orbilia* which included *Habrostictis* and *Hyalinia*. In the present study, most of these seven genera were found to be more or less artificial. All their type species are considered here to belong to the same genus, hence, the oldest of these seven genera, *Orbilia*, is accepted while a number of species are segregated in the newly erected genus *Hyalorbilia* Baral & G. Marson (2001).

For a long time, the genus *Calloria* Fr. (1836) was thought to be closely related to *Orbilia*, until Nannfeldt (1932) segregated a family *Orbiliaceae* by excluding *Calloria*. Prior to Nannfeldt, the only delimiting character was seen in the ascospores, being 1-septate in *Calloria* and non-septate in *Orbilia*. Such an artificial system based on a single ascospore character was in vogue during the Saccardo era. Not only important ascus characters were often overlooked at that time, but also the fact that spore septation depends on the senescence of a population. In fact, members of *Calloria* and *Orbilia* usually eject non-septate spores which may become septate prior to germination in both genera. Within the orbiliaceous fungi a single exception is so far known: the spores of *Orbilia septispora* are generally 1-septate during ejection.

The genus *Orbilia* has frequently been characterized by asci and paraphyses being conglutinate by a gel matrix or at least apically immersed in an epithecial encrustation, also by an ectal excipulum of thin-walled, globose to angular cells (e.g., by Velenovský 1934, Korf 1973, Spooner 1987). However, a strongly gelatinized hymenium occurs only in the rather small genus *Hyalorbilia* (Baral & Marson 2001) though not in every species. This genus was segregated from *Orbilia* based on an ectal excipulum of usually elongate cells at the flanks, being oriented parallel to the surface (textura prismatica), also by more or less unstalked asci which consistently arise from croziers. It is astonishing that a textura prismatica has rarely been reported in the literature in orbiliaceous taxa. Unstalked asci were only used at some infrageneric level by Velenovský (1934), and croziers were entirely neglected within this group, as was generally the case in most other groups of ascomycetes.

Concerning the circumscription of genera and families by previous authors, our studies of *Orbiliaceae* soon provided evidence for an overestimation of features such as waxy, light-coloured apothecia, or capitate paraphyses (Baral 1994, Baral & Marson 2001). Such features obviously developed in various groups of fungi by convergent evolution. Instead, we found the following characteristics as better reflecting higher taxonomic units: (1) structure of the ascus apex, (2) ascogenous system (croziers versus simple septa), (3) presence of spore bodies (SBs) and their number and shape within the living ascospores, (4) type of ectal excipulum, (5) gel among and exudate over the paraphyses.

The genus *Hyalorbilia* is characterized by SBs that occur near both ends of the ascospores in most of the species (bipolar symmetrical arrangement), a more or less homopolar spore shape, and ± translucent apothecia of a whitish to chlorinaceous or yellowish colour. *Orbilia* subgenus *Hemiorbilia* Baral (1994) was established for a group of consistently desiccation-tolerant species with orange to rose-coloured apothecia, based on an apically thickened ascus wall in combination with a non-truncate ascus apex and predominantly uninflated paraphysis apices being often covered by a layer of thick exudate.

Although hardly detectable in herbarium material, SBs were found to belong to the most important characteristics at the species level, but also at higher levels up to the genus. SBs represent a very valuable aid for recognizing the entire class *Orbiliomycetes*, allowing a sharp delimitation from the *Helotiales* (see Baral 1992: 366: fig. 37, as 'VBs').

Confusion at the ordinal or class level due to a macroscopic similarity and neglect of vital characters. Quite a large number of species have erroneously been considered as orbiliaceous in the older literature. They have been misplaced in one or several of the above-mentioned seven orbiliaceous genera, but are today reclassified in genera that belong to very different fungal groups. Confusion occurred predominantly with helotialean genera, such as *Allophylaria*, *Antinoa*, *Ascocoryne*, *Bisporella*, *Calloria*, *Calloriella*, *Calycellina*, *Calycina*, *Dicephalospora*, *Diplonaevia*, *Duebenia*, *Epiglia*, *Hyaloscypha* (incl. *Parorbiliopsis*), *Hymenoscyphus*, *Laetinaevia*, *Mniaecia*, *Mollisia*, *Naeviopsis*, *Ombrophila*, *Pezicula*, *Ploettnera*, *Pseudohelotium*, *Psilachnum*, *Pyrenopeziza*, *Sarcotrochila*, and *Unguiculella*. Confusion also encompasses species now placed in genera of *Pezizomycetes* (*Iodophanus*, *Peziza*, *Pseudombrophila*), *Leotiomycetes* (*Thelebolus*), and *Lecanoromycetes* (*Agyrium*, *Caloplaca*, *Coenogonium*, *Sarea*, *Scutula*). Confusion concerns even non-stromatic members of *Hypocreales*, especially *Bionectriaceae* with light-coloured, soft-walled perithecia which collapse cup-shaped when dry.

Even basidiomycetes of the order *Dacrymycetales* may macroscopically appear so similar that only their strongly gelatinous consistency and microscopic construction reveal their true identity. As an example, specimens of *Orbilia* and *Dacrymyces* occur in Persoon's herbarium under the name *Peziza aurea* Pers. Similarly, *Peziza chrysocoma* Bull. was interpreted by some authors as a *Dacrymyces*, but by others as an *Orbilia*. Even conidial fungi that form apothecioid fructifications and small globose phialoconidia (*Peziza crocina* Mont. & Fr.) were mistaken for an *Orbilia*.

Species of *Orbilia* with hairy apothecia may strikingly resemble helotialean genera such as *Arachnopeziza*, *Lachnellula*, or the polyphyletic genus *Hyalopeziza* (*H. raripila* and '*Habrostictis*' *diaphana*, see p. 1669 under the latter name), so that they are easily confused. They also may be mistaken for members of *Octospora* (*Pezizales*), although *Orbilia* very rarely grows on bryophytes. The list of species ever placed in the seven orbiliaceous genera but now excluded from *Orbiliomycetes* is, therefore, fairly long (see p. 1660 ff.).

We repeatedly came across such deceptive doubles that macroscopically pretend to be an *Orbilia* but microscopically belong to the *Helotiales*. Conversely, we have at first neglected black discomycetes as presumably lecanoralean because of their colour, but an accidental microscopic examination revealed typical orbiliaceous characters. Quite a few here newly described taxa with dark-coloured, smooth apothecia (e.g., *Orbilia patellarioides*, *Liladisca acicola*) strongly resemble genera of *Leotiomycetes*, such as *Claussenomyces* s.auct. and *Durella*, *Dothideomycetes* like *Patellaria*, *Xylonomycetes* (*Symbiotaphrina*), or *Lecanoromycetes* such as *Amandinea*, *Sarea difformis*, or *Sclerococcum*. Likewise, the hairy, dark-coloured apothecia of *Lilapila* are easily mistaken for a *Trichopeziza* or *Perrotia* (*Helotiales*).

Frequently, confusion with the *Calloriaceae* (*Helotiales*) is noted in the literature. Nannfeldt (1932: 192, 253) considered five species originally described or early combined in *Orbilia* as belonging 'most probably' to *Laetinaevia*, though he did not propose new combinations for them, except for *O. rosella*. We found them to represent genuine members of *Orbilia*: *O. flavida* Feltgen, *O. flavidorosella* Rehm, *O. rosella* (Rehm) Sacc., *O. serpentina* Pat., and *O. uvispora* Mouton. *O. serpentina* is one of the very few species which was described with characteristic filiform, refractive spore bodies (see Fig. 151: 1). Based on this feature, the species is easily recognized as an *Orbilia* by a vital taxonomist, whereas Nannfeldt, unaware of SBs in *Orbilia*, tentatively placed those desiccation-tolerant species with often erumpent apothecia in his subfamily *Naevioideae* (= *Calloriaceae*).

The two genera *Patinella* and *Pithyella* are today assigned to the *Helotiales*, according to their type species. However, until recently they contained orbiliaceous species (*Patinella aterrima* Fuckel [≡ *Liladisca acicola*], *P. tenebricosa* Svrček [= *Orbilia polybrocha*], *Pithyella erythrostigma* (W. Phillips) Boud. [≡ *Hyalorbilia erythrostigma*], *P. anonyma* Rehm [≡ *H. anonyma*]). Whereas members of *Pithyella* have never been placed in the *Orbiliaceae* before, the type species of *Patinella* was believed to be orbiliaceous by Nannfeldt (1932) because of its capitate paraphyses.

Confusion up to the level of the class frequently occurred in the literature, mainly because of the rareness of vital studies. We assume that validly described orbiliaceous species still can be discovered in old genera such as *Calloria*, *Pezizella*, *Helotium*, or *Mollisia* (when bright-coloured), or in *Patellaria*, *Patinella* etc. (when dark-coloured).

Species concepts in the literature and misinterpretation. In addition to the inappropriate generic concepts that tempted workers to transfer a species to the genus *Orbilia* in the early times, concepts at the species level were frequently based on more or less unreliable, predominantly macroscopic, but also sporological, or even ecological characters. Whitish apothecia were referred to *O. leucostigma*, yellow ones to *O. xanthostigma*, orange-red ones to *O. coccinella* or *O. rubinella* and so on. Names such as *crenatomarginata*, *crystallina*, or *saccharifera* refer to the presence of whitish teeth or hairs at the apothecial margin. A simplified system of microscopical, mainly sporological characters likewise resulted in artificial concepts. For example, narrow curved spores were thought to point to a relationship with *O. curvatispora*, narrow straight spores to *O. luteorubella* and related species, and tailed spores to *O. occulta*.

Especially in the 19th century, identifications of orbiliaceous species are often dubious. Reexamination of some of the involved collections have demonstrated that different authors had different interpretations of a species, and that some authors mixed two or three different species under one name. Some of the oldest epithets of orbiliaceous fungi have been used over a long period of time in one or more ways different from what the revision of authentic material later revealed (Tab. 37).

Table 37. Five examples of old specific epithets in the genus *Orbilia* (left column) and their interpretation by different authors of the 19th and 20th century (right column, according to the present redefinition of these names based on the type or reference specimens). For *O. auricolor* and *O. coccinella* authentic material exists, which fixes *O. auricolor* as an earlier synonym of *O. curvatispora* and *O. coccinella* for a rare species with 16-spored asci and cashew-shaped spores. Neotypes are proposed in the present study for *O. leucostigma* and *O. xanthostigma* in accordance with the current usage, and *O. vinosa* in the sense of Rehm.

Old specific epithet	Identity of non-authentic collections according to present reexamination
leucostigma Fr.	*Orbilia leucostigma*, *O. eucalypti*, *O. crenatomarginata*, *Hyalorbilia inflatula*
xanthostigma Fr.	*O. xanthostigma*, *O. eucalypti*, *O. tremulae*, *O. auricolor*, *H. inflatula*, *O. ?umbilicata*
coccinella Fr.	*O. eucalypti*, *O. xanthostigma*
auricolor Berk. & Broome	*O. auricolor*, *H. inflatula*, *O. elegans*, *O. javanica*, *O. multiformis*, *O. oligospora*
vinosa Alb. & Schwein.	*O. vinosa*, *O. aurantiorubra*, *O. luteorubella, O. sarraziniana, O. tenuispora*

Similar to the situation noted for higher ranks, the reasons for erroneous species identifications must be sought in the current practice of studying dead herbarium specimens, as well as in the fact that species taxonomy at that time concentrated on spore size and shape.

However, the present research revealed that morphology of the anamorph, or molecular differences may necessitate further splits into species that can hardly be separated by teleomorph morphology alone (p. 16 ff., see also Baral et al. in prep. on the *xanthostigma-leucostigma* complex). Because many collections are without such information, our species concepts certainly includes misidentifications regarding such critical taxa.

Some workers named new species according to the host, perhaps because they believed that they were host-specific. For instance, *O. eucalypti*, *O. abutilonis* and *O. fici* were named after host genera. Also Velenovský named many species after the host. For nearly all such named taxa, the present study revealed a much wider host range than the epithet suggests. However, also we named many of our new taxa after the host, whenever their morphological features did not provide enough peculiarities (see also p. 19–20, Etymology).

Authors of the past centuries believed that the *Orbiliaceae* constituted a rather small family with only a few distinct species. As an example, a rather wide species concept was applied to taxa with a crenulate to hairy margin, which is briefly sketched below, represented by two authors, G. Massee and J.A. Nannfeldt.

Massee (1894b: 99) revised the types of *Peziza cruenta* Schwein. and some other North American taxa (*Peziza fibriseda* Berk. & Curt., *P. saccharifera* Berk., *P. rufula* Schwein., *P. regalis* Cooke & Ellis), all of which he considered to be conspecific because they share a reddish disc and a whitish, crenulate or pruinose to hairy margin. A sixth taxon (*P. conchella* Schwein.) he considered as a further possible synonym. Four of these authentic exsiccatae were reexamined in the present study and found to belong to four very different species. No type material could be located for *P. cruenta*, and in that of *P. conchella* only sporodochia of a hyphomycete could be found.

When Nannfeldt (1932: 252) was dealing with this group of taxa, he followed the opinion of Massee without personal studies. Moreover, he considered *O. cruenta* to belong to *Hyalinia* and to be possibly even conspecific with the European *H. rubella* (Pers.) Nannf. (≡ *O. rubella*) as represented in herb. P.A. Karsten (no. 834). Nannfeldt further believed that the type specimen of *Peziza rubinella* Nyl., which has rather glabrous apothecia, was conspecific with *H. rubella*. *P. rubinella* represents a special case of confusion: intrahymenial parasitism (see Baral 1999). According to a reexamination of the type, the asci described in the protologue belong to a parasite of the widespread genus *Helicogonium* that grows in the hymenium between the paraphyses of *O. vinosa* by lacking an own sporocarp. Parasites of that genus are not easily recognized as such, since their asci are inamyloid like the host asci, and often completely suppress the formation of the host asci. Species of *Helicogonium* are usually readily recognized by their ability to produce phialoconidia directly on the ascospores, a feature never seen in *Orbiliomycetes*.

Many cases of confusion are found in the studies by Feltgen and Velenovský. A revision of 38 specimens included in *Orbilia* in Feltgen's herbarium (LUX) revealed the presence of about 10 orbiliaceous and one helotialean species ('*Orbilia*' *rozei* = *Psilachnum rubicundum*, see p. 1683). Feltgen (1899, 1901, 1903) reported nine species and five varieties in *Orbilia*. However, the names applied by him show little correlation with the identities as evaluated here. For example, behind specimens carrying the name *O. coccinella* hides predominantly *O. xanthostigma* but also *O. eucalypti* and a single time *O.* cf. *luteorubella*. Under *O. luteorubella* he mainly preserved *O. sarraziniana*, while only one collection was *O.* cf. *luteorubella*, a further *O. auricolor*, and another *O. xanthostigma*. Although such discrepancy could in some cases be due to mixed populations, Feltgen's rather superficial microscopic work is obviously the main source for this confusion.

Velenovský's work (1934, 1940, 1947) is characterized by brief descriptions, to which often macro- and microscopic illustrations are added. For instance, he frequently gave only the length of spores while omitting spore width. Although his drawings are seemingly informative (he often illustrated asci with flexuous stalks and 2- to 4-furcate bases, see Fig. 154),

Table 38. Ascospore measurements [µm] of fifteen selected taxa described by Velenovský (1934, 1947) as new species: comparison of values of holo- or lectotypes in the protologue and/or manuscript plates (spore width was mostly omitted by the author and spores were not drawn to scale) to those evaluated by Svrček (1954) and Baral (present study, in KOH or KOH+CR) from the same material. Velenovský's values are often much smaller (75–85 % or even 35–50 %) than those of the revising authors, except for large-spored taxa (highlighted in grey) in which his values concur or exceed the revision values (probably because of the shrinking effect). Svrček's spore length values more or less agree with those of the present study, whereas spore width was in some species distinctly below the values of the present study. * = measurements appearing on manuscript plate.

Velenovský	present monograph	Velenovský (1934, 47)	Svrček (1954)	Present monograph	Approx. deviation
Orbilia connata	*O. epipora*	1–2.5*	3–4.5 × 0.5–0.8	3–4.2 × 0.7–0.8	35–50 %
O. minutispora	*O. minutispora*	1–2*	2.5–4 × 0.8–1	2.7–3.6 × 0.9–1.1	40–55 %
O. aprilis	*O. aprilis*	3–5	–	7–8 × 1.7	45–60 %
O. leporina	*O. leporina*	3–5 × 1	–	(6–)7–8(–9.2) × 1.1–1.3(–1.4)	50–60 %
O. acuum	*O. acuum*	2–3*	3–4 × 0.8–1	3.5–5.2(–6) × (0.8–)1–1.2	55 %
O. millispora	*O. xanthostigma*	1–2	–	2.3–2.6 × 1.1–1.3	50–75 %
O. parvula	*O.* (?)*luteorubella*	4–5*	7–8.5 × 1.2–1.5	5.5–7.5 × 1.4–1.7	60–75 %
O. pellucida	*O. cardui*	3–5	5.5–7 × 0.5–0.8(–1)	(4–)5–7(–7.5) × 1.1–1.2(–1.3)	65–75 %
O. cejpii	*O. cejpii*	2*	1.7–2.3 × 1.2–1.5	2–3.3 × 1.3–2	70 %
O. polypori	*Hyalorbilia polypori*	4–5*	5–7 × 0.8–1	5–7(–8) × 1.5–1.9	70–80 %
O. paradoxa	*O. xanthostigma*	1.8–2.2*	2–2.5 × 1–1.5	2.5 × 1	75–85 %
O. euonymi	*O. euonymi*	2–3*	–	2.5–3.6 × (1.4–)1.8–2(–2.3)	80 %
O. tricuspis	*O. vinosa*	12–15*	12.5–17 × 1.5	12–14.7 × 1.4–1.7	100 %
O. pulcherrima	*O. vinosa*	15–18*	14–15.5 × 1.5	13–15.3 × 1.5–1.7	115 %
O. cardui	*O. cardui*	6–8*	5–7 × 1–1.2	5–7 × 1.2–1.5	115–120 %

Table 39. Ascospore measurements [µm] of five selected taxa reported by Boudier (1904–10): comparison of the values in his descriptions to those evaluated from his plates (in situ length, magnification 820 ×) and from personal reexamination of the same specimens or, in square brackets, from recent collections of the same species. Boudier's values given in the description are partly too high, particularly spore width; values obtained from his drawings are more trustworthy as they often better match those obtained in the present study. § = perhaps measured along curvature (actual length).

	Boudier (text)	Boudier (plate)	Present study
Habrostictis carpoboloides (pl. 459)	15–20 × 2–3	15–19 × 2–2.9	[*(7.7–)8.5–14(–17) × (2–)2.2–2.8(–3.5)]
Orbilia sarraziniana (pl. 462)	7–8 × 1.5–2	7.2–8 × 1–1.2	[*(5.5–)6–8.5(–9) × (1.2–)1.3–1.6(–1.7)]
Orbilia aurantiorubra (pl. 464)	15–18 × 2 §	(11.5–)13–16.5 × 1.2–1.4	†12–14 × 1.1–1.2
Hyalinia roseola (pl. 465)	10–12 × 2 §	8.5–10.5 × 1–1.3	†6.5–9.5 × 0.7–0.8
Hyalinia crystallina (pl. 466)	8–11 × 2 §	8.5–10.2 × 0.9–1.1	[*7–8.5(–9) × (0.6–)0.7–0.8(–0.9)]

Velenovský made a large number of more or less severe errors. This can be concluded from the present reexamination of about 60 available type specimens in which apothecia could be found.

As a consequence, Velenovský's descriptions are often insufficient for the recognition of a taxon. Even in regard to rather well-defined species we were unable to identify them with Velenovský's descriptions. For instance, it was impossible to get an idea of what the protologues of *O. aprilis* or *O. euonymi* might represent, until the types were studied. As opposed to Svrček, who accepted only seven species and one form among Velenovský's 75 new species and varieties, we here accept 18 species which bear Velenovský's name (nine further species are of unclear identity). Our higher number of 18 can be explained by the fact that in some of the type specimens Svrček did no longer find apothecia although they still existed, therefore, he considered taxa as dubious which we here accept as valid. Nevertheless, under about seven different epithets Velenovský described what is here referred to *O. eucalypti*, under six epithets *O. leucostigma* and *O. xanthostigma*, under four epithets *O. cardui*, and under three epithets *Hyalorbilia inflatula*.

Velenovský's errors are manifold: (1) spore measurements of small-spored taxa are highly incorrect (see Tab. 38); (2) stray spores or algae were often misinterpreted as ascospores; (3) the septa of the paraphyses are drawn at rather equal distance in most of the illustrated species of *Orbilia* (Fig. 154), although in many of them the terminal cell was about 2–4 times longer than the lower cells; (4) the only taxon in his work with polysporous asci (*O. euonymi*, 32-spored) was reported by him as octosporous.

Orbilia euonymi and *O. aprilis* are two out of many examples of very inadequately described taxa. Both were gathered only once by Velenovský. The wrong spore number reported for *O. euonymi* later led to the misapplication of this name to the 8-spored *Hyalorbilia erythrostigma*, a very distant species. *O. aprilis* was misleadingly described with 3–5 µm long, ellipsoid ascospores. Reexamination of the rather immature type material revealed only a single (almost) mature ascus with narrowly fusoid, 7–8 µm long spores. Therefore, the name *aprilis* can only with some hesitation be applied to a previously unreported though very common taxon which is easily recognized in the living state. As a consequence, a highly constant and common species carries a somewhat uncertain name.

Tab. 38 illustrates errors in Velenovský's measurements, which are also apparent in other fungal groups treated in his works of 1934, 1940, and 1947. For a spore length in the range of 2.5–8 µm he often evaluated only 1–5 µm, i. e., ~75–85 or even 35–50 % of the true values. Longer spores, however, are more or less correctly reported (*O. tricuspis*, *O. pulcherrima*), and in one case (*O. cardui* s.l.) he reduced spore length from 6–12 µm (1934: 98) to 4–10 µm (1934: 401) which corresponded to the values obtained by later revisions. It seems that Velenovský used a combination of objective and ocular with a false calibration when he studied minute spores. Species published in 1947 (*O. aprilis*, *O. leporina*) show the same error. This is all the more surprising as Velenovský used to study living specimens in which spores are usually slightly larger than in dead specimens. More or less severe errors in calibration and scaling of illustrations are actually not infrequent in the literature.

As a further example, Boudier's (1904–10) values in his descriptions are often too high, whereas those calculated from his plates are more trustworthy (Tab. 39, see also Baral 1992: 347). This is especially true for the width of comparatively narrow elements: Boudier's spore width measurements are here often ~1.5–2 × higher than on his drawings, which in some cases is due to the fact that Boudier avoided to calculate steps smaller than 0.5 µm. In the case of strongly curved spores (Boudier l.c.: pls 464–466), a greater spore length in his descriptions might refer to the actual length (measured along the curvature) rather than to the in situ values (straight distance).

Although Velenovský (1934: 31) emphasized the preferential study of fresh living specimens, his figures usually show dead asci and spores, perhaps because he applied too much pressure on the cover slip in order to separate the hymenial elements. Actually, Velenovský never reported tear-shaped or vermiform SBs in those taxa which possess such bodies, e. g., *O. sarraziniana*, *O. aristata*, *O. aprilis*, *O. vinosa*, and *O. euonymi*. Only in one unpublished drawing of *O. sarraziniana* (as *O. luteorubella*, manuscript plate deposited in PRM) he illustrated vermiform SBs (see Fig. 156: b). Perhaps Velenovský omitted this drawing in his monograph because he considered the structure to be artificial. That the quality of his microscope was sufficient can be concluded, e. g., from his spore drawing of *O. paradoxa* (= *O. xanthostigma*, Fig. 154: 4) which perfectly shows the semicircular spore curvature, though it omits the dorsal warts and gives SBs at both spore ends.

In a number of taxa (*O. alnea* var. *vesiculosa*, *O. linata*, *O. microspora*, *O. paradoxa*, *O. pellucida*, *O. tiliacea*) Velenovský figured spores with two globose drops, one near each end. Such a bipolar (homopolar) guttular pattern is typical of the genera *Hyalorbilia* and *Amphosoma*. However, Velenovský's taxa are members of *Orbilia*, except for *O. linata* (= *Hyalorbilia inflatula*) in which case he reported stray spores. Bipolar globose drops as seen by him seem to refer to LBs in some of the taxa, but in others, e. g. *O. paradoxa*, they clearly represent spore bodies. At least in this species the bipolar arrangement of the drops obviously arose from Velenovský's phantasy.

Velenovský appears to have quite frequently mistaken spores of associated fungi or algal cells as the ascospores of *Orbilia*. This was also affirmed by Svrček (1954) in several cases. In 45 taxa of *Orbilia* (including *Radotinea*) Velenovský (1934) illustrated asci (Figs 154, 156, 174), but only exceptionally he depicted the spores within (*O. euonymi*, Fig. 156: a; *O. polypori*, Pl. 66). In *O. euonymi* he figured an eight-spored ascus although the holotype turned out to be 32-spored (Pl. 207: 5). This discrepancy could be due to a mixture in the type material, but this seems quite unlikely because all the other characters match very well. We conclude that Velenovský rarely saw living mature asci in his preparations, therefore, he only occasionally recognized spores within them and repeatedly reported stray spores in his diagnoses.

A further source of error concerns a mixture of different species in a single convolute. Although Velenovský recognized such a case in the type specimen of *O. fusispora* (≡ *Hyalorbilia fusispora*), which grew in close association with the type of *O. fusispora* var. *microscopica* (= *O. juliae*), it obviously escaped his notice in some other cases. For example, *O. carpathica* was described with long-tailed spores somewhat similar to *O. flagellispora*, but in the preserved type material only apothecia belonging to *O. sarraziniana* could be observed.

Number of accepted taxa (**teleomorph**). The above-mentioned high number of dubious epithets suggests that the total number of acceptable published taxa regarding the teleomorph is much lower than the works of authors like Velenovský suggest. Spooner (1987: 161) noted that 'of some 170 specific epithets' combined in *Orbilia* worldwide 'only about 30 species are reasonably well-known', but 'many of those published were inadequately described'. Kirk et al. (2008) gave the number of taxa of *Orbiliaceae* as 288. However, this calculation includes the anamorph-typified taxa of *Arthrobotrys* etc., whereas the number 'c. 58' under *Orbilia* refers only to the teleomorph taxa.

According to our present literature research, the total number of validly published epithets (including infraspecific, anamorph-typified, and non-orbiliaceous or doubtful taxa) ever combined with the generic name *Orbilia* Fr. up to now (including 2019/20) is about 270 (excluding species and combinations newly proposed in this monograph). Some epithets were invalidly proposed (*O. acicularis*, *O. albomarginata*, *O. albovinosa*, *O. inconspicua*, *O. lenticularis*, *O. quercus* var. *hainanensis*, *O. quercus* var. *hunanensis*). Much fewer epithets were combined with the remaining eight teleomorph-typified orbiliaceous genera. In the following, the first number indicates the total number of validly combined epithets, and the second number indicates, how many of them were also combined with *Orbilia*: *Cheilodonta* Boud. (2/2), *Habrostictis* Fuckel (16/3), *Hyalorbilia* (16/9), *Hyalinia* Boud. (63/28), *Orbiliaster* Dennis (2/1), *Orbiliella* Kirschst. (1/0), *Pseudorbilia* Ying Zhang et al. (1/0), and *Radotinea* Velen. (1/0).

After subtracting all those taxa for which two or more combinations in orbiliaceous genera exist, 51 epithets remain which have ever been placed in orbiliaceous genera other than *Orbilia*. As a consequence, ca. 270 + 51 = ca. 321 teleomorph epithets have ever been validly combined with 1 or more of these 9 orbiliaceous genera up to now. Out of these ca. 321 taxa, 113 either turned out to belong to other groups (predominantly in the *Helotiales*), or remained ambiguous as to their relationship, because authentic material could not be located and the descriptions are too inadequate. Further 15 epithets more or less probably concern orbiliaceous taxa, but their specific identity could not be clarified. Therefore, altogether ca. 128 taxa are treated in the 'List of excluded, doubtful or little-known taxa' (p. 1660 ff.) besides 27 further taxa of various other genera with potential affiliation in the *Orbiliomycetes*.

The remaining ca. 193 teleomorph-typified taxa are accepted here as belonging to the *Orbiliomycetes*, 197 when including 4 invalidly proposed orbiliaceous species (see Suppl. List of previously described taxa). 92 out of these ca. 197 are considered to represent heterotypic synonyms of accepted taxa (51 certain and 41 questionable synonyms). The rest of 105 epithets constitutes the basic stock of previously described teleomorph-typified taxa accepted in the present monograph. In addition to these 105 epithets, 7 further ones are accepted as validly described orbiliaceous species, which were assigned to different helotialean genera such as *Helotium*, *Pezizella*, *Pseudohelotium*, *Pithyella*, *Patinella*, and *Tympanis*, but never in any of the 9 orbiliaceous genera. Further 8 epithets were similarly never assigned to an orbiliaceous genus, but were referred by us to synonymy with accepted species of *Orbiliomycetes*. Hence, a total of ca. 112 epithets from the literature are accepted as validly described orbiliaceous species in the present monograph, and 100 epithets are listed as synonyms of these accepted taxa.

Since vital characters (SBs and SCBs) were not reported for most of these type collections, some critical taxa remain questionable as to their identity. This uncertainty concerns, e.g., *O. serpentina* which was described with subulate SBs in the spores, but for which the presence of crystalloid SCBs is unclear, or *O. fibriseda* and *O. rosella* for which neither SBs nor SCBs were reported. The identity of other taxa is questionable because their anamorph is unknown, and in some type specimens the apothecia are not mature enough (examples: *O. linata*, *O. uvispora*, *O. aprilis*). Until sequence data from old material might become available, we have chosen in such cases what seemed us the more probable identity.

The teleomorph-typified genera – Genera with orbiliaceous type species

Several teleomorph-typified genera show either a phylogenetic or historical relationship to the *Orbiliomycetes*. The more important 18 of these genera will be discussed in the following.

Orbilia Fr., Fl. Scan.: 343 (1836) – Lectotype species: *Peziza xanthostigma* Fr. (designated by Bachman 1909)

Prior to 1836. When the first orbiliaceous species were described in the years between 1791 and 1871, a rather small number of genera has been recognized within the non-lichenized discomycetes. For most species that form apothecia, a very wide concept of the genus *Peziza* Dill. ex Fr. was in use, which included at that time nearly all groups of both operculate and inoperculate discomycetes. Those species later referred to *Orbilia* were arranged by Fries (1822: 146) in a subgroup '*Ceracellae*' of the genus *Peziza*, which in turn was placed in the '*Ordo Cupulati*'.

The first species that clearly belong to the *Orbiliomycetes* were described by Persoon (1801: *Peziza aurea*, *P. rubella* and *P. vinosa* [the latter species is currently referred to Albertini & Schweinitz 1805]), Fries (1815: *P. leucostigma* and *P. xanthostigma*), and Sommerfelt (1826: *P. coccinella*). Also *Peziza chrysocoma* Bulliard (1791) was interpreted as orbiliaceous by some authors, but the taxon is now lectotypified on a basidiomycete (see p. 1665).

1836–1924. When erecting *Orbilia* in 1836, Fries included those two species described by him in 1815, and defined the genus by membranaceous-gelatinous apothecia and 'moniliform' asci. *Orbilia* is referred to the tribe '*Bulgariei*' of his family '*Discomycetes*', together with *Calloria* Fr., which he erected in the same paragraph a few words before, and which he separated from *Orbilia* by 'persistent' clavate asci. The tribe '*Bulgariei*' further comprised the genera *Bulgaria* Fr., *Leotia* Pers., and *Lemalis* Fr., but also *Exidia* Fr., a basidiomycetous genus.

Fries (1836) did not definitely associate the generic epithet *Orbilia* with the two epithets of the included species, as demanded by the Code (ICN Art. 35.2). Their combination in *Orbilia* was validated later, when Fries (1849: 357) added *Peziza coccinella* Sommerf. and *P. epiblastematica* Wallr. [≡ *Scutula epiblastematica* (Wallr.) Rehm, *Lecanorales*] to the genus. The generic diagnosis now reads 'apothecia round, ceraceous-membranaceous, saucer-shaped, marginate, 8 spores arranged in a moniliform row, without asci (at least without conspicuous asci), excipulum absent'. Fries incorrectly believed that the asci dissolved prior to spore liberation. With 'moniliform' he referred to senescent apothecia in which the spores occur in moniliform chains inside disintegrated asci (see, e. g., Pl. 842: 1b).

Orbilia was transferred by Fries (1849) to the family '*Helvellacei*', whereas *Calloria* remained in the '*Bulgariacei*'. Thereby, Fries's concept of *Calloria* was very heterogeneous (see p. 205). According to him, the name *Orbilia* is derived from '*orbis*', which infers to the circular apothecia. In a similar way, the obsolete word '*orbilla*' has been in use in the sense of 'apothecium', e. g., in Sprengel (1807, see Kirk et al. 2008).

Karsten (1861: 36–39; 1869: 106, 173–176) and Nylander (1869: 54–58) relied on the classical wide concept of *Peziza* when treating the discomycete flora of Finland. Nylander doubted Fries's concept of *Orbilia* and *Calloria*, since the microscopic characters provided by Fries appeared unreliable to him. Nylander's orbiliaceous species are, therefore, found in a subgroup of *Peziza*, named '*Orbilia* et *Calloria* Fr.'. Karsten (1861) placed orbiliaceous as well as helotialean taxa in *Peziza* subgenus *Phialea* section *Mollisia*. Later, Karsten (1869) accepted *Orbilia* as a section within *Peziza* (without using subgenera). The very same sectional diagnosis was reproduced in a 'repertorium' by Rabenhorst (1869), who named Karsten's 25 sections 'Untergattungen' (subgenera). Shortly afterwards, however, Karsten (1870: 248; 1871: 11, 97) adopted *Orbilia* at the generic level and placed it in the *Pezizaceae* subfamily *Bulgariaceae*.

Karsten (1861) listed three orbiliaceous species: *Peziza coccinella*, *P. leucostigma*, and *P. vinosa*. In 1869 he treated ten species in section *Orbilia*, nine of them being orbiliaceous: the three former, but also *P. delicatula*, *P. epipora*, *P. inflatula*, *P. luteorubella*, *P. rubinella*, and *P. xanthostigma*. Out of eight species which Nylander recognized in '*Orbilia* et *Calloria*', six are genuine members of *Orbiliomycetes*: *P. coccinella*, *P. epipora*, *P. leucostigma*, *P. luteorubella*, *P. rubinella*, and *P. vinosa*.

Karsten and Nylander were among the first to present more detailed microscopic features of orbiliaceous fungi. As characteristic of the majority of their species, the authors emphasized the capitate to clavate apices of paraphyses, the large, parenchymatous excipular cells, the small asci and spores, and the smooth, hyaline to bright-coloured apothecia without a visible subiculum. Although they introduced spore characters as a valuable means for species delimitation, they continued to attribute macroscopic features like apothecial colour a rather high taxonomic value.

Berkeley (1860: 370) recognized 15 species for Great Britain in *Peziza* subgroup *Mollisia*, three of which are orbiliaceous (*P. vinosa*, *P. xanthostigma*, *P. leucostigma*). Berkeley & Broome (1865) added *Peziza auricolor* which was misinterpreted in the following in the sense of *Hyalorbilia inflatula*, until Spooner (1987) redescribed the type material. The first authors providing detailed microscopic illustrations of orbiliaceous fungi were Berkeley & Broome (1866: pl. IV fig. 31, *Peziza erythrostigma*, subgroup *Mollisia*; 1873, *P. lasia*, subgroup *Dasyscyphae*, Fig. 168) and Crouan & Crouan (1867, *P. carpoboloides*, Fig. 169). Without illustration and microscopic data, Berkeley (1875: 157) described two North American species (*P. fibriseda*, *P. saccharifera*) in subgroup *Mollisia*, which are combined in *Orbilia* in the present monograph. For the British fungus flora, Cooke (1871) reported within the large genus *Peziza* five species that are today recognized as orbiliaceous (*P. leucostigma*, *P. xanthostigma*, *P. vinosa*, *P. auricolor*, *P. erythrostigma*).

Fuckel (1870, 1871, 1874) applied a narrower generic concept when treating the discomycetes of central Germany, but he did not adopt or even mention the generic name *Orbilia*. Fuckel reported five orbiliaceous species which he placed in four different genera (*Calloria chrysocoma* [s. Fuckel], *C. vinosa*, *Habrostictis rubra*, *Pezizella rubella*, *Pezicula aterrima*) and assigned to four different subgroups (*Stictei*, *Patellariacei*, *Bulgariacei*, *Pezizei*, respectively) of his '*Discomycetes*'. In *Calloria* he included two basidiomycetous taxa now recognized in *Dacrymyces* (*Dacrymycetales*), following Fries's (1849) heterogeneous concept of *Calloria*.

Also Gillet (1881–83) did not accept the genus *Orbilia*, but placed nine orbiliaceous species from France in *Helotium*, *Lachnea*, and mainly *Mollisia*. Although his work is rather rich

Figure 148. *Orbilia eucalypti* (Saccardo, Fungi italici, 1883: pl. 1289, as *O. coccinella*).

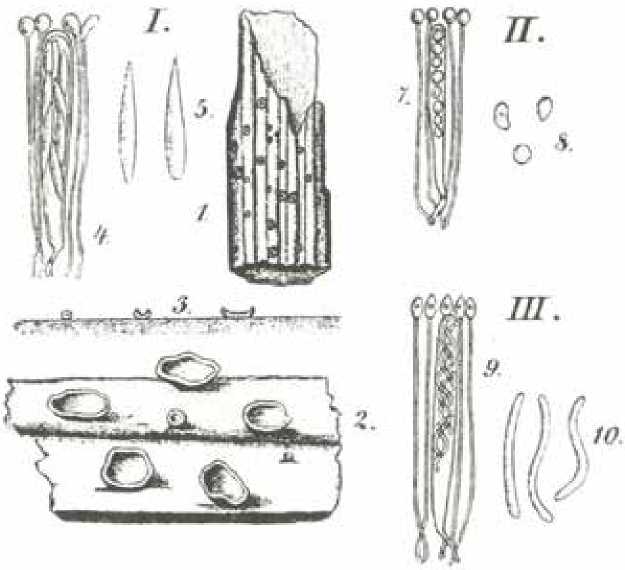

Figure 149. I. *Orbilia* sp. (as *O. vinosa*), II. *O. eucalypti* s.l. (as *O. coccinella*), III. *O. xanthoguttulata* (as *O. curvatispora*). From Rehm (1891: 447).

in illustrations, none of the orbiliaceous taxa are figured. Phillips (1887: 326–335) merged *Orbilia* with *Calloria* under the latter name, which he placed in the '*Bulgarieae*'. Phillips characterized the genus mainly by brightly coloured, gelatinous apothecia without a distinct excipulum. Nine of the 19 accepted British species are orbiliaceous: *Calloria auricolor*, *C. coccinella*, *C. inflatula*, *C. lasia*, *C. leucostigma*, *C. luteorubella*, *C. rubella*, *C. vinosa*, and *C. xanthostigma*.

When compiling diagnoses of the worldwide taxa in his 'Sylloge Fungorum', Saccardo (1889: 621–633) accepted 50 species in *Orbilia*, and disposed the genus in section '*Hyalosporae*' within the *Bulgariaceae* of his '*Discomycetae*'. The diagnosis of the genus (p. 608) includes apothecial characters such as subgelatinous, superficial, mostly red, yellow or white, and spore characters such as elongate-bacilliform or subglobose-ovoid. Only about 21 out of these 50 species are today recognized as orbiliaceous. These include, in addition to European taxa, some from North and South America (e. g., *O. rubrococcinea*, *O. occulta*, *O. gaillardii*, *O. brasiliensis*) and Australia (*O. decipiens*). One of them was reported as having multispored asci (*O. myriospora*), but reexamination of the type revealed that it belongs to the *Calloriaceae*, and that the oil drops in the immature asci were mistaken for ascospores (see p. 1679). In his colour atlas 'Fungi italici', Saccardo (1883: pl. 1289–1293, 1365) provided drawings of five species in the genus *Calloria* and one in *Habrostictis*, four of which are orbiliaceous: *C. coccinella* (Fig. 148), *C. inflatula*, *C. luteorubella*, and *H. rubra*.

In later volumes, Saccardo accepted about 40 further species in *Orbilia* (1892: 40, 2 spp.; 1895: 426–427, 6 spp.; 1899: 802–803, 5 spp., 1 var.; 1902: 767–768, 3 spp.; 1906: 137–140, 11 spp.; 1913: 722–725, 10 spp.; 1928: 1238–1239, 4 spp). In 1906 (p. 139) he enlarged the concept of the genus by adding a small group (*Orbilia* II *Orbiliopsis*) to accomodate a few species parasitic on living leaves (see p. 207).

In his survey of Austria, Germany and Switzerland, Rehm (1891: 453–462; 1896: 1224–5) accepted 15 species and one variety in *Orbilia*, 12 of these species are to be considered as orbiliaceous: *O. coccinella* s. Rehm (= *O. eucalypti*), *O. leucostigma* (incl. *O. xanthostigma*), *O. luteorubella* s. Rehm (?= *H. inflatula*/?= *O. aprilis*), *O. lasia* (= *O. carpoboloides*), *O. vinosa*, *O. chrysocoma* s. Rehm (?= *Hyalorbilia berberidis*), *O. curvatispora* (= *O. auricolor*), *O. rubella*, *O. occulta* s. Rehm (= *O. aristata*), *O. rosella*, *O. flavidorosella*, and *O. pannorum* (= *O. auricolor*). Rehm provided illustrations only for three of them (Fig. 149). He included species with erumpent and superficial, hairy and smooth apothecia with a waxy-gelatinous consistency. The genus is placed together with *Calloria* (which he segregated by septate ascospores following Karsten 1885: 138 and Saccardo 1889), *Agyrium* Fr., and *Stamnaria* Fuckel in the division '*Callorieae*' of the family *Bulgariaceae*.

For three species (*O. coccinella*, *O. luteorubella*, *O. curvatispora*) Rehm drew attention to a high variability in apothecial colour in contrast to a high consistency of their microscopic hymenial characters. For the first time the inamyloidity of the asci is mentioned for 'nearly all' species (except for the non-orbiliaceous *O. succinea* and *O. primulae* with a blue iodine reaction). Rehm also was the first to report the habitat of dry hanging branches as typical of rather many species of *Orbilia*. About seven of his orbiliaceous taxa inhabit xeric substrates, and the generic diagnosis emphasizes a reddish colour of the apothecia which is typical of desiccation-tolerant taxa.

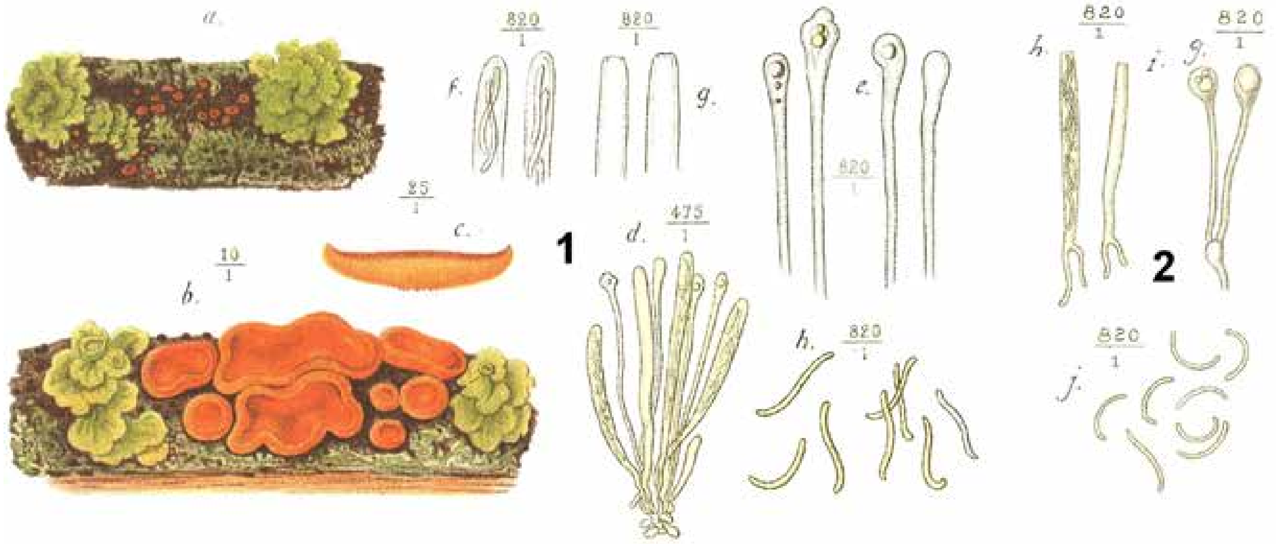

Figure 150: **1**. *Orbilia aurantiorubra*; **2**. *O. auricolor* (as *O. curvatispora*). From Boudier, Icones fungorum (1904–10: pl. 463, 464, from holotype).

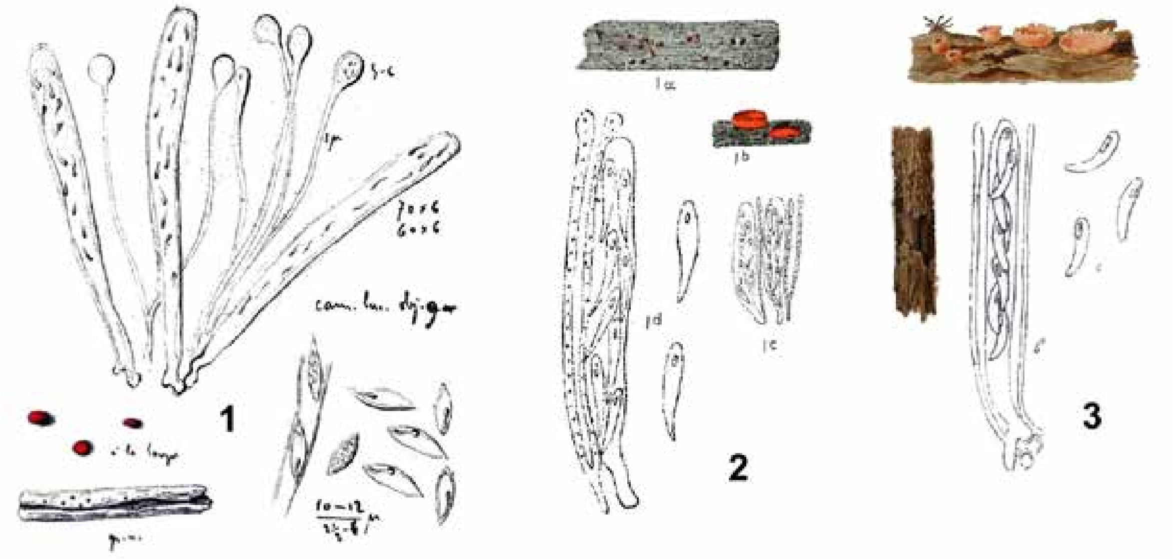

Figure 151. The first reports of spore bodies in the living spores that came to our notice (all from holotype). — **1**. *Orbilia serpentina* Patouillard (1892b, original drawing at PC); **2**. *Orbilia hesperidea* Rolland (1901); **3**. *Hyalinia ulicis* Chenantais (1918). The asci of *O. serpentina* are figured in the dead state, therefore, only the spore bodies are visible. Chenantais' watercolour drawing is taken from the unpublished original plate in the library of the Société Mycologique de France.

Boudier (1885: 114) placed *Orbilia* in the family '*Calloriés*' and characterized the genus by red to orange apothecia with a smooth margin, and capitate (button-shaped) paraphyses. Species with apically non-inflated paraphyses, flat apothecia with a dentate margin, and vermiform spores are treated in a separate genus *Hyalinia*, and those with apically lanceolate paraphyses and cupulate, dentate apothecia in *Cheilodonta* (see p. 201). In his survey on the European discomycetes, Boudier (1907: 102) listed 36 species within *Orbilia*, about 20 of which are to be considered as orbiliaceous.

Rehm was one of the first important herbarium taxonomists in discomycete systematics, and Boudier appears to be the first to have worked consistently on fresh collections with the microscope. Yet, although Boudier favoured the method of vital taxonomy and figured living asci, paraphyses and spores of many discomycetes, he never reported SBs in the ascospores in any of the nine orbiliaceous species treated in his 'Icones Fungorum' (1904–10: 265–270, pl. 459–467). This is astonishing at least regarding three species that have rather conspicuous SBs: *Habrostictis carpoboloides* (pl. 459, Fig. 167), *Orbilia sarraziniana* (pl. 462), and *O. aurantiorubra* (pl. 464, Fig. 150: 1).

Boudier (1886: 156; 1888: 80, pl. 16 fig. 6; 1907: 102; 1904–10: 265–270, pl. 459–467) introduced two new characters as typical of *Orbilia*, but also of *Habrostictis* (= *Cheilodonta*) and *Hyalinia*: (1) he precisely figured the bifurcate ascus base for ± all of the five species treated by him in *Orbilia,* by referring to one of the basal branches as spur-shaped or calcariform ('éperonnées', Fig. 150: 2); (2) he characterized the ascus apex as truncate, especially after discharge (Figs 150: 1g; 2h–i; 167: i).

Boudier's contemporary Patouillard (1892a: 11, b: pl. II fig. 6), likewise a very talented microscopic worker, described and figured living ascospores in a desiccation-tolerant 16-spored species from Tunisia, *Orbilia serpentina* (Fig. 151: 1). This is the first report of both polyspory and SBs in the *Orbiliomycetes*. Patouillard correctly depicted the subulate spore bodies of that species in free spores as well as within the asci. Regrettably he did not continue his essential approach to the vital micromorphology of *Orbilia*, and only two other French mycologists presented similar illustrations of living ascospores in two desiccation-tolerant, 8-spored taxa collected in southern France: *O. hesperidea* (Rolland 1901, Fig. 151: 2) and *Hyalinia ulicis* (≡ *O. ulicis,* Chenantais 1918, Fig. 151: 3).

Schröter (1893: 120) assigned the genus *Orbilia* to the '*Calloriei*' within the family '*Mollisiacei*', and reported six species for the Silesian flora (now Poland), among them the new species *O. pannorum*. Lindau (in Engler 1897) similarly placed both *Orbilia* and *Calloria* in the *Mollisiaceae* of the *Pezizineae.*

In his British Fungus Flora, Massee (1895: 143–149) listed 12 species within *Orbilia*, nine of which being orbiliaceous. He segregated *Calloria* by septate ascospores, but reported occasional occurrence of a spore septum in *O. lasia*. Concerning his study of North American taxa see p. 190.

Feltgen (1899, 1901, 1903) reported nine species and five varieties of *Orbilia* from Luxembourg, which were mostly confirmed to be orbiliaceous in the present reexamination. Illustrations of them can only be found in some of the preserved specimens. Feltgen's taxa concept was highly confusing and inconsistent (see p. 190). For instance, the new species *O. flavida* was described as 8-spored (Fig. 152), but is in fact 32-spored. When Feltgen made a second collection of his new taxon, he did not recognize it and again overlooked the polyspory of the asci.

Figure 152. Original sketch of *Orbilia flavida* Feltgen (in sched., holotype, from Luxembourg).

Hennings (1891, 1899, 1902a, 1902b, 1903, 1904, 1905, 1909) described seven new species in *Orbilia*, two further ones (*Ombrophila geralensis*, *Humaria euphorbiae*) which were later combined in *Orbilia*, and two (*Helotium blumenaviensis*, *H. disseminatum*) which were considered to be orbiliaceous by Dumont (1981: 323, 334). The type collections were from Europe, Africa, Indonesia, Australia, and especially Brazil, and each taxon was only recorded from a single collection. Hennings's rather brief descriptions are without illustration and hardly allow recognition of the species, and, in addition, his spore data are erroneous. Although the holotypes deposited in Berlin (B) were destroyed during the Second World War (see Hein 1988), nine specimens could be located in other herbaria and reexamined in the present study. Five of them (including those described in *Helotium* and *Humaria*) are confirmed to be orbiliaceous.

The three following species are likewise published without illustration: Lindau (1904) described *Orbilia drepanispora* which is a possible synonym of *O. auricolor* in its original sense, Höhnel (1907a) *O. botulispora* which is a synonym of *O. xanthostigma* as neotypified in the present study, and Ade (1924) *O. paradoxa* which is a possible synonym of *O. flavida*. The absence of illustrated microscopic features was detrimental particularly for *O. paradoxa*: the species was described in the living state with polysporous asci and an apical 'spot-like' body in each spore. Since a voucher specimen could not be located, it was impossible to clarify the shape of the spore body (globose or lens-shaped).

Höhnel (1918: 337) stressed the heterogeneity of the genus *Calloria* as emended by Fries (1849), which comprised some orbiliaceous species in Fries's treatment. On p. 343 Höhnel considered the parenchymatous texture of the entire ectal excipulum in *Orbilia* (*O. vinosa*) and *Calloria* to provide evidence for these genera to be simplified *Dermateaceae*. Later, Höhnel (1926a: 68) saw no clear limit between *Orbilia* and *Pezizella*, and found in *Pezizella teucrii* (?= *Calycellina chlorinella*, see p. 1665) an intermediate species with strong affinities to *Orbilia*.

Bachman (1909) provided a key to four species of *Orbilia* (*O. auricolor*, *O. coccinella*, *O. xanthostigma*, *O. vinosa*) found in Ohio, USA, but the identity of these records remains quite unclear. Bachman was apparently the first to select a lectotype of *Orbilia*, *O. xanthostigma*.

Migula (1913: 1293 ff.) mainly copied Rehm's (1891, 1896) descriptions of *Orbilia*. He supplied a key to 18 known species within central Europe, about 13 of which being orbiliaceous, among them *O. drepanispora* and *O. botulispora.*

1931–1976. Clements & Shear (1931: 314) selected *O. leucostigma* as lectotype of *Orbilia*, unaware of Bachman's (1909) study, and this selection was followed by all later workers. Clements & Shear referred *Hyalinia*, *Orbiliopsis* (Sacc.) Syd. and *Pteromyces* E. Bommer et al. to synonymy with *Orbilia*. As this work is a mere listing of taxa, the authors did not provide any discussion of this procedure. The genus *Orbilia* is listed in the *Bulgariaceae* of the *Pezizales*.

Nannfeldt (1932: 250 ff.) was the first to recognize a family *Orbiliaceae* separate from the *Dermateaceae* and *Bulgariaceae*, thus accentuating the microscopic differences between the macroscopically similar genera *Orbilia* and *Calloria* for the first time. All these three families he referred to the new order *Helotiales*.

Among the characters provided in the Latin diagnosis of the *Orbiliaceae*, the small, truncate asci are worth mentioning, but also the 'wax-like substance' that is exuded at the tip of the paraphyses and conglutinates them with the asci, and the apices of paraphyses being either uninflated or mostly subglobose-clavate. Neither of these characters are figured in his work, which predominantly illustrates excipular characteristics. Nannfeldt included three genera in the family: *Hyalinia* (2 spp.), *Orbilia* (min. 4 spp.) and *Patinella* (1 sp.). He followed Höhnel in separating *Hyalinia* from *Orbilia* on account of the presence of marginal hairs that are more or less agglutinated to form teeth.

Nannfeldt (1932: 191, 253) believed that the current concept of *Orbilia* was much too wide. He listed 14 species previously placed in *Orbilia* which he thought to belong to his new genus *Laetinaevia* in subfamily *Naevioideae* of *Dermateaceae*. Most of them have desiccation-tolerant apothecia, according to our knowledge, one being *O. serpentina* (with subulate spore bodies, see also p. 189). Nannfeldt's idea was partly based on a macroscopic similarity with such naevioid genera concerning their erumpent, more or less reddish apothecia growing on dead leaves and herbaceous stems. Nannfeldt (l.c.: 97) similarly retained the desiccation-tolerant genus *Habrostictis* near *Ocellaria* and *Pezicula* in the *Dermateaceae*. Today it is clear that his concept of the *Orbiliaceae* was artificial: several of the species placed by him in the *Dermateaceae* turned out to be orbiliaceous while, on the other hand, he assigned a clearly helotialean taxon (l.c.: fig. 40c, IVV: H.B. 7328, ?*Cistella* sp.) to the genus *Orbilia*.

Such controversial opinion can be explained by the fact that Nannfeldt attached great importance to the development and

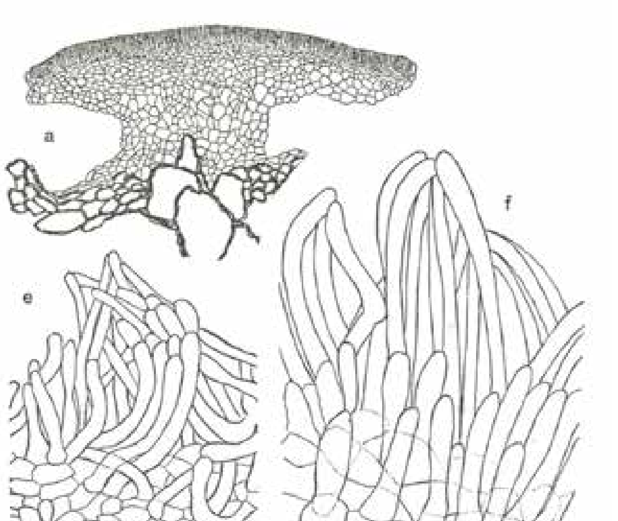

Figure 153: Excipular structure in *Orbiliaceae* as drawn by Nannfeldt (1932: fig. 40): *Orbilia epipora* [a], *O. phragmotricha* (as *Hyalinia rubella*, FFE 834) [e] and *O. crenatomarginata* (as *H. crystallina*) [f–g]. The hyphoid processes that form teeth at the margin are composed in [e] of septate, thick-walled hairs and in [f] of a solid glassy substance with a lumen only at the base, but this is neither obvious on Nannfeldt's drawings nor mentioned by him.

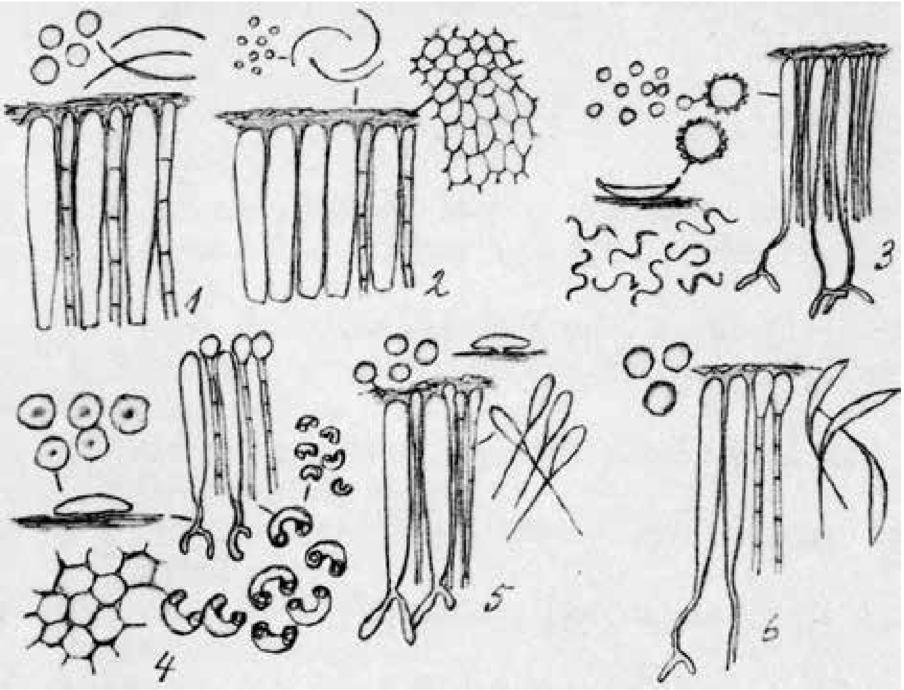

Figure 154: Examples of Velenovský's (1934) drawings regarding orbiliaceous species: pl. XI fig. **1**. *O. polyporacea* Velen. (?= *Hyalorbilia berberidis*), **2**. *O. berberidis* Velen. (≡ *H. berberidis*), **3**. *O. crenatomarginata* Höhn., **4**. *O. paradoxa* Velen. (= *O. xanthostigma*), **5**. *O. occulta* (Rehm) Sacc. (= *O. aristata*), **6**. *O. carpathica* Velen. (?= *O. flagellispora*). Note difference in ascus bases between *Hyalorbilia* (figs **1–2**) and *Orbilia* (figs **3–6**).

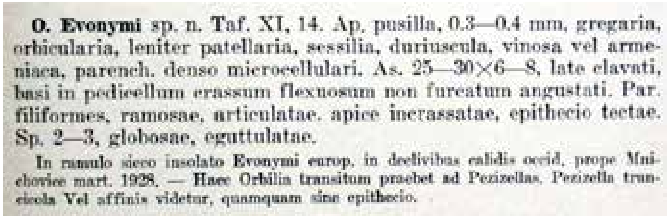
anatomical structure of the apothecia, following the tradition founded by Durand (1901). Therefore, Nannfeldt provided accurate and informative drawings of excipular textures (Fig. 153), but the hymenial characters are given much too little attention, if mentioned at all. For example, the absence of data about asci, paraphyses, and spores in his description of *O. inflatula* (l.c.: 254, ≡ *Hyalorbilia inflatula*) does not even allow recognition of the genus (the textura angularis shown on his fig. 40d might point to a member of *Orbilia* rather than *Hyalorbilia*).



O. Evonymi sp. n. Taf. XI, 14. Ap. pusilla, 0.3—0.4 mm, gregaria, orbicularia, leniter patellaria, sessilia, duriuscula, vinosa vel armeniaca, parench. denso microcellulari. As. 25—30×6—8, late clavati, basi in pedicellum crassum flexuosum non furcatum angustati. Par. filiformes, ramosae, articulatae, apice incrassatae, epithecio tectae. Sp. 2—3, globosae, eguttulatae.

In ramulo sicco insolato Evonymi europ. in declivibus calidis occid. prope Mnichovice mart. 1928. — Haec Orbilia transitum praebet ad Pezizellas. Pezizella truncicola Vel affinis videtur, quamquam sine epithecio.

Figure 155: Example of an *Orbilia* described as a new species by Velenovský (1934: 95; for his pl. 11 fig. 14 see Fig. 156: a).

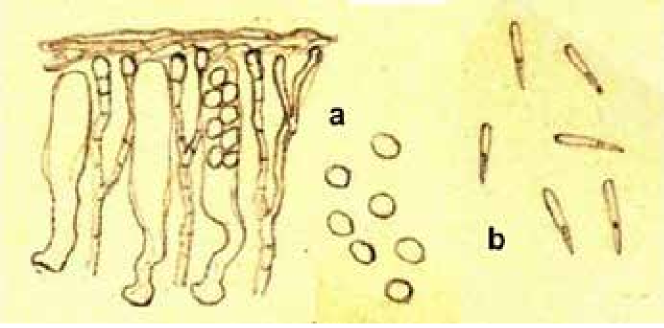


Figure 156: Examples of Velenovský's drawings on his unpublished manuscript plates. — **a**. *Orbilia euonymi* (holotype; the asci are in fact 32-spored, according to the present reexamination); **b**. *Orbilia* '*luteorubella*' (on *Cornus sanguinea*, 1.VII.1925; probably *O. sarraziniana*; the living ascospores contain subulate SBs at the acute end).

Velenovský (1934: 91–103, 1940: 177, 1947: 101–105) described by far the highest number of new taxa in *Orbilia*. For the region of Bohemia and Moravia (Czechia) and adjacent areas he reported a total of 69 species and 12 varieties. Although he supplied microscopic drawings for many of his taxa published in 1934 (see Fig. 154), he left all those unillustrated which he described later (however, drawings of two of his new taxa collected in 1942 and published in 1947 could be found among his manuscript plates, *O. vitrea* and *O. lupini*). The value of Velenovský's work was doubted by later workers, and many of his taxa were found to be synonyms. Nevertheless, his concept of the genus *Orbilia* is a rather natural one: just one verified case of a non-orbiliaceous species came to our notice (*Orbilia veratri* Velen., = *Calycellina* aff. *chlorinella*). It is also difficult to understand why he placed possibly the same desiccation-tolerant species with glassy processes (*O. aristata*) in two different families: in *Orbilia* subgroup *Aristula* (as *O. occulta* or *O. aristata*) in the *Orbiliaceae*, and in the monotypic genus *Radotinea* (as *R. caudata*) in the *Hyaloscyphaceae*.

The very high conformity in the circumscription of the genus is surprising, since Velenovský's work is full of errors regarding nearly every described taxon (see above). Similarly surprising is the fact that, like Boudier, Velenovský never reported (non-globose) spore bodies in the ascospores in any of the species treated, although he claimed to be an advocate of vital taxonomy (see p. 191).

74 out of these 81 taxa were proposed as new species or varieties (50 new species and 12 new varieties in 1934, 12 new species in 1940 & 1947). In 1934 Velenovský distinguished 56 species of *Orbilia*, but estimated that 'surely 200' exist within Europe.

Among the characters on which he based his generic concept, Velenovský stressed the inamyloid asci with their thin flexuous stipe and 2–3-furcate base, also the apices of the non-coherent (!) paraphyses which are either uninflated and covered by an epithecium (= exudate), or inflated and then without epithecium.

Velenovský (1934) proposed the family *Orbiliaceae* without being aware of Nannfeldt's (1932) study. Besides *Orbilia*, he

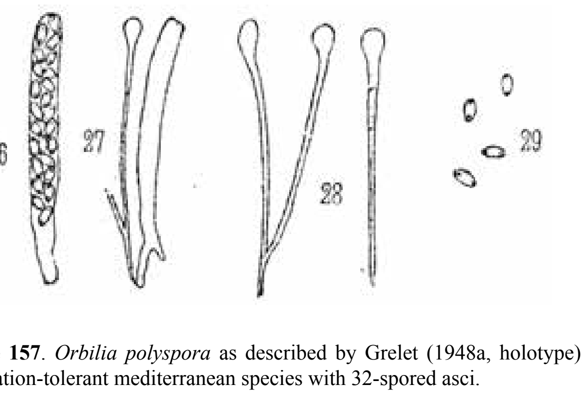

Figure 157. *Orbilia polyspora* as described by Grelet (1948a, holotype), a desiccation-tolerant mediterranean species with 32-spored asci.

Table 40. Infrageneric groups within *Orbilia* (rank not specified) as circumscribed by two Czech authors, based in the first place on spore shape. *Ascophorae* (VI) represents series *Habrostictis* in the present monograph, while *Spirospora* (IIa), *Spirospora* (II1) *Microsporae*, *Orbilia* (Ib) p.p., and *Euorbilia* (I2) *Stenosporae* correspond to the genus *Hyalorbilia*. *Soleina* concerns the single species *O. paradoxa* (= *O. xanthostigma*), *Euorbilia* (I1) *Ovatosporae* represents *O. xanthostigma* s. Svrček (= *O. tremulae*/*O. eucalypti*), and *Aristula* corresponds to series *Hemiorbilia*.

Velenovský (1934, 1940, 1947)	Svrček (1954)
(I) *Orbilia*: spores globose, ellipsoid to acicular, straight	(I) *Euorbilia*: spores not curved
(Ia) paraphyses clavate, without epithecium (25 spp.)	(I1) *Ovatosporae*: spores ovate (1 sp.)
(Ib) paraphyses not inflated, with epithecium (38 spp.)	(I2) *Stenosporae*: straight (8 spp.)
(II) *Spirospora*: spores very narrow, sickle-shaped	(II) *Spirospora*: spores sickle-shaped
(IIa) asci unstalked, not bifurcate (5 spp.)	(II1) *Microsporae*: spores small (2spp.)
(IIb) Asci stalked, bifurcate (6 spp.)	(II2) *Macrosporae*: spores large (2 spp.)
(III) *Hyalinia*: spores very narrow, strongly helicoid (1 sp.)	*Hyalinia* (recognized at the generic level)
(IV) *Soleina*: spores strongly allantoid-hemicircular ('soleiform', 1 sp.)	(III) *Soleina*: spores allantoid-hemicircular (1 sp.)
(V) *Aristula(e)*: spores fusoid, with a long thin tail (3 spp.)	(IV) *Aristula*: spores with a long and thin tail (1 sp.)
(VI) *Ascophorae*: asci min. 50 µm long, paraphyses with fusoid apex, without epithecium (1 sp.)	*Habrostictis* (recognized at the generic level)

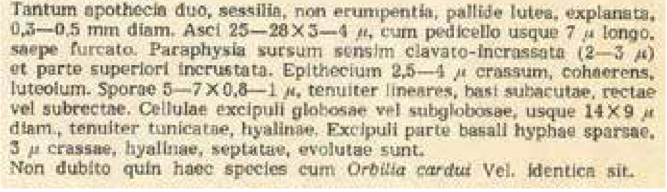
placed six further genera in that family: in 1934 *Agyrium* Fr., *Orbiliopsis* Velen., *Laricina* Velen., *Calloria* Fr., and *Stamnaria* Fuckel, and in 1940 *Algincola* Velen. Yet, almost all of the species assigned by him to these genera are clearly non-orbiliaceous (for *Algincola quercina* and *Laricina mollis* see p. 1682 and p. 1679).

Velenovský (1934) divided the large genus *Orbilia* into five subgroups, and in 1947 he added a sixth one (see Tab. 40). His infrageneric system is primarily founded on spore shape but also on paraphysis apex and ascus base features. His subgroup IIa comprises only species here referred to *Hyalorbilia*, while all those *Hyalorbilia* species with straight spores were placed in subgroup Ib. Subgroup VI corresponds to *Habrostictis*.

For the discomycetes of France, Grelet (1948a: 49f.) listed 16 species in *Orbilia*, 10 of which are with certainty orbiliaceous. The new species *O. polyspora* (Fig. 157) was reported with '24-spored' asci with a bifurcate base ('souvent éperonnées à la base').

Seaver's (1951: 152) account on the North American inoperculate discomycetes comprises 20 species in the genus *Orbilia.* About ten of these are non-orbiliaceous, and only one out of six species transferred by him to the genus (*O. cruenta*) appears to be orbiliaceous. The mentioned generic characters include brightly coloured, mostly smooth apothecia, often subglobose to pyriform tips of paraphyses (in *O. cruenta* rarely also lanceolate), and minute spores 'often difficult to diagnose'.

In Svrček's (1954) revision of 69 species and 12 varieties referred to *Orbilia* by Velenovský, he accepted 15 species and two forms in *Orbilia*, for which he provided a dichotomous key, and two species in two other genera: *O. vacini* in *Habrostictis* (as *H. rubra*), *O. crenatomarginata* and *O. roseohyalina* in *Hyalinia* (both as *H. crystallina*). Among Velenovský's new taxa (62 species and 12 varieties), Svrček accepted only seven species and two forms, while he considered the remaining taxa to be either dubious or synonymous. Svrček's descriptions (Fig. 158) are only insignificantly more detailed than those of Velenovský, but his observations are more reliable, though illustrations are completely lacking in this paper.



Orbilia luzularum Vel., Mon. Disc. Boh. p. 99, 1934.
Holotypus: Hrusice prope Mnichovice (Bohemia centr.), ad folium emortuum anni praecedentis Luzulae pilosae, VIII. 1924, leg. Velenovský (hMNP 150028).
Tantum apothecia duo, sessilia, non erumpentia, pallide lutea, explanata, 0,3—0,5 mm diam. Asci 25—28 × 3—4 µ, cum pedicello usque 7 µ longo, saepe furcato. Paraphysis sursum sensim clavato-incrassata (2—3 µ) et parte superiori incrustata. Epithecium 2,5—4 µ crassum, cohaerens, luteolum. Sporae 5—7 × 0,8—1 µ, tenuiter lineares, basi subacutae, rectae vel subrectae. Cellulae excipuli globosae vel subglobosae, usque 14 × 9 µ diam., tenuiter tunicatae, hyalinae. Excipuli parte basali hyphae sparsae, 3 µ crassae, hyalinae, septatae, evolutae sunt.
Non dubito quin haec species cum *Orbilia cardui* Vel. identica sit.

Figure 158: Example of a redescription by Svrček (1954) in his revision of *Orbilia* taxa erected by Velenovský.

The present revision confirms Svrček's species concept to a large extent, though in a number of taxa a different conclusion was attained. For instance, Svrček listed *O. juliae* and *O. polypori* as synonyms of *O. inflatula*, but we treat these three taxa as separate species within *Hyalorbilia*; in the type of *O. alnea* var. *vesiculosa* he observed ellipsoid spores, hence he assigned the taxon to *O. xanthostigma* s. Svrček (= *O. tremulae*/*eucalypti*), but the present examination revealed cashew-shaped warted spores typical of *O. xanthostigma*. For ten of Velenovský's new taxa Svrček could not trace type material. For further eleven taxa he was unable to detect any apothecia on the substrate, and for two he found only immature apothecia. Svrček probably did not rehydrate the dry specimens prior to scanning: in the present study mature apothecia could be detected in six of those apparently empty specimens (*O. euonymi*, *O. cardui* var. *farfarae*, *O. aristata*, *O. leporina*, *O. spinosae*, *O. vitrea*).

Svrček's arrangement of the accepted taxa of *Orbilia* follows Velenovský's system, but is more simplified since it is merely based on spore shape. He recognized four main groups (see Tab. 40). Svrček's arrangement is very different from the present system, and undoubtedly highly artificial. For instance, the three taxa *O. berberidis*, *O. inflatula* and *O. oreadum* are clear members of *Hyalorbilia*, whereas Svrček distributed them to three of his categories, which also include members placed by us in *Orbilia* subgenus *Orbilia*. Svrček's neglect of the ascus base (unstalked vs. stalked-furcate) is astonishing since Velenovský

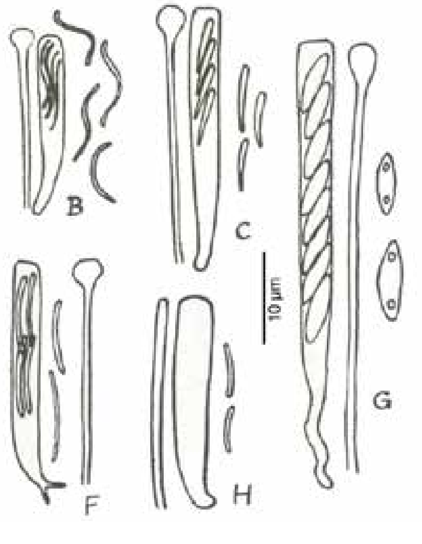


Figure 159: *Orbiliaceae* from tropical America, drawn by Dennis (1954: fig. 6), all from type material (except for C). B. *Orbilia curvatispora* var. *minor* (?= *O. crenatomarginata*), C. *O. juruensis*, F. *O. tenuissima*, G. *Helotium marmolense* (= *O. carpoboloides*), H. *O. andina* (≡ *Hyalorbilia andina*).

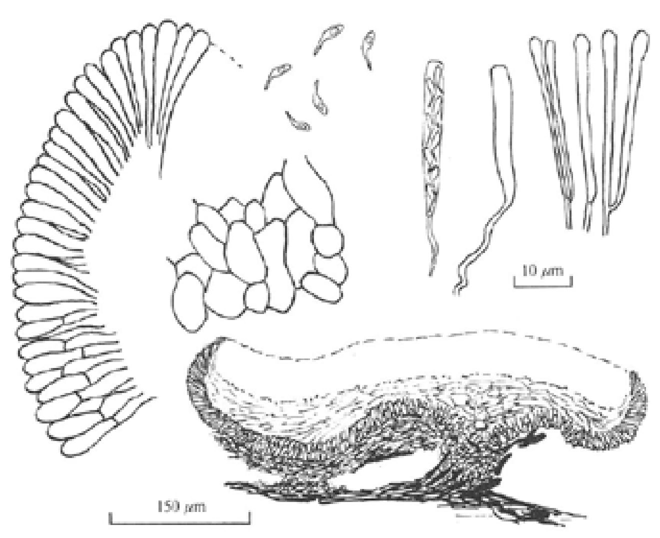

Figure 160: *Orbilia comma* (Great Britain, Warwickshire, holotype), drawn by W.D. Graddon (1977: fig. 17), spores in the living state.

already recognized to a certain extent the present concept of *Hyalorbilia* at some infrageneric level.

Dennis (1954: 295) provided a key to the seven orbiliaceous species known from the Caribbean region, with brief descriptions and illustrations (Fig. 159). When treating the fungi of Venezuela and adjacent countries, Dennis (1970: 351) reported nine species in *Orbilia*. All these Caribbean and South American taxa are obviously orbiliaceous (two of them belonging to *Hyalorbilia*), and most of them were reexamined in the present study. When Dennis studied *O. andina* (Fig. 159: H), he overlooked the isolated position of the genus *Hyalorbilia*, similar as Svrček did. According to the present reexamination, that species shows the typical characteristics of *Hyalorbilia*: unstalked asci arising from croziers, uninflated paraphyses, and a horizontal textura prismatica (see Pl. 75).

Moser (1963) included a key to the central European taxa of *Orbiliaceae*, with eight species recognized in *Orbilia* and three in *Hyalinia*. All of them are orbiliaceous according to the present knowledge. When using apothecial colour as a diagnostic character, Moser was apparently unaware of Rehm's (1891) statement that pigmentation in *Orbilia* is a rather unreliable character.

1977–2020. Jeng & Krug (1977) gave a brief history of the genus *Orbilia* when describing *O. fimicola*, a member of the difficult *O. auricolor* complex. The authors obviously viewed the coprophilous habitat as characteristic of their taxon, but did not notice its obvious similarity with *O. auricolor*.

For the British ascomycetes flora, Dennis (1968, 1978: 187, 196) treated seven species in *Orbilia*, apart from one in *Hyalinia* and one in *Habrostictis*. Among them is a non-orbiliaceous taxon (*O. marina*) with asci with amyloid apical rings, which was later transferred to *Laetinaevia* (Kirk & Spooner 1984: 568) and recently to *Calycina* (Baral & Rämä 2015). Dennis stressed the asci of *Orbilia* to be 'exceptionally small, often with a characteristically forked base and truncate tip, not blued by iodine', and the hymenial elements to 'cohere firmly to give the waxy texture peculiar to the family'. Ellis & Ellis (1985) keyed out twelve British species in *Orbilia*, while treating two others in *Habrostictis* and *Hyalinia*. One of them, *O. comma*, was described by Graddon (1977), who observed the spore body in the living spores (Fig. 160).

Ahmad (1978: 210) briefly described three species of *Orbiliaceae* from Pakistan: *O. auricolor* s.auct. (= *H. inflatula*), *O. curvatispora* (= *O. auricolor*), and *O. leucostigma*. Thind & Sharma (1980) gave detailed descriptions of species collected from the Indian subcontinent, which they identified with four European taxa: *O. auricolor* s.auct., *O. curvatispora*, *O. luteorubella*, and *O. xanthostigma*. However, the hymenial characters are illustrated with only slight deviations among these four taxa, so that their differentiation seems hardly possible. The spores of *O. curvatispora* are depicted nearly straight, although they are strongly curved on a sketch (possibly by A. Raitviir) on the label of the here examined duplicate in TAAM. The reported amyloidity of the asci was found to be an error (see p. 48). In the generic diagnosis the statement sounds strange that the asci of *Orbilia* usually have unbranched bases and non-truncate apices. This would point to members of *Hyalorbilia*, but the paraphyses are drawn with abruptly swollen apices and the ectal excipulum with isodiametric cells. Later, Thind et al. (1983) added a detailed description of a further species, *O. rubrococcinea* (Rehm) Sacc. Also Pande (2008) reported only five species for India: *O. auricolor* (s.auct., ?= *H. inflatula*), *O. coccinella*, *O. sarraziniana*, *O. vinosa*, and *O. xanthostigma*. Her descriptions are very brief and leave species identity quite unclear.

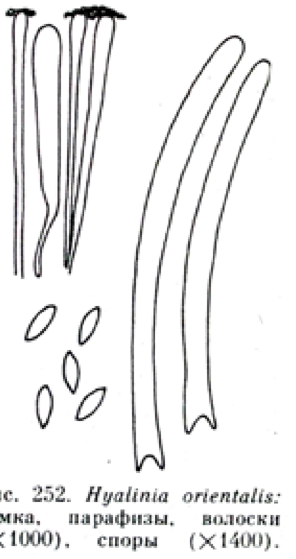

Figure 161: *Hyalinia orientalis* (Primorje, Russian Far East, holotype, ≡ *O. orientalis*), drawn by A. Raitviir (1991: fig. 252) in the dead state.

The apparent paucity of *Orbilia* species in Asia is in conflict with a statement by Batra & Batra (1963: 151) in a checklist on the Indian discomycetes, according to which many species of both *Orbilia* and *Hyalinia* are known from India. The authors

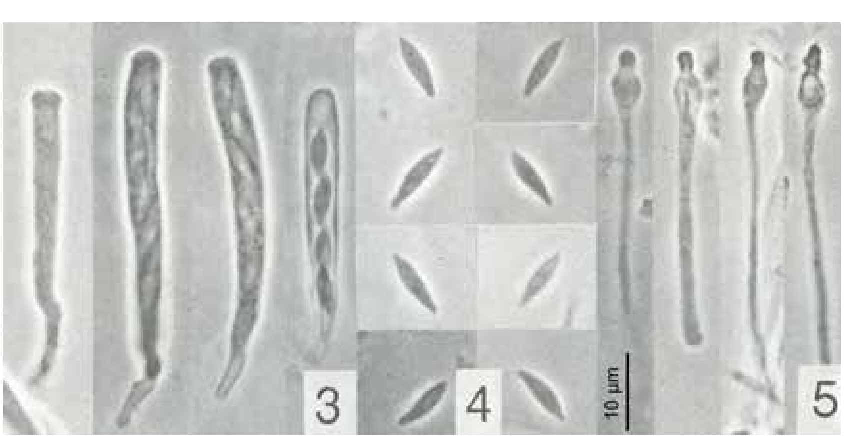

Figure 162: *Orbilia piloboloides* (Québec, Canada, holotype, = *O. carpoboloides*), photographed by Haines & Egger (1982) in the dead state.

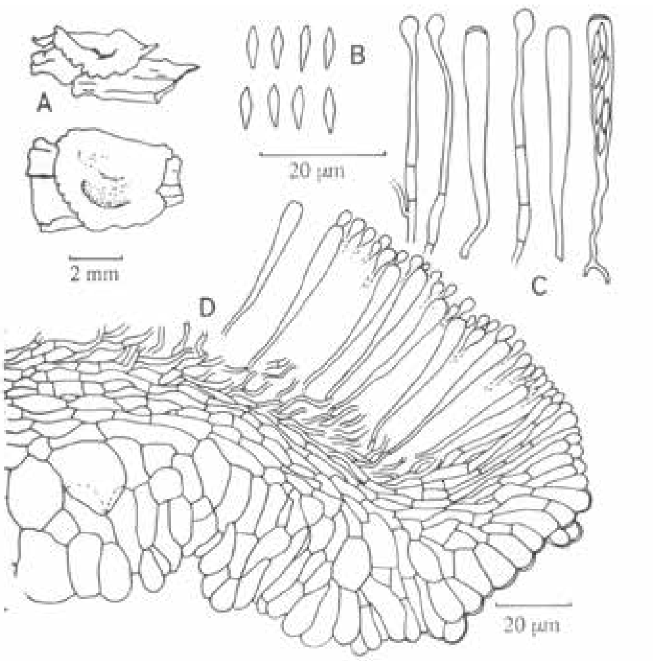

Figure 163: *Orbilia juruensis* (Solomon Islands, Melanesia), drawn by Spooner (1987: fig. 24) in the dead state.

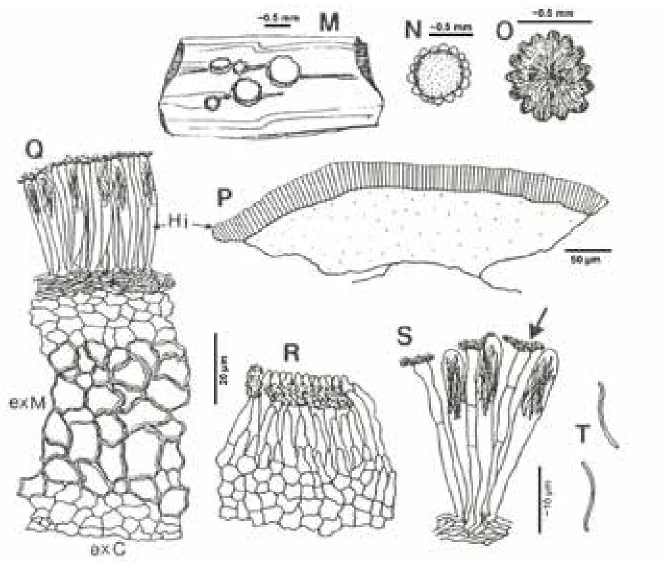

Figure 164: *Hyalinia scolecospora* (Buenos Aires, Argentina, ≡ *Orbilia scolecospora*), drawn by Romero (1994, some scale bars adjusted).

stated that they did not determine specific names since no authentic material for comparison was available. Regrettably, they did not present descriptions, and did not cite any voucher material.

In their ascomycetes flora of Switzerland, Breitenbach & Kränzlin (1981: figs 250–254, 261) presented colour photographs of four species in *Orbilia* (*O. coccinella*, *O. curvatispora*, *O. sarraziniana*, *O. xanthostigma*), one in *Hyalinia* (*H. rosella*), and one in *Habrostictis* (*H. rubra*). Although these species were photographed in the fresh state, the authors made their microscopic drawings consistently from dead, dried material.

For the Russian Far East, Raitviir (1991: 356–362) provided descriptions and a key to eight orbiliaceous species in the genus *Orbilia* (one of them, *O. inflatula*, belonging to *Hyalorbilia*), and two species with glassy processes in *Hyalinia*. One of his rather schematic sketches is shown in Fig. 161.

Haines & Egger (1982) described the North American *O. piloboloides* (Fig. 162), a desiccation-tolerant species on bark

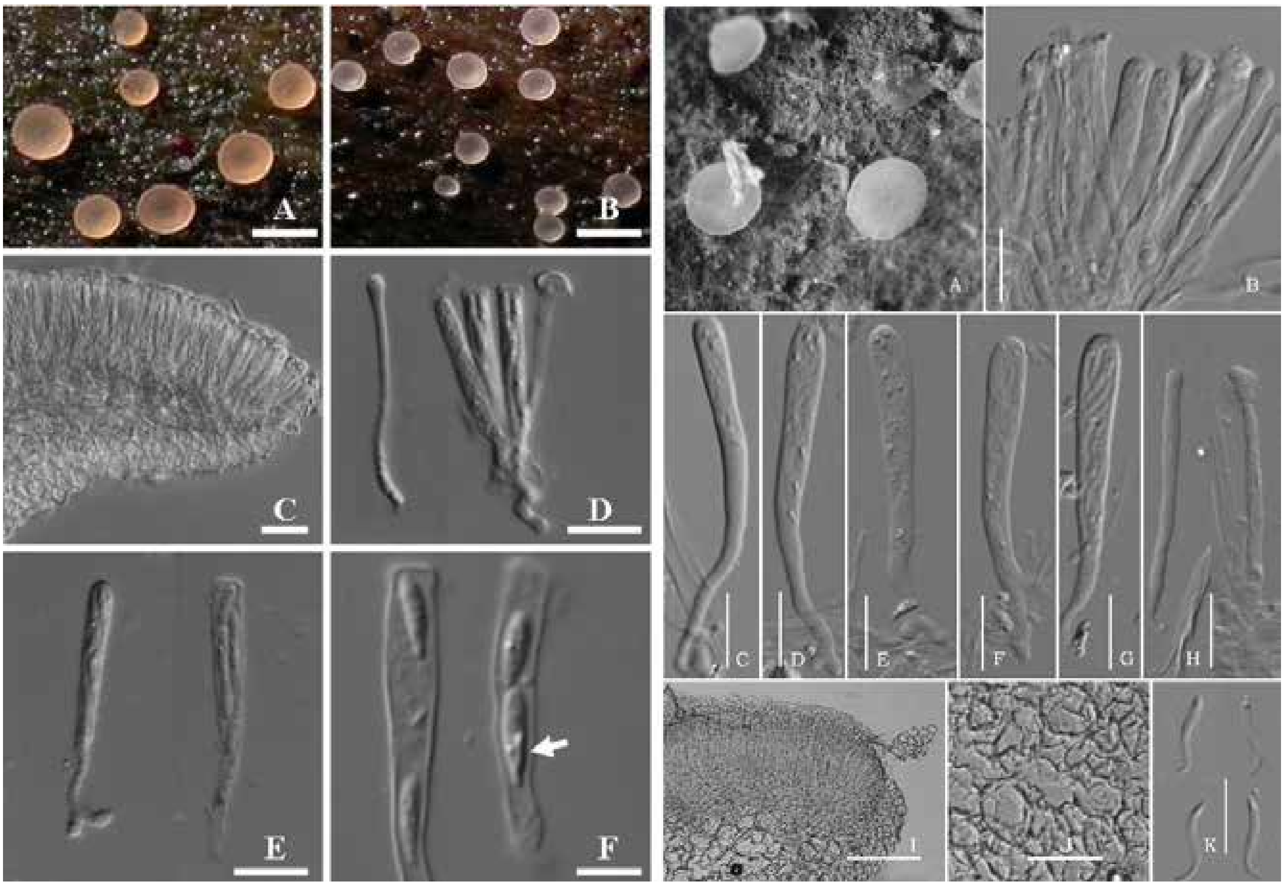

Figure 165: **left**: *Orbilia sarraziniana* (Beijing, China, from Liu 2006: fig. 41); **right**: *O. vermiformis* (Yunnan, China, holotype, from Yu et al. 2007a).

of *Ulmus*. The authors stressed the extraordinary shape of the *Pilobolus*-like apices of paraphyses, and reported an anamorph obtained in pure culture. They obviously overlooked that their species is very similar to the European *Habrostictis rubra* (= *O. carpoboloides*, likewise often found on bark of *Ulmus*), with which it even appears to be conspecific (see p. 1033). The examination of a later collected topotype of *O. piloboloides* in the living state (Pl. 573: 1) supplies the vital characters of this species, which were previously not reported due to unfavourable preparation methods.

When treating the *Helotiales* of Australasia (including Melanesia), Spooner (1987) provided detailed descriptions and illustrations of seven species accepted in *Orbilia* (Fig. 163), one in *Hyalinia*, and one in *Habrostictis*, most of them being collected by G. & K. Beaton in the warm-temperate humid southeast of Australia. *Orbiliaster* was accepted as a further genus of the *Orbiliaceae* unknown in Australasia. Spooner's generic concept is mainly based on the presence and construction of the hairs, and the shape of paraphysis apices. For the first time the warted dorsal surface of the ascospores of *O. delicatula* (= *O. xanthostigma*) is reported.

Baral (1989) described *O. septispora*, which remained until now the only known species of the large genus *Orbilia* having septate ascospores within the living asci (Pl. 683). The remarkable subulate SBs in the spore apices of this and some other species gave the impetus to the present monograph.

Korf (1992) investigated the *Orbiliaceae* of Macaronesia, with *Orbilia* as the only known genus. He presented a key to eight species, two of which (*O. inflatula* and the new species *O. lunata*) are assigned to *Hyalorbilia* in the present study. Korf followed a rather wide species concept, according to the present reexamination: for instance, under *O. epipora* he merged specimens belonging to *H. inflatula* and *O. ?dryadum*, and under *O. occulta* specimens that belong to *O. pisciformis* and *O. euphorbiae*.

In an unpublished poster, Baral (1993b) provided an overview of 29 mainly European species of *Orbiliaceae*. In another poster (Baral & Marson 1994) 35 desiccation-tolerant North American species were presented, 33 of which being considered as undescribed, thereby extending the concept of *Orbilia* to include species with olivaceous-black apothecia. Baral (1994) divided the genus *Orbilia* in two subgenera based on the structure of the ascus apex when viewed in the dead state. *Orbilia* subgenus *Hemiorbilia* was defined by hemispherical apices with an apical thickening, and *Orbilia* subgenus *Orbilia* by thin-walled, more or less truncate (shouldered) apices. *Habrostictis*, *Hyalinia*, and *Orbiliaster* were referred to synonymy with *Orbilia*, and within this genus all were thought to belong to subgenus *Orbilia*. Baral segregated a small group around *O. inflatula*, which was later described as a new genus *Hyalorbilia* (Baral & Marson 2001). The truncate, shouldered, thin-walled type of ascus apex was also described by Descals et al. (1999, see Fig. 32: a), and the rounded type with a pronounced apical thickening was reported by Kohlmeyer et al. (1998, Pl. 390: 4).

In her floristic and ecological study about micromycetes on *Eucalyptus viminalis* stumps in Argentina, Romero (1994) reported four desiccation-sensitive species (three in *Orbilia*, one in *Hyalinia*). An example of her study is given in Fig. 164. Similar as in Nannfeldt's drawing of *Hyalinia crystallina* (Fig. 153), the glassy nature of the marginal processes (Fig. 164: R) is not clearly recognizable.

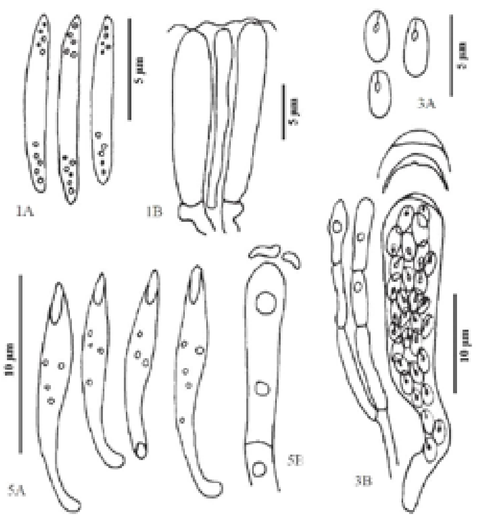

Figure 166: *Hyalorbilia juliae* (1), *Orbilia euonymi* (3), *O. aurantiorubra* (5), drawn by Priou (2005) in the living state.

Since 1994 a series of papers was published on connections between anamorphs and teleomorphs within the *Orbiliomycetes*, mainly from Chinese isolates (see Tab. 41). Various new species of *Orbilia* s.str. were published during these years, predominantly from living material and often dealing also with their anamorphs (Kohlmeyer et al. 1998, Webster et al. 1998, Karasch et al. 2005, Liu et al. 2005a, Liu et al. 2006b, Yu et al. 2007a, b [see Fig. 165 right], Zhang et al. 2009b, Su et al. 2011c, Friebes 2011, Ekanayaka et al. 2018, Shao et al. 2018, Zhang et al. 2020a).

Priou (2005) reported six desiccation-tolerant species of *Orbiliaceae* (five of *Orbilia*, one of *Hyalorbilia*) in the living state, all from atlantic Europe, and emphasized their restricted occurrence on xeric substrate. Quijada et al. (2014b) investigated by morphological and molecular methods *O. aurantiorubra* and three new species, *O. jugulospora*, *O. xanthoguttulata*, and *O. succulenticola*. Quijada et al. (2016) presented descriptions, images, and a key to 18 *Orbilia* species recorded in Tenerife, but he included only described species, whereas many further species, being newly described in the present monograph, were recorded from this island.

Liu et al. 2006b provided a key to the species of *Orbiliaceae* known from Tibet (two of *Hyalorbilia*, eleven of *Orbilia*). In his unpublished thesis, Liu (2006) presented keys and descriptions of 20 species and one variety of *Orbilia* known from China (see Fig. 165 left). For the identification of taxa, such as *Orbilia aprilis*, *O. euonymi*, or *O. orientalis*, these authors had the unpublished type studies of the present monograph at their disposal.

Cheilodonta Boud., Bull. Soc. Mycol. Fr. 1: 114 (1885) –
Lectotype species: *Peziza carpoboloides* P. & H. Crouan (indirectly designated by Höhnel 1917: 333)

The genus was erected for two species, *Peziza carpoboloides* (on rotten cord) and *P. lasia* Berk. & Broome (on bark of *Ulmus*). It was characterized by apothecia with a dentate margin (from this the name *Cheilodonta* is derived), being first closed and cupulate when young, and by the acuminate-spathulate tips of paraphyses. Lindau (in Engler 1897: 217) considered *Cheilodonta* to be a possible synonym of *Orbilia*. Boudier placed *Cheilodonta* in his '*Calloriés*' near *Orbilia* and *Hyalinia*. Later (1907: 102, 1908: 265) he placed *P. carpoboloides* and *P. lasia* in *Habrostictis*, a name which he obviously had overlooked, and retained this genus close to *Orbilia* (the name *Cheilodonta* is not

Figure 167: *Habrostictis carpoboloides* (≡ *O. carpoboloides*), drawn by Boudier (1904–10, pl. 459), ascospores in the dead state.

further mentioned). Höhnel (1917: 330f.) suggested to maintain the genus *Cheilodonta* based on *P. carpoboloides* as distinct from *Habrostictis*, since he saw no teeth at the apothecial margin in the type material of *H. rubra* (on bark of *Ulmus*), which he considered to be undoubtedly synonymous with *O. lasia*, although Fuckel described them as 'margine lacerato-fimbriato'. However, Nannfeldt (1932: 96) accepted the synonymy of *Cheilodonta* with *Habrostictis*. Based on type studies, Baral (1994: 119) found that *P. carpoboloides* and *H. rubra* represent the same species. Because of a similar ascus structure he placed *Habrostictis* (= *Cheilodonta*) in synonymy with *Orbilia*. *P. lasia* was already found by Rehm (1891: 456) to be a synonym of *H. rubra*.

Habrostictis Fuckel, Jahrb. Nassau. Ver. Naturkd. 23/24: 249 (1870) – Lectotype species: *H. rubra* Fuckel, designated by Höhnel (1917: 330).

The genus was named after the resemblance to a *Stictis* (the prefix habro means soft-fleshed). It was defined by soft, translucent apothecia and fusiform('lanceolate')-cylindric or egg-shaped ascospores. Besides *H. rubra*, Fuckel included three further taxa: *Stictis ocellata* (Pers.) Fr. [≡ *Pezicula ocellata* (Pers.) Seaver], which he validly transferred to *Habrostictis* a year later (Fuckel 1871), *Schmitzomia chrysophaea* (Pers.) Fr. [as 'Rbh.', ≡ *Ramonia chrysophaea* (Pers.) Vězda], and '*Stictis lecanora* (Pers.) Fr.'. The protologue was apparently influenced by the broadly ellipsoid-ovoid ascospores of *P. ocellata*.

Fuckel (1870) described the type species with erumpent, at first closed, then lacerate-fimbriate apothecia, and apically capitate-ovate paraphyses. He placed *Habrostictis* in the '*Stictei*' between *Naevia* and *Stictis*. Boudier (1907, 1904–10) accepted *Habrostictis* with *H. carpoboloides* and *H. lasia* (the name *H. rubra* was not mentioned). He placed the genus close to *Orbilia* and modified the circumscription by including truncate asci (after spore discharge) and correcting the shape of paraphysis apices to markedly lanceolate (Fig. 167). Phillips (1887), Massee (1895), Rehm (1891) and others did not hesitate to include a species in *Orbilia* (under the synonym *O. lasia*) which has hairy, erumpent apothecia that open rather late, and acute paraphyses. Also Haines & Egger (1982) did so with their *O. piloboloides* (= *O. carpoboloides*). Nevertheless, later authors followed Höhnel (1917: 330f., 1926b: 96) who accepted *Habrostictis* as a genus distinct from and not even related to *Orbilia*.

Höhnel (1917) excluded *Stictis ocellata* and *Schmitzomia chrysophaea* from *Habrostictis* by stating that *H. rubra* is the type of the genus. On account of an ectal excipulum composed of isodiametric cells and erumpent, orange apothecia in the type of *H. rubra* and, as he believed, a similar anamorph, Höhnel transferred *Habrostictis* to the '*Dermateen*' (1917) or '*Stictideen*' (1926b) in the vicinity of *Ocellaria* and *Dermatea.* Höhnel, followed by Nannfeldt (1932: 96), included in *Habrostictis* a non-orbiliaceous species, *H. roseoflavida* (Rehm) Höhn., which is considered here to belong to *Cistella* (see p. 1683).

The placement of *Habrostictis* close to *Ocellaria* was followed, e.g., by Nannfeldt (l.c.), who had both in the *Peziculoideae* of *Dermateaceae*, Korf (1973), Sherwood (1977), and Breitenbach & Kränzlin (1981). Grelet (1948a), however, placed *Habrostictis* close to *Orbilia*, following Boudier.

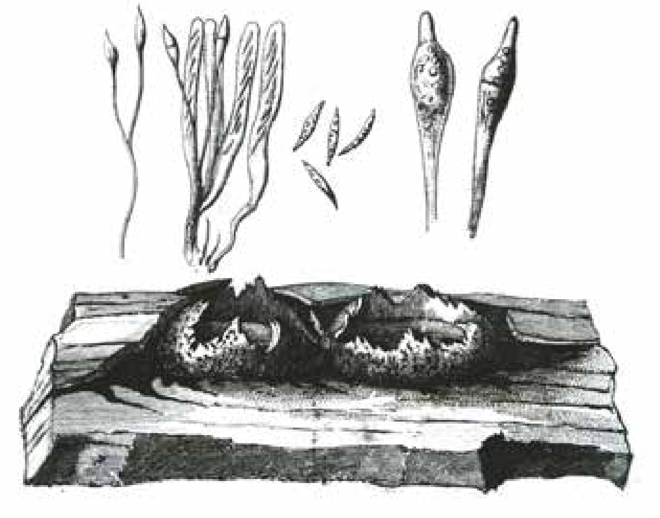

Figure 168: Holotype of *Peziza* (*Dasyscypha*) *lasia* (= *Orbilia carpoboloides*, on bark of *Ulmus*), drawn by M.J. Berkeley in the dead state (from Berkeley & Broome 1873: pl. VIII fig. 10).

Figure 169: Holotype of *Peziza carpoboloides* (≡ *O. carpoboloides*, on decayed twine), drawn by H.M. Crouan in the dead state (**left**: from Crouan & Crouan 1867: pl. suppl. fig. 10; **right**: unpublished watercolour sketch).

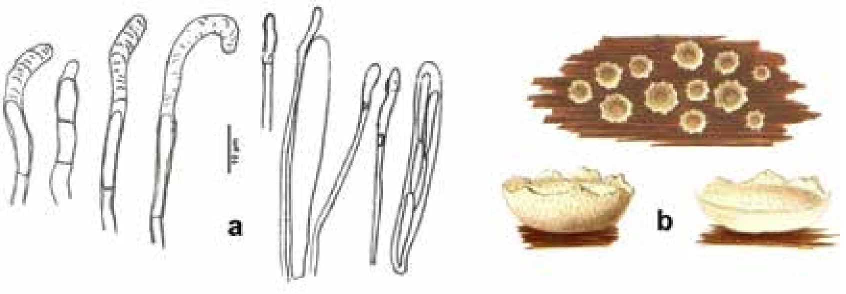

Figure 170: **a**. *Orbilia albovinosa*: dead asci, paraphyses, marginal cortical cells terminated by glassy processes, drawn by Maire (in sched., as *Hyaloscypha albovinosa*); **b**. *Hyalinia crystallina* (= *O. crenatomarginata*): apothecia with a dentate margin, drawn by Boudier (1904–10: pl. 466).

Dennis (1960a: 111; 1968: 176; 1978: 187, 196) recognized a similarity with the *Orbiliaceae* but retained *Habrostictis* in the *Dermateaceae*. Hein (1976: 9) gave a history of the genus which he excluded from the *Naevioideae* (= *Calloriaceae*). Spooner (1987: 159, 192) considered *Habrostictis* as clearly orbiliaceous, mainly because of the ascus characters (truncate apex, base sometimes forked), but he kept the genus separate from *Orbilia* on account of 'lanceolate to flame-shaped' apices of paraphyses, asci mostly exceeding 50 µm in length, and erumpent, fimbriate apothecia, with a marginal ectal excipulum composed of parallel septate hyphae. Verkley (1999: 151) accepted placement of *Habrostictis* in *Orbiliaceae* by emphasizing that it is 'not even remotely related' to *Dermateaceae*. This high phylogenetic distance is also seen in Phyl. 1.

Habrostictis was placed in synonymy with *Orbilia* subgenus *Orbilia* by Baral (1994), because very closely related species (e.g., *O. serpentina* and *O. trapeziformis*) deviate in having capitate paraphyses and non-fimbriate apothecia, though featuring strikingly similar characters of asci and ascospores, particularly the same type of vermiform-subulate or filiform spore bodies.

In the present monograph, species with lanceolate to spathulate-lageniform paraphyses similar as in *O. carpoboloides* are assigned to a small group (series *Habrostictis*, p. 1024) within the very large section *Habrostictis*, which exclusively comprises desiccation-tolerant species. At the subgeneric level we here use the name *Habrostictis* by inclusion of sections *Aurantiorubrae* and *Helicoon* which likewise mostly possess elongate SBs. Placement of series *Habrostictis* within the present large concept of *Orbilia* is demonstrated by molecular phylogenetic methods (see p. 1025).

Hyalinia Boud., Bull. Soc. Mycol. Fr. 1: 114 (1885), nom. illegit. (Art. 53.2 ICN), non *Hyalina* Stackh. 1809 (= *Desmarestia* Lamouroux 1813, nom. cons., *Phaeophyceae*) – Type species: *Helotium crystallinum* Quél.

The name of this genus refers to the translucency of the slightly pigmented apothecia. Boudier (1885) differentiated *Hyalinia* from *Orbilia* by subhyaline apothecia with a dentate margin (Fig. 170: b), non-inflated apices of paraphyses, and vermiform ascospores. In his survey on the European discomycetes, Boudier (1907: 103) enlarged the concept of *Hyalinia* to include species with an even margin, e.g., *H. rectispora*. Here he treated in *Hyalinia* no less than 45 species, but only about five of them are with certainty orbiliaceous. Among the remaining ones, many are members of *Helotiales* (often related to *Calycina*, *Calycellina* and other genera of *Hyaloscyphaceae*), some belong to *Lecanorales*, and many are nomina dubia (see p. 1660 ff.). Filiform paraphyses and vividly coloured ('gaie'), usually translucent apothecia with an often denticulate margin are mentioned by Boudier as characteristic of *Hyalinia*. Because of the marginal teeth, Lindau (1897: 205) referred *Hyalinia* to synonymy with *Cyathicula*.

In contrast to Boudier, Höhnel (1907a: 133) reduced the differences between *Hyalinia* and *Orbilia* to the marginal teeth, since the paraphyses were capitate in his *Hyalinia crenatomarginata*. However, no apical inflation of the paraphyses was seen in the type material of this taxon, which is considered to be conspecific with *Hyalinia crystallina* (Quél.) Boud. in the present study. Saccardo (1889 and later volumes of Sylloge Fungorum) never adopted *Hyalinia* as different from *Orbilia*, and also Clements & Shear (1931) listed *Hyalinia* as a synonym of *Orbilia*.

Nannfeldt (1932: 251), however, accepted *Hyalinia* in the modified sense of Höhnel by neglecting the shape of the paraphyses, but further included all species with hyphoid marginal processes, irrespective of being agglutinated as teeth (*H. crystallina*) or not (*H. rubella*). Kanouse (1939) appears to have treated a *Hyalorbilia* when she combined *Orbilia breviasca* Henn. into *Hyalinia* by stressing the non-inflated paraphyses as characteristic of *Hyalinia*. Grelet (1948b: 105) treated 14 species in *Hyalinia*. However, only five of them are with certainty orbiliaceous. Contrary to Höhnel and Nannfeldt, Grelet delimited the genus by apically non-inflated paraphyses and considered the marginal processes as unimportant at the generic level.

Moser (1963: 68) and Dennis (1978: 189) accepted *Hyalinia* in Nannfeldt's (1932) circumscription, and recognized three and one species, respectively. Spooner (1987: 159, 188) reexamined the type material of *Hyalinia crystallina* and also *H. scolecospora* G.W. Beaton, an Australian species described in Beaton & Weste (1978). Spooner accepted *Hyalinia* as distinct from other orbiliaceous genera on account of the marginal 'hairs', which he was the first to describe with a solid, glassy apical portion (in the present monograph referred to as 'glassy processes') and a lumen confined to the base of the 'hairs'. The absence of a lumen and the frequently observed stratification in the glassy part of the processes was precisely depicted already by Maire (in sched.) in *O. albovinosa* (Fig. 170: a), possibly in 1920, but was overlooked by other authors prior to Spooner, including Nannfeldt. For those species with septate hairs with a lumen up to the tip, Spooner (l.c.: 159) accepted the genus *Orbiliaster* Dennis. Among the seven species of *Hyalinia* recognized in the Checklist of the British Ascomycetes (Cannon et al. 1985) only one is surely orbiliaceous (*H. rubella*).

Hyalinia was placed in synonymy with *Orbilia* subgenus *Orbilia* by Baral (1994) because of the thin-walled, truncate ascus apices. The value of the glassy processes as a generic character was questioned because they were found to vary strongly in length. Moreover, very closely related species or even different collections of a single species often differ in this character between long, short, and completely absent. In the present monograph, *Hyalinia* comprises only species with helicoid ascospores and is accepted as a series of subgenus *Habrostictis* section *Aurantiorubrae*. The original key character, the glassy processes at the margin, is only present in some of

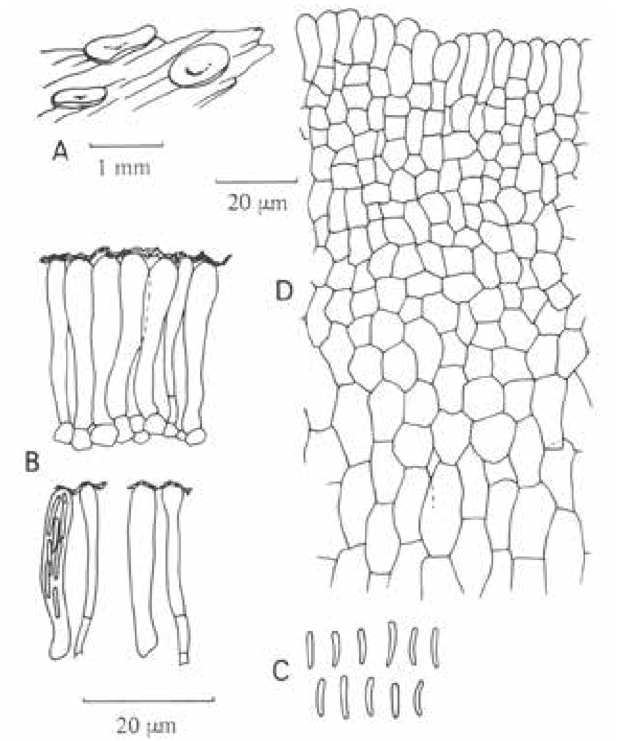

Figure 171. *Orbilia inflatula* (≡ *Hyalorbilia inflatula*). Victoria, Australia (Beaton 176), drawn by Spooner (1987: fig. 23) in the dead state.

the included species, while they occur in many other series of *Orbilia* as well.

The name *Hyalinia* Boud. is considered to be an illegitimate homonym of the older *Hyalina* Stackh. (brown algae), a name which is in concordance with the Code (ICN Art. 53.2; see, e.g., Kirk et al. 2008). The similarity of the two differently spelled names and their ease of confusion is illustrated by the fact that different listings erroneously spell both taxa in the same way. For example, Kirk et al. (l.c.) wrote '*Hyalinia*' for both names, whilst the Index Nominum Genericorum wrote '*Hyalina*' for both. In fact, Stackhouse's genus was originally spelled *Hyalina* and Boudier's *Hyalinia*. To our knowledge, *Hyalinia* has never been conserved against *Hyalina*, hence it must be considered as illegitimate.

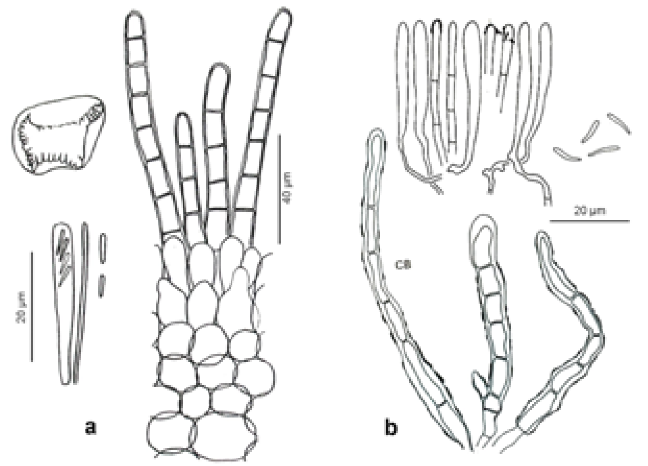

Figure 172: Septate hairs are the key character of *Orbiliaster* (drawings from holotypes in the dead state). — **a**. *O. pilosus* (≡ *Orbilia pilosa*), from Dennis (1954), from Lesser Antilles, Trinidad; **b**. *O. paradoxus* (≡ *Orbilia phragmotricha*), from Huhtinen (1992), from Finland, Varsinais-Suomi.

Hyalorbilia Baral & G. Marson, Micologia 2000: 44 (2001) – Type species: *Orbilia berberidis* Velen.

The genus was named after the pale colour and translucency of the apothecia. It was erected for five species, including *Orbilia inflatula* (P. Karst.) Sacc., based on a number of characteristics: asci with hemispherical apices without wall thickenings, base ± unstalked, arising from croziers, hymenial elements conglutinate in a gelatinous matrix, exudate on the surface of apothecia frequently forming minute warts, ascospores with a ± homopolar shape and in most species also with a homopolar guttule pattern formed by the SBs, ectal excipulum of horizontally oriented textura prismatica, and paraphyses apically not or only slightly inflated. Since type material of the well-known *O. inflatula* could not be located, a less known but well typified taxon, *O. berberidis* Velen., was chosen as type species. Although Spooner (1987) described most of these characteristics in a specimen identified as *O. inflatula* (Fig. 171), with exception of ascus croziers and guttules in living spores, he did not consider the possibility of a separate genus.

Liu et al. (2005b), Wu et al. (2007), and Su et al. (2011c) described four new species in the genus. Liu et al. (2006a) supported separation of *Hyalorbilia* from *Orbilia* at the generic level for the first time by molecular phylogenetic data. In his unpublished thesis, Liu (2006) presented a key to eight species of *Hyalorbilia* known from China, with descriptions and photo plates, and Quijada et al. (2014a) did so with six species and two unidentified *Hyalorbilia* spp. from Macaronesia. Liu et al. (2007b) presented three species of *Hyalorbilia* from China and Guo et al. (2014a, 2014b) eight. In all these works, *Hyalorbilia andina*, *H. erythrostigma*, *H. fusispora*, *H. juliae*, *H. oreadum*, and *H. polypori* were identified using the unpublished type studies of the present monograph.

Orbiliaster Dennis, Kew Bull. 9: 294 (1954) – Type species: *O. pilosus* Dennis

The genus was erected for a single tropical collection from Trinidad (Fig. 172: a). It is named after the long septate marginal hairs that may give the apothecia a star-like appearance. Later, Dennis (1970: 351) stated that the genus was perhaps not sufficiently distinct from *Hyalinia* emend. Nannf., probably because both have hair-like structures and apically uninflated paraphyses.

Huhtinen (1992) added a temperate species to the genus, *Orbiliaster paradoxus*, based on a recent record from Finland (Fig. 172: b). However, he was unaware of the presence of this species in Karsten's herbarium under the name *Orbilia rubella*. In fact, Karsten (1870, 1871) and Nannfeldt (1932: fig. 40e, see Fig. 153: e) overlooked septa in the hairs of their specimens (s. Karsten, e.g., FFE 834, see Pl. 429: 5). Nannfeldt treated *O. rubella* in *Hyalinia*; however, we propose the new name *Orbilia phragmotricha* for *Orbiliaster paradoxus* by keeping *O. rubella* as a close but separate species.

Baral (1994) placed *Orbiliaster* in synonymy with *Orbilia* subgenus *Orbilia*, because the presence of hairs was not found to be correlated with any other character that would support a separate genus. A later examination of the holotype of *Orbilia pilosa* and some other, apparently conspecific collections (Pl. 1001) confirmed the minor taxonomic value of hair-like structures in *Orbiliomycetes*. *Orbiliaster* is referred here to synonymy with series *Drechslerella* (section *Arthrobotrys* of subgenus *Orbilia*), because one of the specimens referred to

O. pilosa produced constricting rings in pure culture (Pfister 1997: 16, as *Orbilia* sp.; see also p. 1630).

Orbiliaster paradoxus (≡ *Orbilia phragmotricha*, = *O. rubella* s. Karsten) and *O. rubella* are treated in the present monograph in series *Rubellae* of subgenus *Habrostictis* section *Aurantiorubrae*. In Baral (1994) a close relationship between *Orbiliaster paradoxus* and *Hyalinia crystallina* (= *O. crenatomarginata*) was assumed, but our phylogenetic analyses indicate that the latter species is better placed in a separate series *Hyalinia* of section *Aurantiorubrae*.

Dennis used the name *Orbiliaster* as having a feminine gender. However, the traditional use of the suffix *-aster* is masculine, therefore, we believe that the two epithets need to be corrected to *pilosus* and *paradoxus* (Art. 62.1, Turland et al. 2018).

Orbiliella Kirschst., Ann. Mycol. 36: 374 (1938) – Type species: *O. armeniaca* Kirschst.

According to Kirschstein, *Orbiliella* differs from *Orbilia* mainly in the presence of a subiculum (*Orbiliella* is a diminutive of *Orbilia*). The genus was cited as a possible synonym of *Orbilia* by Spooner (1987). The presumed anamorph, referred by Kirschstein to *Trichothecium* Link, could be rediscovered close to the apothecia in the type specimen and is identified here as *Arthrobotrys* cf. *superbus*. It matches the anamorph obtained in pure culture of *Orbilia auricolor* by Pfister & Liftik (1995) who referred it to the very similar *A. cladodes* var. *macroides.* The teleomorph of *Orbiliella armeniaca* concurs with *Orbilia auricolor* as redefined by Spooner (1987). Since *O. auricolor* turned out to be an aggregate of several, more or less cryptic taxa, sequence data would be necessary to clarify the identity of *Orbiliella armeniaca*.

Pseudorbilia Ying Zhang, Z.F. Yu, Baral & K.Q. Zhang, Fungal Diversity 26: 306 (2007) – Type species: *P. bipolaris* Ying Zhang, Z.F. Yu, Baral & K.Q. Zhang

The genus was recently erected for a single species which shares characters of both *Orbilia* and *Hyalorbilia* (see p. 305). Because of the lack of DNA data, the phylogenetic affiliation of *Pseudorbilia* is unknown, but a close relationship to *Hyalorbilia* seems probable.

Radotinea Velen., Monogr. Discom. Bohem.: 298, pl. 17 figs 57, 58, 70 (1934) – Type species: *R. caudata* Velen.

The genus *Radotinea* was named after Radotín, now a village discrict in the southwest of Praha. Velenovský thought the type species to be intermediate between *Orbilia* and *Olla* Velen. (= *Unguicularia* s.auct.), but placed it in the *Hyaloscyphaceae* because of solid (glassy), 15–35 µm long 'hairs' with a lumen only at the very base (Fig. 173). Although the holotype was found to be empty by Svrček (in sched.) and also in the present study, the described and illustrated flexuous, bifurcate ascus bases and the exudate over the paraphyses clearly assign this taxon to the genus *Orbilia*, as was already stated by Baral (in Eriksson et al. 2003). The figured spermoid ascospores with a filiform tail of about the length of the ellipsoid upper part (total length 15–20 µm) and the glassy processes fit *O. aristata* as already noted by Svrček (in sched., as *O. occulta*) or perhaps *O. subaristata* (p. 719). These species belong to series *Hemiorbilia* of *Orbilia* subgenus *Hemiorbilia*, but also *O. pseudoaristata* (p. 947), a member of series *Albovinosae* (subgenus *Habrostictis*), cannot be excluded with certainty, although it has much less exudate over the paraphyses contrary to Velenovský's sketch. Mainly *O. subaristata* and *O. pseudoaristata* have long glassy processes comparable to those depicted for *R. caudata*. This might explain why Velenovský (1934: 102, 1947: 104) assigned *O. aristata* to *Orbilia* subgroup *Aristula*, without reference to *Radotinea*, as his genus concept of *Orbilia* excluded taxa with marginal hairs. In fact, Velenovský's type specimen of *O. aristata* has only very indistinct marginal teeth with 8–15 µm long glassy processes. However, one of Velenovský's (1947) later collections assigned by him to *O. aristata* has longer glassy processes (15–25 µm) which, however, form distinct teeth, but Velenovský appears to have overlooked this feature as he did not mention it.

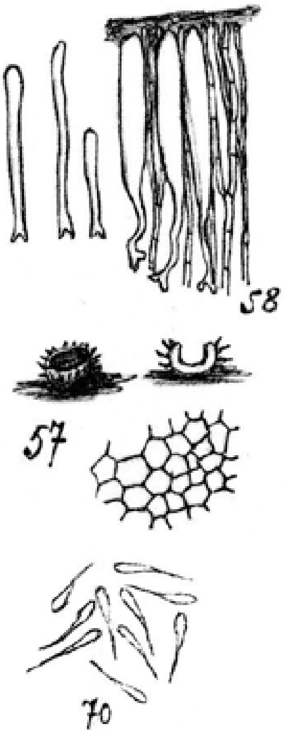

Figure 173: *Radotinea caudata* [(?)= *Orbilia aristata*], holotype, drawn by Velenovský (1934) in the dead state.

The genus *Radotinea* is placed here in synonymy with *Orbilia*. It would offer a valid name for *Orbilia* subgenus *Hemiorbilia* Baral (type *O. occulta*) if one prefers to attribute that group generic rank, but we recommend to use *Hemiorbilia* instead of *Radotinea*, because of the uncertain identity of the type species of *Radotinea* (Baral et al. 2017b).

Genera with non-orbiliaceous type species

Calloria Fries, Fl. Scan.: 343 (1836) – Lectotype species: *Peziza fusarioides* Berk. (designated by Clements & Shear 1931, = *Calloria urticae* (Pers.) J. Schröt.)

The first, very brief description by Fries (1836) placed the genus *Calloria* together with *Orbilia* in the '*Bulgariei*' (see p. 192). Later, Fries (1849: 359) listed nine species in *Calloria*: three basidiomycetous taxa now assigned to *Dacrymyces*, four ascomycetous taxa today recognized in the *Helotiales* [*Calloria urticae*], *Phacidiales* [*Claussenomyces atrovirens* (Pers.) Korf & Abawi], *Orbiliomycetes* [*Orbilia vinosa*], and *Pezizales* [*Iodophanus testaceus* (Moug.) Korf], besides two dubious taxa.

For a long time, *Calloria* was placed in vicinity of *Orbilia*, or it was even united with it. Nylander (1869) doubted the limits as outlined by Fries, and Phillips (1887) united both genera under *Calloria*. Karsten (1885), Saccardo (1889), and Rehm (1891) segregated *Orbilia* by its permanently non-septate ascospores from *Calloria* in which the spores are finally 1(–3)-septate (see also p. 188). In doing so, the authors included in *Calloria* only non-orbiliaceous taxa. They placed the two genera in the subfamily *Callorieae* of *Bulgariaceae*, while Boudier (1885), who characterized *Orbilia* by capitate paraphyses, recognized a separate family ('Famille XI. – *Calloriés*'), followed by Marchand (1894, 1896) who used the name *Calloriacés*. Also Höhnel (1907b, 1918) followed Karsten's concept, but placed the two genera in the *Dermateaceae*. Nannfeldt (1932) erected the new family *Orbiliaceae* and retained *Calloria* in the *Dermateaceae*. Although *Orbilia* and *Calloria* are today segregated in different classes, Velenovský (1934) still saw a close relationship between them by retaining *Calloria* in the *Orbiliaceae*. *Calloria* was accepted by Hein (1976) with three species in the *Naevioideae* of the *Dermateaceae*. Johnston et al. (2014b) changed the current name *Calloria neglecta* to *C. urticae*, the older name of its anamorph *Cylindrocolla urticae*, but proposed to keep the name *Calloria* instead of adopting the younger *Cylindrocolla* Bonord.

A molecular analysis presented by Baral & Rämä (2015) placed *Calloria urticae* and *Laetinaevia carneoflavida* (Rehm) Nannf. ex B. Hein in a supported clade within the *Helotiales*. Their sequences and one of *Duebenia compta* (Sacc.) Nannf. ex B. Hein, all gained by G. Marson from apothecia and representing typical species of the respective genera, provide arguments for raising the *Naevioideae* to family level (see also Phyl. 1). Consequently, Baral (in Jaklitsch et al. 2016) resurrected the family '*Calloriaceae* Marchand' by tentatively including various naevioid genera. However, the family names *Calloriés* Boud. and *Calloriacés* Marchand are invalid because of their non-Latin termination. Since this family has never been validly published, validation was done recently:

Calloriaceae Baral & G. Marson, Index Fungorum 407: 1 (2019)
≡ *Calloriaceae* Marchand [as '*Calloriacés*'], Bull. Soc. mycol. Fr. 10(3): 153 (1894), nom. inval., Art. 32.1 ICN (see also Art. 18.4)
Type: *Calloria* Fr., Fl. Scan.: 343 (1836)
Diagnosis: see Baral in Jaklitsch et al. (2016: 171).

The high molecular similarity of *Laetinaevia carneoflavida* with *Pezizella epithallina* (W. Phillips & Plowr.) Sacc. and with species of the anamorph-typified genus *Tetracladium* De Wild., and the relative phylogenetic distance of *Duebenia compta* need further attention (see Phyl. 1), as do the relationship to *Vandijckellaceae* and the unexpected placement of *Naevala perexigua* (= *N. minutissima*) in *Discinellaceae* (Johnston et al. 2019).

Deltopyxis Baral & G. Marson, Andrias 19: 176 (2012) – Type species: *Deltopyxis triangulispora* Baral & G. Marson

The fungicolous *Deltopyxis triangulispora* is the only species known in the genus. It was compared with *Orbiliomycetes* by Baral & Marson (2012) because of its triangular spores in multispored inamyloid asci, but was excluded based on rDNA data. The present analysis of the 5.8S+LSU region revealed a relationship with the *Ostropomycetidae* (*Lecanoromycetes*), in which it clustered in a medium supported clade with *Coenogonium* Ehrenb. (*Gyalectales*) and *Cryptodiscus* Corda (*Ostropales*) (Phyl. 1). *Deltopyxis* was recently included with *Phaeopyxis* in a new family *Deltopyxidaceae* by Ekanayaka et al. (2019) who proposed a relationship with *Cyttariales*. Also '*Patinella*' *abietina* belongs in this family (see p. 1660).

Gelatinopsis Rambold & Triebel, Notes R. bot. Gdn Edinb. 46(3): 375 (1990) – Type species: *Gelatinopsis geoglossi* (Ellis & Everh.) Rambold & Triebel

The genus includes discomycetes with inamyloid asci growing parasitic on other fungi or lichens. *Gelatinopsis geoglossi* differs from members of *Hyalorbilia* in having asci without croziers and spores with large glycogen bodies, but otherwise strongly resembles that genus. However, the species is up to now only documented in the dead state (for a redescription see Baral & Marson 2001). Some other members recognized in *Gelatinopsis* were studied in the living state (Baral & Marson l.c.), and they always lacked spore bodies. Problematic is that a few taxa which undoubtedly belong in *Hyalorbilia* tend to lack spore bodies (e.g., *H. rotifera*, *H. pleioerythrostigma*), or possess inconspicuous SBs.

ITS and LSU rDNA data were available for *Gelatinopsis exidiophila* Baral & G. Marson (MN047447), *G. fungicola* (Kirschst.) Baral (GU727556), and *G. hysteropatellae* Baral & G. Marson (MF322772), but none for *G. geoglossi*. *G. fungicola* was uploaded in GenBank as *Mollisia incrustata* (New York, on *Trametes versicolor*), but a sequence of *G. fungicola* from Switzerland on the same host (MH221520, MH485386) deviates by only two gaps in the ITS and is thus conspecific. *M. incrustata* is a *Hyphodiscus*, *H. incrustatus* (Ellis) Raitv. with coarsely warted hairs (see p. 1674 and IVV).

In our analysis of the 5.8S+LSU region (Phyl. 1), the three *Gelatinopsis* species clustered in the *Leotiomycetes*, each of them highly supported with another taxon: *G. exidiophila* with *Fulvoflamma eucalypti* Crous, *G. fungicola* with *Geltingia associata* (Th. Fr.) Alstrup & D. Hawksw., and *G. hysteropatellae* with an unnamed member of *Cordieritidaceae*. From this analysis it appears that *Gelatinopsis* is heterogeneous: *G. exidiophila* and *G. fungicola* belong in the *Phacidiales* in the wide sense as adopted by Baral (in Jaklitsch et al. 2016), whereas *G. hysteropatellae*, which forms its minute apothecia intrahymenially, belongs in the *Cordieritidaceae* (*Helotiales*).

In Jaklitsch et al. (2016) the family *Helicogoniaceae* was recognized for fungicolous genera with inamyloid asci, either forming superficial to immersed apothecia (*Gelatinopsis*, *Geltingia* Alstrup & D. Hawksw. etc.) or living as intrahymenial parasites which entirely lack apothecia (*Helicogonium*). For the bryophilous genus *Mniaecia* a separate lineage was proposed. In the present analysis, *G. exidiophila* and *Fulvoflamma* formed a sister clade of *Mniaecia*, while *G. fungicola* and *Geltingia* clustered unresolved within the *Phacidiales*. No sequence data were available for any of the species of *Helicogonium*.

Habrostictis Clem., Gen. Fungi: 63, 174 (1909), nom. illegit. (Art. 53.1 ICN), non *Habrostictis* Fuckel – Type species: *Pseudopeziza pallida* Fuckel
≡ *Naevia* subgroup *Habrostictis* Fuckel s. Rehm, Rabenh. Krypt.-Fl. 1.3: 137 (1888)

Rehm (1888: 137) adopted *Habrostictis* Fuckel in a sense very different from Fuckel: he reduced it to an infrageneric group of *Naevia* Fr. to accomodate 16 species [including *Naevia pallida* (Fuckel) Rehm] which today reside mainly in the *Calloriaceae* and the *Hysteropezizella* complex (*Helotiales*). In the same volume of Rabenhorst's Kryptogamen-Flora, Rehm (1891: 456) placed the type of *Habrostictis* (*H. rubra*) in *Orbilia*, as a synonym of *O. lasia*. It remains a mystery why Rehm (1888) disregarded the nomenclature rules, and not even commented in 1891 on his 1888 concept of *Habrostictis* as a subgroup of *Naevia*.

Clements (1909: 174), followed by Clements & Shear (1931: 310), relied on Rehm's (1888) interpretation of *Habrostictis*

Fuckel when stating that *H. pallida* (Fuckel) Clem. (≡ *Pseudopeziza pallida* Fuckel, ≡ *Naevia pallida*) is the type of that genus. However, selection of a taxon as lectotype, which was not included in the original concept, is against the Code (Art. 10.2, Turland et al. 2018). The reason why Clements considered this rather poorly known species as type of *Habrostictis* might be sought in the fact that it is the only one within *Habrostictis* s. Rehm that was described by Fuckel. Clements's (1909) procedure was interpreted as the erection of a new genus, *Habrostictis* Clem., because the author treated *Habrostictis* under his 'List of new genera and types', although later Clements & Shear (1931) explicitly refer to '*Habrostictis* Fkl.'.

Rehm (1888: 139) stated that the iodine reaction in *N. pallida* was unknown. Nevertheless, he listed this species within his subgroup *Habrostictis*, which he characterized as 'Ascus pore in iodine stained violet or blue'. Apparently therefore, Clements (1909: 63) keyed *H. pallida* under 'ascus pore blue with iodine'. Based on this statement, Hein (1976: 9) listed *Habrostictis* Fuckel under genera with a positive iodine reaction. Concerning the identity of *Habrostictis pallida* see also p. 1681.

Ombrophila Quél., Compt. Rend. Associated Franç. Avancem. Sci. 11: 402 (1883) ['1882'] [nom. illegit., Art. 53.1] – Type species: *Ombrophila rubella* (Pers.) Quél.

This illegitimate genus, which is a later homonym of *Ombrophila* Fr., is listed in Index Fungorum and MycoBank with one species, *O. rubella* (Pers.) Quél. [≡ *Orbilia rubella* (Pers.) P. Karst.]. Quélet (1883) did not intend to erect a new genus when he proposed the new combination *Ombrophila rubella*. In a footnote he gave a clear reference to the genus *Ombrophila* Fr. ('l'ancien genre de Fries'), by mentioning *Ombrophila lilacina* (Fr.) P. Karst. (≡ *Ascocoryne lilacina* (Fr.) Baral et al.), described and illustrated by him in Quélet (1873: 413 [erroneously as 409], pl. V fig. 12) as *Ombrophila lilacina* Wulfen. Quélet interpreted the genus *Ombrophila* Fr. as basidiomycetous ('espèces exosporées'), i.e., a member of *Auriculariales* (= *Tremellales*, as 'Trémellinées') close to *Exidia* Fr., and his illustrations of *O. rubella* and *O. lilacina* show basidia and basidiospores. Species with gelatinous ascomata and ascospores ('endosporées') he referred to the genera *Calloria* Fr. and *Helotium* Tode. Thus, he did not erect a new genus but changed the interpretation of *Ombrophila* Fr.

Orbiliopsis Höhn., Ber. Dtsch. Bot. Ges. 37: 109 (1919), nom. inval. (ICN Art. 38.11) – Type species: *Peziza subcarnea* Schumach. [≡ *Phaeohelotium carneum* (Fr..) Hengstm.]
≡ *Orbiliopsis* Höhn., Mitt. bot. Inst. tech. Hochsch. Wien 3: 101 (1926), nom. inval. (ICN Art. 38.11) et illegit. (ICN Art. 53.1) – Lectotype species: *Peziza subcarnea* Schumach. (designated by Nannfeldt 1932)

The genus *Orbiliopsis* Höhn. was established for three species, *O. austriaca* (Höhn.) Höhn., *O. pudica* (Rehm) Höhn., and *O. subcarnea* (Schumach.) Höhn. Although mentioned at the third place by Höhnel (1926), *O. subcarnea* was named by Nannfeldt (1932: 194) 'pseudotypus' of the genus, a term used by this author mostly in the sense of the first species rule (Nannfeldt 1932: 8). This exception could be explained by the fact that the new genus was already proposed by Höhnel (1919: 109), who included there solely *O. subcarnea*. However, Nannfeldt did not mention Höhnel's (1919) very brief and hidden first publication of the genus. No diagnosis was supplied by Höhnel in either work, and his indirect reference to the included species is not sufficient (ICN Art. 38.11), therefore, the name *Orbiliopsis* Höhn. is invalid. This was the reason why Spooner & Dennis (1986) erected the genus *Parorbiliopsis* (see below).

O. subcarnea was transferred by Dennis (1971) to *Phaeohelotium* Kanouse. However, the original identity of the species is not very clear, though it was extensively treated by Hengstmengel (2009). In general agreement it is a member of *Helotiales*. Similarly unclear is *O. pudica*. *O. austriaca* is found to be a synonym of *Leptodontidium trabinellum* (P. Karst.) Baral, Platas & R. Galán, according to a restudy of type material (see p. 1686). Based on molecular methods, *Phaeohelotium trabinellum* (P. Karst.) Dennis was found to be a synonym of *Leptodontidium elatius* (F. Mangenot) de Hoog, the type of *Leptodontidium* de Hoog which is of unclear relationship within the *Helotiales* (Baral 2015).

Orbiliopsis (Sacc.) Syd., Ann. Mycol. 22: 308 (1924) – Lectotype species: *Orbilia coleosporioides* Sacc. (designated by Sydow 1924)
≡ *Orbilia* subgroup *Orbiliopsis* Sacc., in Sacc. & D. Sacc., Syll. Fung. 18: 139 (1906)

The unranked infrageneric taxon was introduced by Saccardo for two orbilia-like species parasitic on living leaves: *Orbilia coleosporioides* (on *Didymaea mexicana* from Mexico) and *O. myristicae* P. Henn. (on *Myristica fragrans* from Java). Sydow (1924) raised the group to generic level and selected the type species, but did not explicitly mention *O. myristicae*. He added a third species, *Orbiliopsis callistea* Syd. (on *Hebe subalpina* from New Zeeland, as *Veronica subalpina*), which he believed to be very similar to the type species. The genus is characterized by broadly sessile, irregularly-shaped, confluent apothecia with a reduced excipular tissue, developing subcuticular, and by large, ellipsoid ascospores surrounded by a gel sheath. Also Nannfeldt (1932: 253) assumed from the description of *O. callistea* that the genus resembles *Orbilia* merely by its yellow to yellow-red colour and fleshy consistency, and that it could instead be of the ascolocular type. Clements & Shear (1931: 314), however, placed *Orbiliopsis* in synonymy with *Orbilia*.

Orbiliopsis callistea was recently rediscovered in New Zealand on the type host by P.R. Johnston (pers. comm.), who made a detailed unpublished study on it. Among other features are the inamyloid asci with an overall slightly thickened wall which is thinner at the very apex (comparable to *Pithyella*, see Fig. 174). A sequence taken from the apothecia (PDD 97932: HQ533049, HQ533050) referred the species to the *Helotiales* incertae sedis. *O. myristicae* was found in the present study to resemble the genus *Micropeziza* Fuckel (*Pezizellaceae*), according to the reexamination of an isotype (see p. 1679), whereas *O. coleosporioides* never seems to have been redescribed.

Orbiliopsis Velen., Monogr. Discom. Bohem.: 103, pl. 17 figs 35–37 (1934), nom. illegit. (ICN Art. 53.1) – Type species: *O. graminum* Velen.

Velenovský placed this genus in the *Orbiliaceae*. However, the 3-septate, fusoid ascospores and clavate asci with obtuse apices appear to exclude *Orbiliopsis graminum* from the

Orbiliomycetes. A pronounced 'epithecium' covers the filiform, apically uninflated paraphyses. The author failed to indicate the iodine reaction of the asci, and compared the species with genera such as *Durella* and *Orbilia*. The relationship of *O. graminum* is certainly to be sought within the *Helotiales*, but assignment to a family requires reexamination of the type.

Parorbiliopsis Spooner & Dennis, Sydowia 38: 303 (1986). –
Type species: *P. minuta* Spooner & Dennis
(?= *Hyaloscypha intacta* Svrček)

In order to avoid heterogeneity in the genus *Phaeohelotium* Kanouse, and because of the homonymy with the older *Orbiliopsis* (Sacc.) Syd., the new genus *Parorbiliopsis* Spooner & Dennis (1986) was erected to replace *Orbiliopsis* Höhn. The authors chose a new species as type, *P. minuta* Spooner & Dennis. They placed also *Phaeohelotium extumescens* (P. Karst.) Dennis in the genus, but left the generic position of *Orbiliopsis subcarnea* open (see under *Orbiliopsis* Höhn.).

We have found *P. minuta* to be a desiccation-tolerant species that is very common on various woody angiosperms in central Europe. Contrary to Spooner & Dennis who described *P. minuta* as hairless, the apothecia have actually very short, more or less flask-shaped hairs (also in the holotype, IVV: H.B. 5753). Due to variation among the collections in the length of the bristle-like part of the hairs, some doubt remains as to whether or not *P. minuta* and *Hyaloscypha intacta* are distinct at the species level. In both taxa the asci are inamyloid and arise from simple septa. Because of this strong similarity we consider *Parorbiliopsis* as a synonym of *Hyaloscypha* Boud. Molecular data confirm this view (Phyl. 1), therefore, *P. minuta* was combined in *Hyaloscypha* (Baral 2015). The type material of *P. extumescens* (IVV: H.B. 5249) was found to be strongly overmature, but proved to have very distinct hairs typical of *Hyaloscypha*, and the taxon might be a synonym of *Hyaloscypha albohyalina* (P. Karst.) Boud.

Patinella Sacc., Grevillea 4: 22 (1875) – Type species:
P. hyalophaea Sacc.

The genus was named after its dark pigmented apothecia. Saccardo characterized *P. hyalophaea* (Italy, on wood of *Fagus*) by strongly inflated, globose, dark brown apices of paraphyses (misidentified as conidia), and by small, ovoid, hyaline, non-septate ascospores. The genus was later enlarged, e. g., by Saccardo (1889: 769–774), Rehm (1889: 310–313), and Massee (1895: 92–95), to include many dark-coloured discomycetes that also resemble members of the genus *Patellaria* Fr. (*Patellariales*). Generic concepts at that time were mainly based on spore characters. Among the hyaline-spored genera, *Patinella* was defined by non-septate spores, *Patellea* (Fr.) Sacc. by 1-septate spores, and *Patellaria* by at least 2-septate spores. Migula (1913: 889) provided a key to nine central European species of *Patinella* in this sense.

Clements & Shear (1931: 315) designated *Patinella sanguineoatra* (Rehm) Sacc. as lectotype, a decision which is against the Code (Art. 10.2, Turland et al. 2018), and recognized the genus in the *Patellariaceae* of the *Pezizales*. Nannfeldt (1932: 256) discussed the genus in detail and accepted only two species with apically inflated paraphyses (*P. hyalophaea*, *P. aloysii-sabaudiae* Sacc.). With some hesitation, he placed *Patinella* in his new family *Orbiliaceae* close to *Orbilia*, mainly because of the shape of the paraphyses and the construction of the ectal excipulum made up of isodiametric (paraplectenchymatic), angular cells (obviously by mistake, the protologue of *Patinella* says 'excipulo minute prosenchymatico'). The dark brown pigmentation, especially of the subhymenium and tips of paraphyses, was quite unusual at that time in orbiliaceous fungi, therefore, Nannfeldt took *Patinella* as a link to the *Mollisioideae* in the *Dermateaceae*.

Because of similar truncate thin-walled asci, Bellemère (1968: 474) saw a close relationship between typical *Orbiliaceae* with light-coloured apothecia and a specimen tentatively referred by him to *Patinella*. It cannot be excluded that this specimen of unclear identity might, in fact, represent a dark-coloured member of *Orbiliomycetes*.

Spooner (1987: 158) reexamined the type material of *P. hyalophaea*, apparently the only known collection of that species at that time, but did not present a detailed redescription. He excluded it from the *Orbiliaceae* because the asci have a rounded apex and a simple, unforked base, and referred it to the *Dermateaceae*, apparently because of the dark brown excipulum of textura angularis.

The present reexamination of the type and a recent perfectly corresponding Canadian collection on coniferous wood (Baral & Carter 2013) revealed asci with basal croziers and inamyloid apical wall thickenings, and paraphyses with strongly capitate to clavate apices with dark brown apical wall thickenings (0.5–2 µm thick). A sequence of rDNA (ITS and LSU, KT876978) taken from the Canadian sample surprisingly revealed a very close relationship to the type species of *Holwaya* Sacc., *H. mucida* (Schulzer) Korf & Abawi (3.5 % distance in the ITS region, 0.5 % in the D1–D2 of LSU, see Phyl. 1), a genus referred to the new family *Tympanidaceae* of the *Phacidiales* (Baral et al. 2015, Jaklitsch et al. 2016). Although *H. mucida* has phragmosporous ascospores and a synnematal anamorph, *H. mucida* and *P. hyalophaea* indeed share several characters, such as black apothecia with a brownish, non-ionomidotic ectal excipulum of textura angularis, capitate paraphyses with brown exudate, and inamyloid 8-spored asci with croziers and with a rounded, thick-walled apex.

A few of the many taxa being combined in *Patinella* were reexamined in the present study. They are treated in the Excluded list, except for two which were found to be orbiliaceous: *P. aterrima* (Fuckel) Rehm and *P. tenebricosa* Svrček. The former is placed here in the new genus *Liladisca*, whereas the latter was found to belong to series *Drechslerella* of *Orbilia* subgenus *Orbilia*, because it forms constricting rings in culture (Pfister 1997: 14f.). Svrček (1977) thought *P. tenebricosa* to belong to *Orbiliaster* by misleadingly describing the marginal glassy processes as clavate hyphae (see under *O. polybrocha*, p. 1634).

Pithyella Boud., Bull. Soc. Mycol. Fr. 1: 118 (1885). – Type species: *Mollisia hypnina* Quél.
= *Helotiopsis* Höhnel, Sitzungsber. Kaiserl. Akad. Wiss. Wien, Math.-Naturwiss. Kl., Abt. 1, 119: 623 (1910) – Type species: *Peziza apicalis* Berk. & Broome

Probably because of the globose ascospores, Boudier (1885) believed that *Pithyella* was related

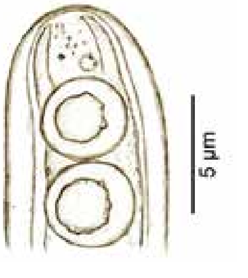

Figure 174: Apex of submature ascus of *Pithyella apicalis* (type, in KOH).

to *Pithya* Fuckel which he both placed in the 'Inoperculés'. Later (1907), Boudier enlarged *Pithyella* to include seven species and retained it near *Trichoscypha* Boud. (= *Lachnellula* P. Karst.), while he treated *Pithya* in the 'Operculés' (*Pezizales*). Nevertheless, Clements & Shear (1931: 328) reduced *Pithyella* to synonymy with *Pithya* in the *Pezizaceae*.

Sherwood & Korf (1976) and Korf & Zhuang (1987) reassessed *Pithyella* to comprise finally five species with globose to subglobose spores. Sherwood & Korf used the name *Helotiopsis* and defined the genus, e. g., by the inamyloid ascus apex with a rather thick apical wall. The two type species, *Pithyella hypnina* (Quél.) Boud. and *P. apicalis* (Berk. & Broome) Korf & Zhuang, are bryophilous and possibly conspecific (Korf & Zhuang, l.c.), and the pteridicolous *P. jenkinsii* (Sherw. & Korf) Korf & Zhuang is also very similar. Both *P. apicalis* and *P. jenkinsii* have globose spores with prominent warts.

Two of the species included by Korf & Zhuang (l.c.) in *Pithyella*, *P. erythrostigma* (Berk. & Broome) Boud. and *P. anonyma* (Rehm) Korf & Zhuang, are found to be orbiliaceous in the present monograph, according to the study of type material and of recent collections of the former species including molecular data (see Phyl. 2). The two taxa are very similar in having subglobose, smooth ascospores and lacking any apical or lateral ascus wall thickening. A refractive, globose, eccentric spore body characterizes the living ascospores of *P. erythrostigma* (see Pl. 126: 1, 5, 7), and this previously neglected character is faintly perceptible in the type specimens of both taxa (see Pls 126: 2a; 132: 1a). It clearly refers these two taxa to the *Orbiliomycetes*, and here to the genus *Hyalorbilia*, where *P. erythrostigma* was transferred by Baral & Marson (2001) based, e. g., on the hemispherical ascus apex and presence of croziers. This and a third very similar species with subglobose spores, *H. brevistipitata* Bin Liu et al., were confirmed to be orbiliaceous by molecular methods, and they cluster in *Hyalorbilia* not far from each other (Liu et al. 2005b, 2006a).

Reexamination of the type material in K (VV: H.B. 5352) indicates that *Pithyella apicalis* is not orbiliaceous but possibly a member of *Helotiaceae*. The inamyloid asci with a hemispherical apex have a laterally thickened wall, 1–1.2 µm in KOH thick in their subapical part, whereas the apical region is thin-walled (Fig. 174). This is in contrast to Sherwood & Korf's (1976) report of a thick-walled apex in an isotype (FH) of the same collection. The eight ascospores are subglobose, prominently warted, and contain a single large LB (perhaps by confluence). The paraphyses are filiform and very distantly septate, apically without any exudate. Especially the laterally thickened ascus wall and the large amount of lipid in the spores exclude this species from the *Orbiliomycetes*.

Döbbeler (2004) added a further bryophilous species, *Pithyella frullaniae* (Chal.) Döbbeler (= *P. chalaudii* Priou), which was here studied from a recent living collection (IVV: H.B. 7288). The finely warted spores each contain one eccentric LB, the inamyloid asci arise from croziers and have nearly no apical thickening (dead state, also the lateral wall is thin), and the living paraphyses and marginal hairs are densely filled with globose, medium refractive VBs (multiguttulate). Closely related with this species is probably *Muscicola dubia* (Velen.) Svrček, a bryophilous discomycete with ellipsoid, warted ascospores, an ascus apex with an euamyloid apical ring, and long uncinate hairs (IVV: H.B. 3570, 3878).

Pithyella in its restricted sense clearly belongs to the *Helotiales*. It was placed in the *Leotiaceae* by Sherwood & Korf (1976), but resides in the *Hyaloscyphaceae* in Lumbsch & Huhndorf (2010). Even though *Muscicola dubia* looks hyaloscyphaceous, it might rather be related to genera of the *Helotiaceae*, such as *Bryoscyphus* and *Cyathicula*, on account of its guttulate paraphyses and *Hymenoscyphus*-type of apical ring.

Pteromyces E. Bommer, M. Rousseau & Sacc., in Saccardo, Ann. Mycol. 3: 507 (1905) – Type species: *P. ambiguus* E. Bommer, M. Rousseau & Sacc.

Pteromyces was tentatively placed in the *Bulgariaceae* near *Orbilia* by Bommer et al. (in Saccardo 1905). The authors segregated the genus by apothecia having indistinct margins though remaining 'urceolate for apparently a long time', and by an extraordinary substrate, rotten pins from feathers of a pheasant, after which the genus was named. Clements & Shear (1931: 314) were apparently unimpressed by these characters when referring *Pteromyces* to synonymy with *Orbilia*.

P. ambiguus was described with densely gregarious, minute (0.07–0.1 mm diam.), pale brownish-rose apothecia developing subcuticular, a reddish-brown paraplectenchymatous ('pseudoparenchymatous') excipulum, asci 18–22 × 7–8 µm, 8-spored, young obovoid, then clavate, with rounded apices and short, narrow bases, spores ovoid, hyaline, 3–4 × 1.5–2 µm, outside asci 6 × 3 µm, paraphyses bacillar, apically slightly clavate, often curved.

The holotype of *P. ambiguus* (Belgium, Furnes, La Panne, III.1904, M.H. Rousseau, IVV: H.B. 8917a) contains a number of quite undecayed feathers. Near the basal end of the quill the apothecia grew in groups together with pycnidia of *Phoma ornithophila* E. Bommer, M. Rousseau & Sacc. Due to their minuteness (rehydrated 0.05–0.1 mm diam.) they are easily overlooked under the dissecting microscope. While the associated pycnidia remain subcuticular, the rehydrated apothecia are superficial and show a distinct, somewhat crenulate, hardly protruding, bright brown margin and a brownish-cream, slightly convex disc. The saccate 8-spored asci measure 23–27 × 9.5–11 µm and are not stained in IKI. They have a hemispherical apex with a 1.2 µm thick apical dome when immature, and a very short base that arises from croziers. The ellipsoid, firm-walled, smooth ascospores are eguttulate in KOH and measure 7–8.8 × 4–4.8 µm. The paraphyses have strongly capitate, partly asymmetrical apices 3.5–5 µm wide, with light brown walls. The ectal excipulum is of a textura angularis with small, irregularly tangentially elongated cells embedded in bright ochraceous exudate.

All these characters fit well ***Thelebolus microsporus*** (Berk. & Broome) Kimbr., a mainly coprophilous species which is known from dung of various animals but also from intestines and feathers of birds (De Hoog et al. 2005: 63, fig. 12). Consequently, *Pteromyces* becomes a synonym of *Thelebolus* Tode. The small spore measurements in the protologue might refer to the protoplast of the dead spores which had a size of 5–6.5 × 2–3 µm in the present reexamination.

Table 41. Chronological list of anamorphs connected to teleomorphs of the genera *Orbilia* and *Hyalorbilia* as being reported in the literature up to now, with indication of the current holomorph name, mainly based on cultural studies (except for Kirschstein 1938 and Korf 1992). See also tab. 1 in Zhuang & Mo (2006: 21).

HISTORY OF ANAMORPH GENERA

The *Orbiliomycetes* are characterized by a pleomorphic life cycle which comprises two very different states: in addition to the apothecial state (teleomorph), many species of this class are known to form a conidial state (anamorph). Conidia are asexual propagules. In the *Orbiliomycetes* they are freely formed on short to long conidiophores which arise from superficial hyphae of effuse mycelia, often in more or less close association with the apothecia, sometimes from apothecial tissue, but almost never in conidiomata. Conidiophores and conidia are always hyaline and thin-walled, and conidiogenesis is consistently holoblastic (see also p. 109 ff., Morphology of the anamorph).

Connections between anamorph and teleomorph are as yet uncertain or unknown for many of the recognized species, however. This means that a lot of teleomorph-typified taxa are without a known anamorph and, vice versa, a lot of anamorph-typified taxa are without a known teleomorph. Our research suggests that most if not all species with teleomorph are able to produce an anamorph, but it is often very difficult in this class to obtain conidia in pure culture. Because apothecia are not easily formed in pure culture, the question is still open whether anamorph-typified taxa exist which have actually lost their sexual reproduction ability.

Anamorphs previously connected to orbiliaceous teleomorphs. Tab. 41 lists all connections between anamorph and teleomorph within the genera *Orbilia* and *Hyalorbilia* known to us from the literature until now. These reports predominantly concern desiccation-sensitive species growing in continually moist habitats.

Schulzer v. Müggenburg (1878) was apparently the first to report conidia associated with a species of *Orbilia.* He described spindle- to club-shaped conidia on apothecia which he identified as *Peziza leucostigma*. Such conidia are typical of the genus *Dactylella*. However, the identity of his specimen is unclear concerning both anamorph and teleomorph (*Hyalorbilia* or *Orbilia*). The second was Costantin (1888) who examined ascocarps of an *Orbilia* which he thought to be *O. vinosa*, an ambiguous name at that time which included species of section *Helicoon* as well as section *Hemiorbilia*. Quite probably Costantin's fungus belonged in the scope of *O. luteorubella*. However, the ovoid conidia observed by him most likely do not belong to an *Orbilia*. Costantin suspected that they arise by detachment of the upper parts of the moniliform heads of the paraphyses, but this interpretation seems to be erroneous, as we never observed natural detachment of paraphysis heads in any species of *Orbiliomycetes*.

Brefeld (1891: 304, pl. XI fig. 69) obtained an anamorph in pure culture from a specimen identified by Rehm as *O. coccinella* (= *O. eucalypti* in the present monograph). This produced at first unbranched, subcylindrical and later forked conidia which appears to represent *Dicranidion fragile*. The illustrated asci with cashew-shaped spores (l.c.: fig. 68) belong to another collection (probably *O. leuco-* or *xanthostigma*) which did not form a mycelium.

Velenovský (1934: 97, pl. 11 fig. 29) described *O. tricuspis* Velen. (= *O. vinosa*) with tricuspidate structures growing out of the basal excipulum. These could no longer be found in the type material, but they very probably represent conidia of the trinacrium-like anamorph of *O. vinosa* which we have repeatedly obtained in pure culture and observed on the natural substrate (see Pls 258, 261).

Drechsler (1937a: 458, fig. 18 R) obtained apothecia of an unidentified discomycete (obviously an *Orbilia*) in a single nematode-infested culture of *Arthrobotrys superbus*. However, he could not exclude a contamination (see p. 1530, *O. auricolor*).

Kirschstein (1938) observed two-celled conidia emerging from the subiculum of his new genus and species *Orbiliella armeniaca* Kirschst., a later synonym of *Orbilia auricolor*, according to our study of the type (Pl. 950: 2). He regarded this imperfect fungus as the anamorph, and tentatively referred it to *Trichothecium* Link. Our restudy of this anamorph showed that it is a species of *Arthrobotrys* (*A. ?superbus*) and undoubtedly the anamorph of the associated *Orbilia*.

In their overview of connections of the anamorphs and teleomorphs in discomycetes, Hennebert & Bellemère (1979) listed only two credible connections within the *Orbiliaceae*. Since that time various further connections were published (see Tab. 41 and under the different anamorph-typified genera). For instance, Mo et al. (2005a) listed 19 and Zhang et al. (2011a) 32 connections. However, the identity of the reported taxa is not always clear, and in several cases the same name of a teleomorph appears as being connected to different anamorphs. Such cultural differences from seemingly conspecific teleomorphs are mostly supported by deviating molecular data, which indicate that different species are involved.

The present monograph accepts about 145 connections between anamorphs and teleomorphs as certain. Out of these 145 connections, ca. 45 have earlier been reported in the literature, and 14 of these 45 reports were affirmed in the present study from recent collections. Further ca. 90 connections are reported as presumed, because conidia were observed on the natural substrate only, being not assured by pure culture and/or molecular data (see Appendix 4).

In the following, an overview of the anamorph-typified genera (including form genera) is given, in which species were placed for which a connection to the *Orbiliomycetes* could be demonstrated (20 genera) or is presumed (*Haptocara*, *Tripoconidium*). A large number of the known anamorph-typified species belongs to five of these genera (*Arthrobotrys*, *Dactylella*, *Dactylellina*, *Drechslerella*, *Gamsylella*), which represent the anamorphs of *Orbilia* section *Arthrobotrys* (p. 1432). These usually have long conidiophores (much longer than the conidia) and ellipsoid-ovoid, fusiform or cylindric-clavate, almost exclusively unbranched conidia, and are mainly desiccation-sensitive, including their teleomorphs. The remaining genera belong to other sections of *Orbilia* or other genera of *Orbiliomycetes*. Those with unbranched conidia include *Anguillospora*, *Brachyphoris*, *Helicoon*, *Lecophagus*, *Microdochiella*, and *Vermispora*, whereas *Curucispora*, *Dicranidion*, *Dwayaangam*, *Descalsia*, *Mycoceros*, *Retiarius*, *Tridentaria*, and *Trinacrium* are defined by branched conidia. All these remaining genera have often more or less short conidiophores, and the conidia or conidial arms and stipes are usually comparatively long and narrow. Many of the species are desiccation-tolerant, including their teleomorphs.

A further genus, *Pseudotripoconidium*, occupies a morphologically isolated position. The conidia are obpyramidal, with more or less prominent denticle-like protuberances, and are formed on rather long conidiophores. Molecular data indicate a close relationship to those anamorphs of *Orbilia* with narrow, unbranched anguillospora-like phragmoconidia.

For most of these anamorph-typified genera a teleomorph has been reported. *Microdochiella* and *Vermispora* are placed here in synonymy with *Hyalorbilia* based on molecular similarities of a typical *Hyalorbilia* teleomorph (*H. rotifera*) that clustered in the so far purely anamorphic *Vermispora* clade. *Curucispora*, *Descalsia*, and *Tridentaria* are reported here for the first time as anamorphs of *Orbilia*, and also for *Lecophagus* a connection to an orbiliaceous teleomorph is established. *Haptocara* shows affinities with *Lecophagus* regarding similar very broad mycelial cells containing cubical bodies and conidiophores bearing phragmoconidia in an apical cluster. Its conidia are characterized by a filiform subapical appendage and an apical adhesive knob.

Judging from its morphology, also *Tripoconidium* is very probably an orbiliaceous anamorph. It combines long conidiophores with branched (staurosporous) conidia, a feature also noted in a few species assigned to *Arthrobotrys*, *Dicranidion*, and *Tridentaria*. Only for a single taxon with this combination of characters, *Arthrobotrys iridis* (= *Dactylella ramiformis*), a connection to a teleomorph is so far known (see p. 1547, *Orbilia multiformis*). For the similar genus *Pseudotripoconidium* a connection to a number of teleomorphs have been established, but its conidia with short protuberances can hardly be termed staurosporous.

Five of the mentioned anamorph-typified genera (*Arthrobotrys*, *Dactylellina*, *Drechslerella*, *Gamsylella*, and *Lecophagus*) are characterized by the ability of every included species to prey by means of trapping organs on nematodes or other invertebrates such as rotifers, tardigrades, springtails, and copepods. Yet, also a species of *Tridentaria* and the type species of *Tripoconidium* and *Haptocara* are reported as nematophagous. Parasitism on eggs of nematodes, rotifers, or insects is known in some species referred to *Brachyphoris*, *Dwayaangam*, *Trinacrium*, and *Vermispora*. Rhizopods are captured by some species referred to *Brachyphoris*, *Dicranidion*, *Dwayaangam*, *Gamsylella*, *Trinacrium*, and *Tridentaria*. Parasitism on spores of oomycetes and zygomycetes is known in some species referred to *Brachyphoris*, *Dactylella*, *Tridentaria*, and *Vermispora*. Parasitism on pollen grains was reported for *Mycoceros* and *Retiarius*, a genus with conidia very similar to either *Dwayaangam* or *Trinacrium*. Apart from *Lecophagus*, which is named after its ability to trap rotifers by means of adhesive pegs, the etymology of most of these names of anamorphs refers to the morphology of conidia or conidiophores.

Classification. Phylogenetic studies by Liou & Tzean (1997), Ahrén et al. (1998), Scholler et al. (1999), Hagedorn & Scholler (1999), Li et al. (2005), and Yang & Liu (2006) using rDNA sequence data of predominantly nematophagous species revealed that within this group, assigned to section *Arthrobotrys* in the present monograph, trapping devices provide the main morphological criterion for a natural delimitation of phylogenetic groups. Scholler et al. (1999) obtained four well-separated clades, which differ among each other in their mode of trapping nematodes, but hardly so in conidial or conidiophore morphology. Thereupon they accepted four anamorph-typified genera and reassessed their circumscription: *Arthrobotrys* with adhesive networks, *Drechslerella* with constricting rings, *Dactylellina* with stalked adhesive knobs and non-constricting rings, and *Gamsylella* with adhesive columns, loops, bridges, and adhesive knobs which are predominantly unstalked. The large genus *Monacrosporium* is treated as a synonym of *Arthrobotrys* from their type species, while many members of both genera were reallocated, mainly to *Arthrobotrys*, *Dactylellina*, and *Drechslerella*. Moreover, the concept of *Dactylellina* and *Drechslerella* is strongly enlarged, each of which formerly containing only a single species. Li et al. (2005) and Yang & Liu (2006) did not accept *Gamsylella* as a separate genus, but assigned its members partly or altogether to *Dactylellina*. In this monograph we accept the concept of *Gamsylella* in a restricted sense.

In a similar way, Chen et al. (2007a–c) presented a new generic concept within the *Dactylella* complex, in which conspicuous organs of capture are unknown, based mainly on sequence data (ITS). The authors segregated three well-founded groups: *Dactylella* for anamorphs belonging to *Orbilia* in the present circumscription (with straight, rarely slightly curved conidia and predominantly long conidiophores), *Vermispora* without known teleomorph (with slightly curved conidia and short to long conidiophores), and *Brachyphoris* as anamorph of *Hyalorbilia* (with straight to slightly curved conidia and short conidiophores).

In most of the remaining anamorph-typified genera conspicuous trapping devices have so far likewise never

Table 42. Conidial types including conidiophores and trapping organs of *Orbiliomycetes* recognized in this monograph, with their symbols as used in Baral et al. (2017b). Only those types marked by an asterisk are used by us in a phylogenetic sense, whereas the others represent form genera. The conidial symbols shown here were included in some phylograms of our phylogenetic analyses.

been observed. Our culture studies suggest that a majority of *Orbiliomycetes*, especially the desiccation-tolerant species, do not produce trapping organs in the presence of nematodes or rotifers. Some of the recognized, apparently non-predacious anamorph-typified genera are highly heterogeneous. For instance, a majority of *Anguillospora* species, including the type, are not connected to the *Orbiliomycetes*. The circumscription of these anamorph-typified genera is based merely on conidial morphology, e. g., in the case of branched conidia on the number and type of branching, or on the curvature of conidia and length of conidiophores when conidia are unbranched.

These more or less artificial genera are not even sharply differentiated from each other by their morphology. Their application is complicated by different kinds of variation which were quite frequently encountered during our study and also by other authors: generic limits may be obscured by (1) strong variability in conidial shape within a species, (2) frequent but inconsistent simultaneous occurrence of different conidial types within a single isolate, such as branched and unbranched conidia, or micro- and macroconidia, and (3) the existence of intermediate conidial types. For instance, straight and distinctly curved conidia, or Y-shaped (*Trinacrium*) and tunefork-shaped conidia (*Dicranidion*), do not represent clear-cut character states, but are connected by intermediate forms. Likewise, the number of arms in *Dicranidion* is often not consistent within a strain.

Our molecular phylogenetic analysis of *Orbiliomycetes* in Baral et al. (2017b) coincides to a large extent with the classification we have achieved from teleomorph morphology. Concerning the anamorphs, however, the analysis indicated that the different conidial types frequently show a scattered, polyphyletic distribution, i. e., they are often not significantly correlated with the mono- or paraphyletic clades which we here classify as subgenera, sections and series. Actually, very similar conidial types, e. g., referable to *Trinacrium*, occur scattered in rather distant infrageneric groups of *Orbilia*, and even in separate genera (*Hyalorbilia* and *Amphosoma*). Vice versa, different conidial types were found to belong to very closely related teleomorphs. For instance, vermispora- and trinacrium-like conidia occur in section *Lentiformes*, even within a species complex (*O. lentiformis*, *O. ocellata*) that shows hardly any differences in the teleomorph.

All these observations indicate the minor systematic value of morphology in most of the conidial types. With the new rules (ICN, Turland et al., 2018) the anamorph-typified genera lose their subordinate status concerning priority. Most of the anamorph-typified orbiliaceous genera are now to be treated as synonyms, mainly of the genus *Orbilia* which is older than all of them, or of a few anamorphic genera when applying a narrow generic concept. For practical reasons we continue to use anamorphic names, but in an informal, descriptive way with the suffix '-like', being aware that several of them represent polyphyletic form genera, which might reflect some ecological adaptation by convergent evolution rather than phylogenetic entities. For instance, the statement 'anamorph trinacrium-like' may either refer to triradiate conidia of series *Hemiorbilia*, to which the type of *Trinacrium* probably belongs, or to an anamorph with morphologically similar conidia but more or less distant position. This form of typography follows suggestions by Cannon & Kirk (2000) and Hawksworth (2011: 14), and makes clear that these designations are not scientific names governed by the Code. With this kind of approach, a given species may simultaneously produce two or three different anamorph-typified form genera within a single Petri dish, mainly regarding different types of conidial branching (see Tab. 42).

Only in some groups a striking morphological homogeneity in the anamorphs was noted. In two sections of *Orbilia* the included series show homogeneity with respect to either trapping organs (section *Arthrobotrys*) or conidial shape (section *Helicoon*). In *Lecophagus* the anamorph shows homogeneity in the trapping organs as well as conidial shape. The anamorph-typified genus *Brachyphoris* includes rather homogeneously shaped conidia which are always ± straight and unbranched, and comparatively short conidiophores. We accept it here in a phylogenetic sense restricted to the teleomorph-typified genus *Hyalorbilia*, to which it is a synonym. However, there is evidence that some species of *Hyalorbilia* form branched conidia, e. g., curucispora-like, dwayaangam-like or trinacrium-like ones, the latter strongly resembling in their curved arms conidia of *Amphosoma* and some species of *Orbilia*, apparently by convergent evolution.

The anamorph-typified genera

Anguillospora Ingold – (Pl. 1)

The genus was erected in 1942 for the single species *A. longissima* (Sacc. & P. Syd.) Ingold. It is characterized by filiform, multiseptate, hyaline conidia which resemble an eel (= *anguilla*). *Anguillospora* is heterogeneous in the present circumscription, because of different patterns of conidial secession (rhexolytic vs. schizolytic, i. e. with or without a separating cell that splits during secession) and teleomorphs belonging to different orders (Webster & Descals 1979, Descals et al. 1999, Belliveau & Bärlocher 2005, Baschien et al. 2006). Belliveau & Bärlocher (l.c.) support the polyphyletic origin of *Anguillospora* by sequence analyses of nSSU rDNA. The eight species included in their study were distributed among the classes *Dothideomycetes* (2), *Leotiomycetes* (5), and *Orbiliomycetes* (1). According to Belliveau & Bärlocher (l.c.) the genus includes ten generally accepted species and three poorly known taxa.

In the type species conidial secession is rhexolytic, whereas in most of the remaining species secession appears to be schizolytic. The rhexolytic conidial secession in *A. longissima* was observed by Ingold (1942), Willoughby & Archer (1973) and Webster & Descals (1979) in British strains, and by Baschien et al. (2006) in strains from an alpine stream in Germany. In the original description of the type collection from Belgium by De Wildeman (1894, as *Fusarium elongatum* De Wild., non *F. elongatum* Cooke) this feature is not visible, however, instead percurrent extensions growing from central cells of the detached conidia were drawn, which are reminiscent of those percurrent extensions at the conidial base as reported, e. g., in *A. rubescens* Gulis & Marvanová (*Dothideales*) and which appear to represent germ tubes. The latter species was classified by Gulis & Marvanová (1999) as schizolytic, and showed percurrent proliferations at the conidiogenous tips. But also Baschien et al. (2006) illustrated basal percurrent extensions in conidia of *A. longissima*.

The observation of proliferation by De Wildeman might tell that the type species of *Anguillospora* is not orbiliaceous. However, Baschien et al. (2006) and Descals et al. (1999) stated that also *A. rosea* shows percurrent proliferation, and L. Marvanová observed this feature in her isolates of *A. rosea*. Whether the current interpretation of *A. longissima* is correct we

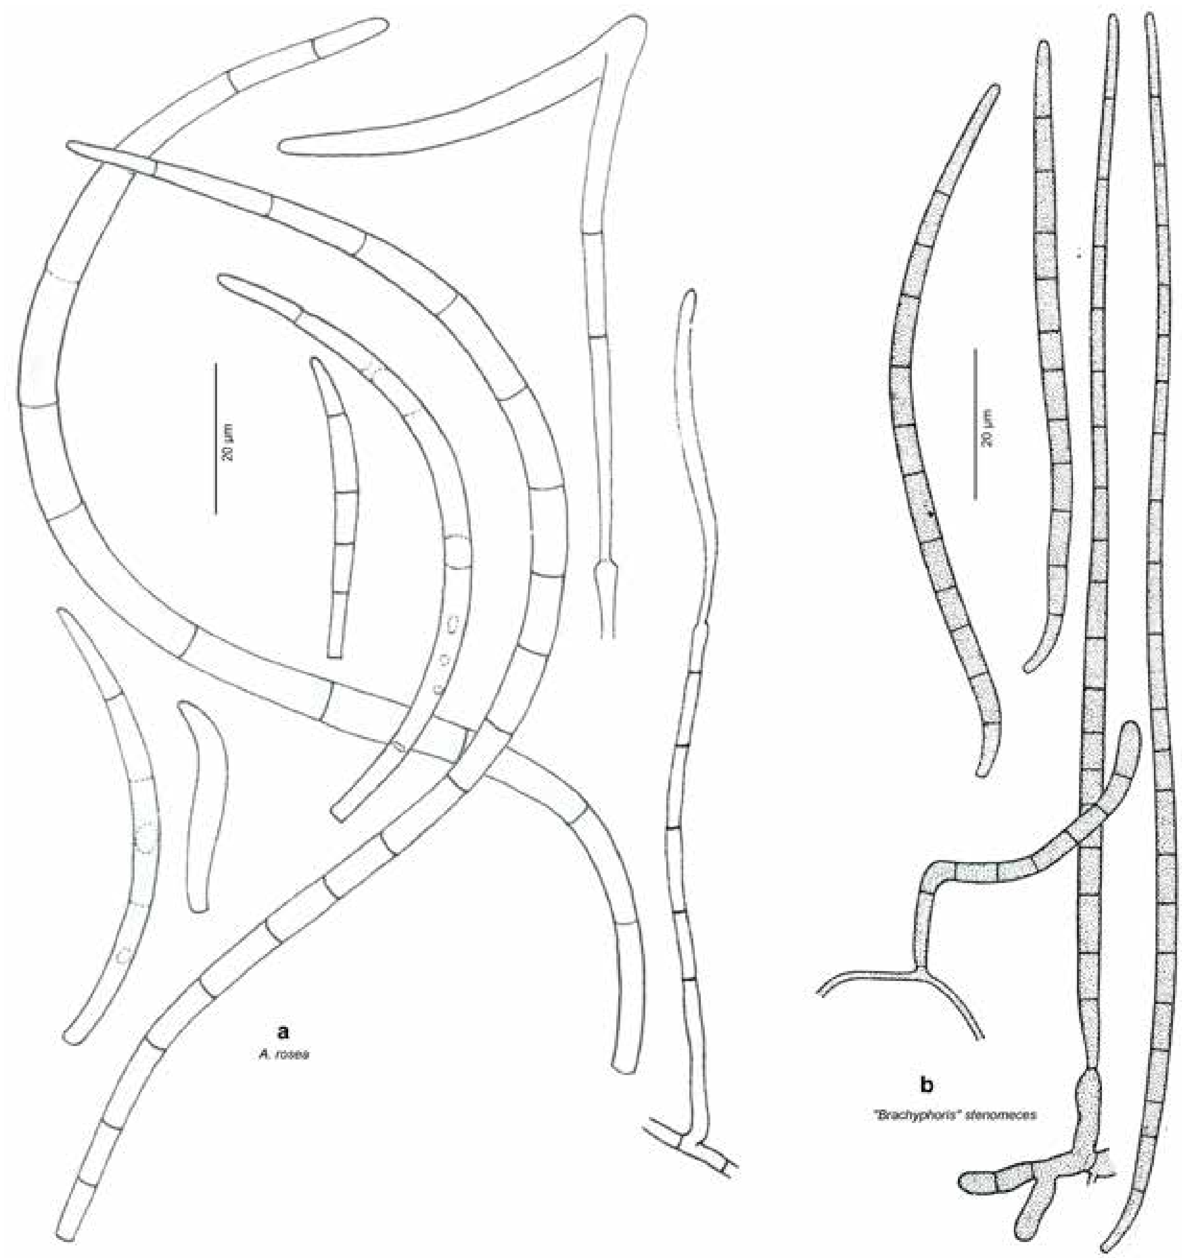

Plate 1. Two orbiliaceous species referable to the form genus *Anguillospora* (conidiophores and conidia). — **a**. from Descals et al. (1999), with microconidia; **b**. from Drechsler (1963). The scale of the two right elements of *A. rosea* was enlarged to 168 % of that given by Descals et al., because we believe that their fig. 4 has a wrong scale, the correct scale being that on their fig. 6.

cannot comment. Baschien et al. (2006) found great variability in conidial size and considered that *A. longissima* might be a species aggregate. Willoughby & Archer (1973) and Webster & Descals (1979) determined a connection of *A. longissima* to a teleomorph (as *Massarina* sp., *Massarinaceae*, *Pleosporales*). However, Baschien et al. (2006) believed that it could rather be a *Lophiostoma*. Morphological and molecular data supplied by Zhang et al. (2009a) indicate that *A. longissima* represents a fourth species of the genus *Amniculicola* Y. Zhang ter & K.D. Hyde, which was recently erected to accomodate three newly described species in the new family *Amniculicolaceae*, which is a segregate of *Lophiostomataceae*. Rossman et al. (2016) combined *A. longissima* in *Amniculicola* and suggested to change the type species of *Anguillospora*. That Zhang et al. (2009a) did not obtain conidia in their cultures of *Amniculicola* spp. can be explained by the fact that they did not submerge them in sterile water, a method found by Webster & Descals (1979) to be essential for conidial induction. Based on the similarity in the analysed gene regions and in the observed teleomorphs, a congruence between *Anguillospora* s.str. and *Amniculicola* seems highly probable.

Only for one species of *Anguillospora*, *A. rosea* Webster & Descals (Pl. 1: a), an *Orbilia* teleomorph was reported (Webster & Descals 1979, Descals & Chauvet 1992, Descals et al. 1999, as *Orbilia* sp.), apart from the unnamed anamorph of *O. yuanensis* (Qiao et al. 2015) with anguillospora-(to vermispora-) like conidia. Pfister (1997) connected *Anguillospora* sp. with an *Orbilia* which he tentatively identified as *O. luteorubella*. Descals et al. (1999) assumed that Pfister's *Anguillospora* is *A. rosea*, but they hesitated to link *O. luteorubella* to *A. rosea*, because Pfister did not provide a full description of the anamorph and none of the teleomorph. In both reports, much shorter, pauciseptate microconidia occur along with the macroconidia. The connection of *A. rosea* to the genus *Orbilia* is confirmed by Belliveau & Bärlocher (2005) by molecular analysis of a paratype strain from England. Molecular data are unavailable for two further species, *Dactylella stenomeces* Drechsler and *D. helminthodes* Drechsler, which were recently placed in *Brachyphoris* by Chen et al. (2007b) mainly because of their short conidiophores. However, especially *D. stenomeces* (Pl. 1: b) with its long and slender conidia might instead belong to *Orbilia* series *Helicoon* (section *Helicoon*) or to *O. caulicola* of series *Commatoideae* (section *Aurantiorubrae*, see also under *Brachyphoris*, p. 217–219).

Anguillospora-like species have mostly been sampled in aquatic environments. Pfister (1997) emphasized the similar conidial morphologies in *Anguillospora* as pointing to convergent evolution in aquatic or semiaquatic habitats.

In the present study we accept typification of *Anguillospora* as a member of *Dothideomycetes*. We obtained anguillospora-like anamorphs in pure culture only in a few species, particularly in those of series *Helicoon* (section *Helicoon*), including *A. rosea* which is confirmed to be the anamorph of an *Orbilia* of the *O. luteorubella* aggregate (*O. rosea*). Similar anamorphs with shorter, anguillospora- to vermispora-like phragmoconidia are found in *O. hoana* and *O. yuanensis*. Also in *O. caulicola* (section *Aurantiorubrae*) we obtained anguillospora-like conidia in pure culture.

In their short conidiophores these orbiliaceous anamorphs resemble those of *Vermispora* and *Brachyphoris*, which are, however, genetically quite distant from *Orbilia* and here included in *Hyalorbilia* (see p. 311).

Arthrobotrys Corda – (Pl. 2, Tab. S7)

The genus *Arthrobotrys* was erected in 1839 by Corda for the single species *A. superbus* Corda. Numerous investigators worked on the genus, e.g., Drechsler (1937a, 1944a), Haard (1968), Jarowaja (1970), Schenck et al. (1977), Van Oorschot (1985), and many others. For a long time, the main characteristics of the genus were the didymosporous conidia formed on swollen fertile nodes in roundish clusters, combined with the ability of trapping nematodes. The Greek suffix *botrys* describes these clusters, and the prefix *arthro* refers to the chain-like arrangement of the clusters along the very elongate conidiophore in the type species. However, Liou & Tzean (1997), Ahrén et al. (1998), Scholler et al. (1999), and Yang & Liu (2006) have shown by molecular phylogenetic methods that the morphology of the trapping devices provides more valuable key characters to circumscribe natural groups. Scholler et al.'s (l.c.) concept of *Arthrobotrys* is no longer restricted to 1-septate conidia, but includes non-septate and multiseptate forms, and conidia borne singly at the tip of long conidiophores. A number of species were found to produce microconidia (see p. 113). All of the included species trap nematodes by means of more or less 3-dimensional adhesive networks. Molecular data in GenBank are available for numerous *Arthrobotrys* species (see p. 1515, Phyls 28–31, Tab. S7).

According to Scholler et al. (l.c.), eight further generic names are synonyms of *Arthrobotrys* (see p. 1513). The reasons for their original erection were manifold: *Candelabrella* was proposed for species with pronounced denticles in a candelabrum-like terminal arrangement (candelabrelloid), *Didymozoophaga* because of two-celled conidia, *Duddingtonia* based on absent nodules, *Geniculifera* (= *Genicularia*) because of the geniculate conidiophore apex, *Monacrosporiella* and *Monacrosporium* based on conidiophores that produce a single acrogenous conidium, and *Nematophagus* and *Woroninula* because of conidiophores with nodules aggregated on ± swollen nodes (arthrobotryoid) and conidia with predominantly more than one septum. However, all these genera form adhesive networks in culture, and molecular data show that they cluster within the *Arthrobotrys* clade (no sequence was available for the type of *Nematophagus*, *N. azerbaijanicus*). Seifert et al. (2011) added the genus *Roigiella* as a ninth synonym of *Arthrobotrys* in the narrow sense. This is confirmed by comparison of an unpublished sequence of the type strain (CBS 222.85) of the type species *R. lignicola* which forms synnemata on wood. No trapping organs were reported in pure culture, probably because no nematodes were added.

Despite these results, some modern authors (e.g., Li et al. 2005, Su et al. 2005, Kim et al. 2006) retained *Monacrosporium* as circumscribed by Subramanian (1964), Liu & Zhang (1994), and Rubner (1996). This genus was separated from *Arthrobotrys* based on frequently broadly fusiform conidia with usually more than one septum and an inflated middle cell, which are formed only singly or in small groups at the tip of the conidiophore.

The following connections between anamorphs and teleomorphs have been reported in *Arthrobotrys* until now. In seven of them the morphologically hardly distinguishable teleomorph is the collective species *O. auricolor*: *A. cladodes* var. *cladodes* (Liu 2006), *A. cladodes var. macroides* (Pfister & Liftik 1995), *A. oligosporus* var. *oligosporus* (Pfister & Liftik 1995, Liu 2006); *A. elegans* (Rubner 1996, as *Monacrosporium psychrophilum*); *A. javanicus* (Liu 2006); *A. multiformis* (Mo et al. 2005a, as *A. yunnanensis*); *A. superbus* (Pfister 1994, as *O. fimicola*). Li et al. (2009) reported *A. nonseptatus* as anamorph for an unidentified *Orbilia* with subglobose ascospores and Qiao et al. (2012) connected *A. vermicola* to *O. blumenaviensis*.

Within the *O. auricolor* complex, problems exist in morphological delimitation between *A. oligosporus*, *A. superbus*, and *A. cladodes* (see under *O. auricolor*, p. 1531), or between *A. psychrophilus* and *A. oudemansii* (see under *O. elegans*, p. 1554). Shenoy et al. (2007) suggested significant phenotypic variation within a species caused by external factors as one reason for these problems. The authors also imagined that one teleomorph (*O. auricolor*) may produce several different anamorphs at a time by occurring in all possible combinations. This idea is contradicted by the absence of, e.g., any isolate that produced both *A. oligosporus* and *A. psychrophilus* anamorphs. Today's available molecular data suggest a high phylogenetic diversity within the *O. auricolor* complex and the existence of a number of different species.

Arthrobotrys species live in moist habitats, in soil, on decaying plant material, or on dung. They are capable of capturing nematodes, and show a worldwide distribution. Because of the large number of publications and described taxa concerning *Arthrobotrys* (Scholler et al. 1999 accepted 46 species) we refrain here from a detailed listing (but see Tab. S7).

In the present study, the genus *Arthrobotrys* was reduced to a section and series of *Orbilia*. Besides the above-mentioned connections between anamorphs and teleomorphs we here add the new species *O. menageshae* with a known anamorph. With regard to the rather high number of known *Arthrobotrys* species we expect for the future a distinct increase of newly reported

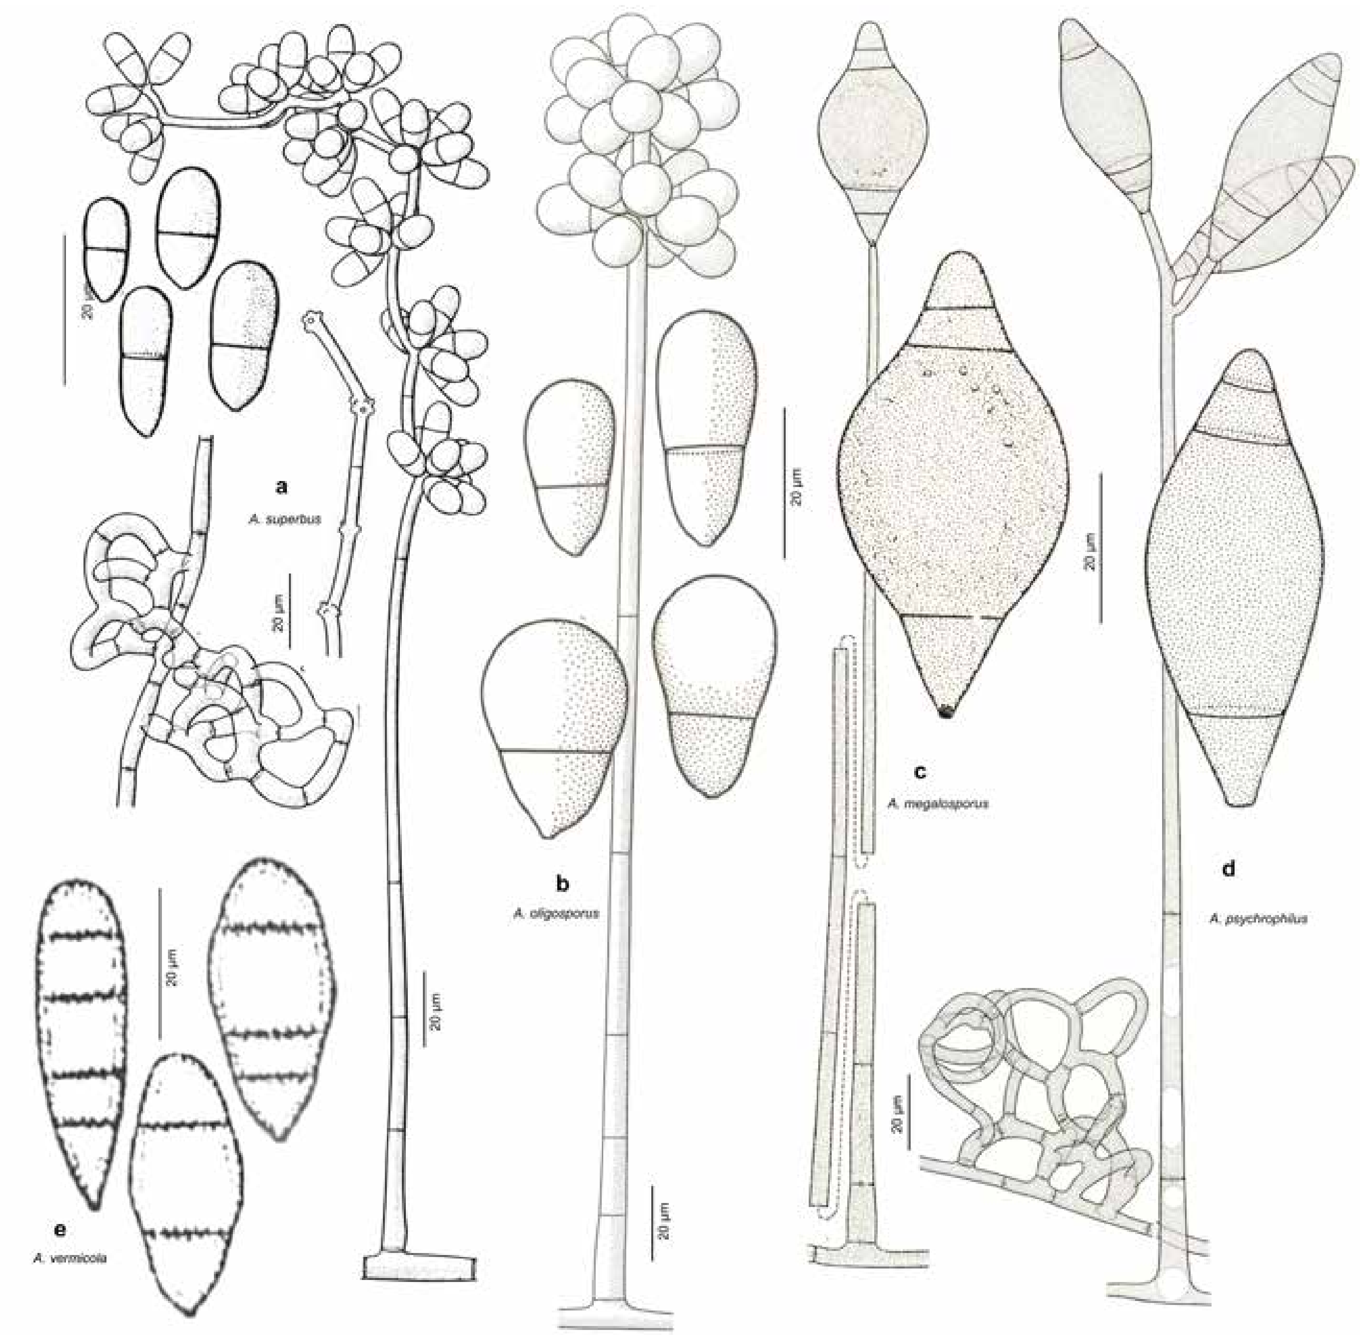

Plate 2. Some selected species of *Arthrobotrys* (conidiophores, conidia, and adhesive networks). — **a–b**. from Drechsler (1937a), **c**. from Drechsler (1954), **d**. from Drechsler (1944a), **e**. from Cooke & Satchuthananthavale (1965).

connections. The teleomorphs are often nearly identical or without striking morphological differences, e.g., between *O. auricolor*, *O. elegans*, and *O. oligospora*. Species distinction without the anamorph or genetical data is, therefore, impossible. But even cryptic species appear to exist, therefore, it could not be clarified which *Arthrobotrys* species belongs to *O. auricolor* in its original sense.

Brachyphoris Juan Chen, L.L. Xu, Bin Liu & Xing Z. Liu – (Tab. 43, Pl. 3)

In a phylogenetic analysis of 37 dactylella-like isolates, Chen et al. (2007a: fig. 1) obtained three distinct groups which were morphologically supported to some extent: the largest clade (*Dactylella* s.str.) comprised most of the species previously assigned to *Dactylella*, with the exception of *D. oviparasitica*, *D. brevistipitata*, *D. tenuifusaria*, and *D. spermatophaga*. Whereas *D. spermatophaga* formed a distinct clade with the newly described *Vermispora fusarina* and *V. leguminacea* (see p. 246, under *Vermispora*), the other three *Dactylella* species formed a third group. For this group the authors described the genus *Brachyphoris* (with *B. oviparasitica* as type species), with the following main characteristics (Chen et al. 2007c): conidiophores simple or occasionally branched, very short or at least distinctly shorter than conidia, producing mostly a single conidium at the tip, conidia spindle-shaped, filiform or elongate-fusoid, straight or slightly curved [3–22-septate]. The name *Brachyphoris* refers to the short conidiophores. Chen et al. distinguished *Vermispora* from *Brachyphoris* by often somewhat curved conidia formed on sympodially proliferating conidiophores. Based on morphological similarities of conidiophores and conidia it cannot be excluded that the genus *Paradactylella* Matsush. represents an earlier synonym of

Table 43. Overview of the accepted species of *Brachyphoris* (*B. stenomeces* is also treated under *Anguillospora*).

Species	Conidial size (in µm)	Number of septa	Spore shape	Habitat	References
‘*Dactylella*’ *lignatilis* M.H. Mo & K.Q. Zhang (≡ *Hyalorbilia lignatilis*)	25–51 × 2.5–6.3	(1–)3–4(–6)	fusiform to cylindrical	on decayed *Pinus* twig, China	Mo et al. 2005b
B. brevistipitata (Bin Liu et al.) Juan Chen et al. (≡ *Hyalorbilia brevistipitata*)	23–52 × 3–4	3–5	narrowly fusoid	on decaying twigs of broad-leaved tree, China	Liu et al 2005, Chen et al. 2007c
B. oviparasitica (G.R. Stirling & Mankau) Juan Chen et al. **Type species** (≡ *Hyalorbilia oviparasitica*)	31–65 × 2.7–5	4–7	fusiform	from roots of *Prunus persica*, USA, parasitic on eggs of *Meloidogyne* sp.	Stirling & Mankau 1978, Chen et al. 2007a, c
B. helminthodes (Drechsler) Juan Chen et al.	53–84 × 2.8–3.7	7(–8)	elongate fusiform	leaf mould, USA, parasitic on *Pythium* oospores and *Cochlonema* zygospores	Drechsler 1952, Chen et al. 2007b
‘*Dactylella*’ *passalopaga* Drechsler	60–80 × 4.5–6	6–8	elongate fusiform	in decaying plant roots, in soil, and leaf mould, capturing rhizopods, *Pythium* oospores, USA, Japan	Drechsler 1936, Morikawa & Saikawa 1992, Barron 2008

[*B. stenomeces* (Drechsler) Juan Chen et al.]	55–170 × 2.5–3.2	8–22	filiform	on decaying leaves, USA, parasitic on *Pythium* oospores	Drechsler 1963, Chen et al. 2007b

Brachyphoris (but see p. 220, under *Dactylella*).

In Chen et al.’s circumscription, *Brachyphoris* contains five species, all of which were previously included in the genus *Dactylella*. Liu et al. (2005) described *D. brevistipitata* as anamorph of *Hyalorbilia brevistipitata*, therefore, *Hyalorbilia* was regarded by Chen et al. to be the teleomorph of *Brachyphoris*. In the same year, Mo et al. (2005b) described as anamorph of a *Hyalorbilia* sp. the similar *D. lignatilis*, which is obviously also brachyphoris-like (see under *H. lignatilis*, p. 359). Sequence data are lacking in two species with medium to very long, vermiform, multiseptate conidia, *B. helminthodes* and *B. stenomeces*. Chen et al. assigned them to *Brachyphoris* obviously because of the short conidiophores and parasitic habit, although the morphology of conidia and conidiophores, especially in *B. stenomeces*, resembles also the anamorph of species of series *Helicoon* or *Commatoideae* of the genus *Orbilia*, to which they might instead belong. *B. stenomeces* is, therefore, figured on the *Anguillospora* plate. Possibly, further species listed at present in *Dactylella* are anamorphs of *Hyalorbilia*. Potential candidates would be the four species with short to medium long conidiophores which parasitize *Pythium* oospores: *D. arrhenopa*, *D. polyctona*, *D. anisomeres*, and *D. stenocrepis*. In the conidia of the former three species as figured by Drechsler (1943, 1952, 1963) one can discern small globose/cubical bodies which would be typical of *Brachyphoris*.

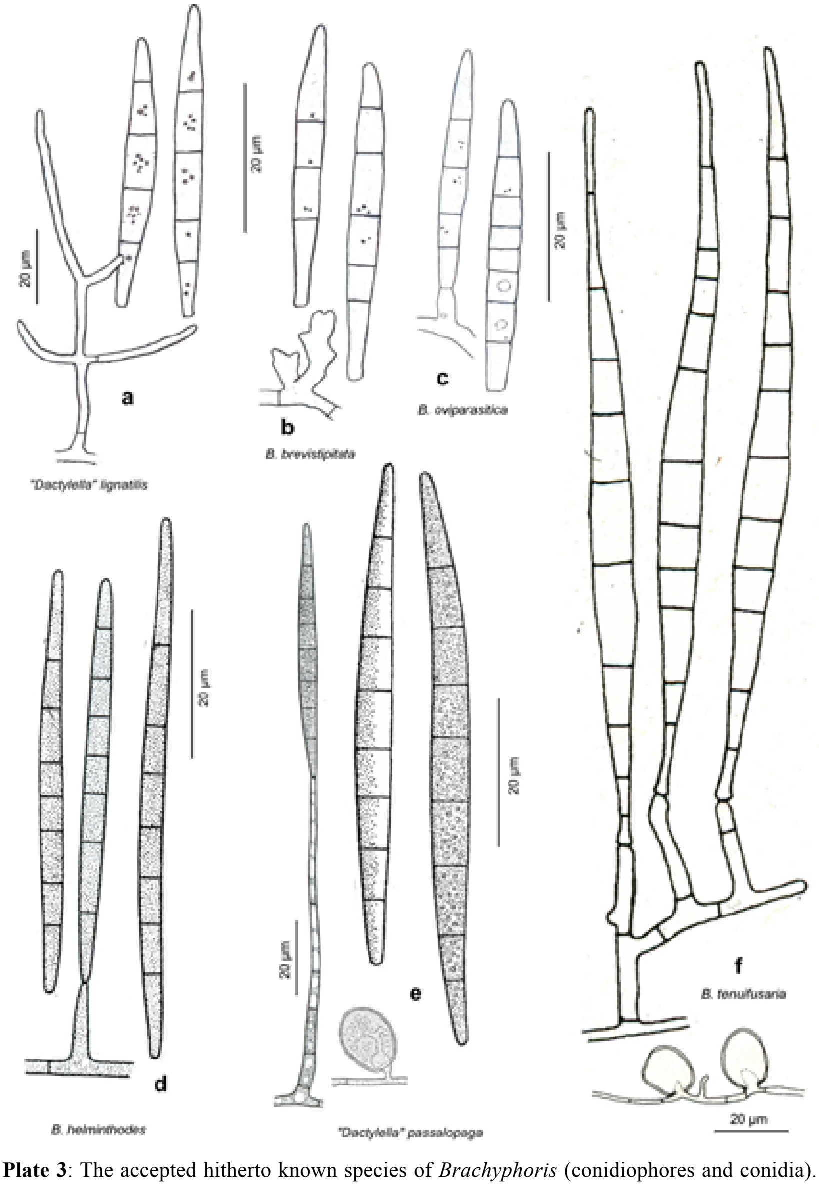

Plate 3: The accepted hitherto known species of *Brachyphoris* (conidiophores and conidia). — **a**. from Mo et al. (2005b), **b**. from Liu et al. (2005b), **c**. from Chen et al. (2007c), **d**. from Drechsler (1952), **e**. from Drechsler (1936), **f**. from Liu et al. (1996); **e** and **f** with captured rhizopods on adhesive pegs.

When isolating DNA from wood, litter and soil, Smith & Jaffee (2009) found in their phylogenetic analysis of the 28S rDNA eleven unidentified *Brachyphoris* species which formed a monophyletic group with *B. oviparasitica*. The employed method did not include pure cultures, therefore, morphological features are unknown for all these DNA isolates, and only two of the sequences were similar enough to existing sequences in order to give them specific names (see under *Hyalorbilia*, p. 317).

Brachyphoris species live in moist but also xeric habitats on decaying plant material, and are known from Asia, Europe and North Amer-

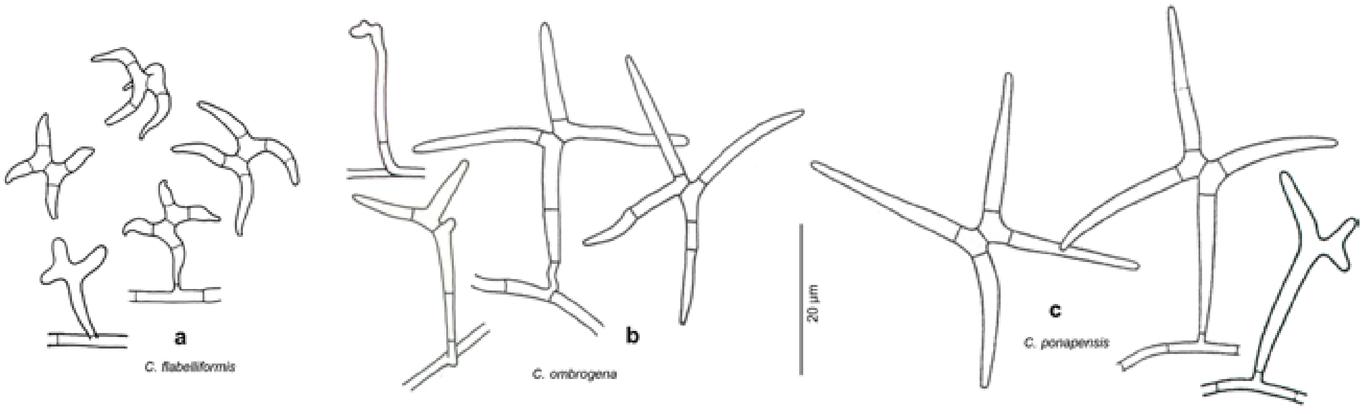

Plate 4. The accepted, hitherto known species of the form genus *Curucispora* (conidiophores and conidia). — **a**. from Ando (1993), **b**. from Ando & Tubaki (1984a), **c**. from Matsushima (1981).

ica. Some are capable of invading nematode eggs or cysts, '*D.*' *passalpoaga* forms adhesive knobs that capture rhizopods, and *B. helminthodes* and *B. stenomeces* are parasites on spores of oomycetes and zygomycetes.

In the present study, the term brachyphoris-like is exclusively used for anamorphs of *Hyalorbilia*. *Brachyphoris* and also *Vermispora* are synonymised with *Hyalorbilia* (but note that we use 'vermispora-like' for morphologically similar anamorphs in *Orbilia*). In addition to the known connections in *H. brevistipitata* and '*D.*' *lignatilis*, brachyphoris-like anamorphs are reported by us from cultures of four species: *H. fagi*, *H. inflatula*, *H. polypori*, and *H. tortuosa*. In contrast to those taxa included by Chen et al. (2007a–c), the conidiophores in these anamorphs sometimes attained a length of over 100 µm. Because of morphological similarities of the conidia, *D. passalopaga* is considered by us to belong to *Hyalorbilia*, possibly to *H. inflatula* (see p. 349). No sequence data are available for this brachyphoris-like anamorphic species, but the striking similarity of the conidia and the capacity to capture rhizopods as reported by Drechsler (1936) and Barron (2008) leave no doubt about its relationship with *Hyalorbilia*. We observed in *Hyalorbilia* also trinacrium-like (*H. erythrostigma*, *H. orbiliicola*) and curucispora-like (K-shaped) conidia (*H. subfusispora*, *H. latispora*) as hitherto undescribed anamorphs. A dwayaangam-like anamorph, *D. quadridens*, was combined in *Hyalorbilia* by Baral et al. (2017b).

A conspicuous small organelle of the living conidia was seen in several species and appears to be characteristic of the genus. It is referred here to as cubical body, because it resembles those more or less cubical bodies seen in *Lecophagus*, although the light microscope does not permit to decide whether it is globose or angular (see p. 94–95). This refractive organelle is also clearly visible on Barron's (2008) photos of *D. passalopaga* (see Pl. 59: a).

Curucispora Matsush. – (Tab. 44, Pl. 4)

Matsushima (1981) erected the genus for one species, *C. ponapensis*. Ando & Tubaki (1984a) described *C. ombrogena*, and Ando (1993) *C. flabelliformis*. The main characteristics of the genus are the tetraradiate, ┼-shaped conidia, to which the generic name refers which derives from the Latin *crux*. The conidia consist of three arms and a similarly shaped stipe, and develop from short denticles on intercalary conidiogenous cells. A teleomorph has not been reported so far, and molecular data are not available.

There is some confusion about the generic name *Curucispora*. Matsushima (1993) changed it to *Crucispora*, whereas Ando (1993) believed that the linguistically wrong but legitimate original spelling *Curucispora* must be retained. Because *Crucispora* Horak antedates this genus, Matsushima (2005: 145) proposed the new name *Cruciconidiifera* for it, obviously as he considered the original spelling *Curucispora* to be an 'orthographic' or 'typewriting error'. We follow Ando (l.c.) in maintaining the name *Curucispora*, because Matsushima did not change the original spelling in a corrigendum of the 1981 volume, and because the correction proposed in 1993 affects the first syllable of the generic name (Art. 60.3 ICN).

The three conidial arms do not emerge from one point because the conidium develops by dichotomous branching, thereby one of the two arms very early undergoes a second branching. Indeed, the three arms are formed almost simultaneously, as can be seen from the sketches by Matsushima (1981, see Pl. 4: c right), Ando & Tubaki (1984a, Pl. 4: b left), and Ando (1993, Pl. 4: a, lower left). Matsushima believed that in *C. ponapensis* one arm belongs to the main axis, and later the two other arms emerge from the centre of the main axis like a 'V'. However, an initial stage with a main axis without branches is only seen on his schematic sketch (Matsushima 1981: fig. 62). Ando & Tubaki believed that in *C. ombrogena* one arm is a later lateral outgrowth below the 'V', but their fig. 5A (Pl. 4: b, upper left)

Table 44. Overview of the accepted hitherto known species of the form genus *Curucispora* (*data evaluated from illustration).

Species	Conidial total size (in µm)	Arm width (in µm)	Habitat	Reference
C. flabelliformis K. Ando	15–20 × 13–18.5*	1.5–2	on fallen leaves of *Livistona chinensis*, Japan	Ando 1993
C. ombrogena K. Ando & Tubaki	~27–35 × 25–35 µm	1.3–2*	in rainwater from *Phyllostachys bambusoides*, Japan	Ando & Tubaki 1984a
C. ponapensis Matsush. **Type species**	~35–50 × 35–50 µm	2–2.5(–3)	decaying petioles of *Cocos nucifera*, Ponape, Caroline Islands, Micronesia	Matsushima 1981

shows that initial stages of all three arms may very early be present as small protuberances.

Similar tetraradiate conidia occur in *Descalsia* and *Tridentaria* (see there), and in *Arborispora paupera* Marvanová & Bärlocher (1989). In *Arborispora* the lateral arms insert in the middle of the main axis and are always very strongly constricted at their base, and sometimes a third arm emerges from another cell of the main axis or from one of the primary branches. The basidiomycetous anamorph-typified genus *Cruciger* Kirschner & Oberwinkler (1999) has similar but non-septate conidia, and conidiophores with clamps.

Species of *Curucispora* were isolated from decaying palm leaves, bark and leaves of broad-leaved trees, or from rainwater draining from the tree canopy. Collections are from eastern Asia, Micronesia, South America (Matsushima 1993), and Europe (Gönczöl & Révay 2006).

In the present study, *Curucispora* is treated as a possible synonym of *Hyalorbilia*, because we observed curucispora-like conidia in two *Hyalorbilia* species: *C. ponapensis* is reminiscent of the presumed anamorph of *H. subfusispora*, and *C. flabelliformis* strongly resembles the anamorph of *H. latispora*.

Dactylella Grove – (Tab. 45, Pls 5–6, see also Tab. S8)

The generic name was derived from *Dactylium candidum* Nees, a species characterized by 3–4 conidia at the conidiophore apex, resembling fingers (Greek *daktylo*) of a hand. In contrast to this, the monotypic genus *Dactylella* (Grove 1884), based on *D. minuta*, was described as forming always only a single terminal conidium (Pl. 6: e). *Dactylium* Nees is a nomen utique rejiciendum (ICN: appendix V) following a proposal by Gams & Rubner (1997), who argued that the type species *D. candidum* was a nomen dubium and an earlier synonym of the widely used *Monacrosporium* (an interpretation of *D. candidum* by Drechsler 1937a concerns *Dactylellina haptotyla*). The circumscription of *Dactylella* was emended several times by different authors (e. g., Subramanian 1964, Van Oorschot 1985, Zhang et al. 1995, Rubner 1996, Chen et al. 2007b). The main characteristics are: conidiophores ± long, sometimes branched, conidia clavate, ellipsoid or fusiform, straight, produced singly at the apex of conidiophores or on short branches.

Zhang et al. (1995) included 34 species in *Dactylella*, part of which are predacious (nematophagous). Rubner (1996: 105) provided a checklist of epithets used in *Dactylella*. She excluded all nematophagous species and transferred them to *Monacrosporium*, because *D. minuta* is most probably not capable of capturing nematodes. Based on molecular and morphological analyses, Chen et al. (2007a, b) found that *Dactylella* is a phylogenetically heterogeneous group. The authors accepted 28 species in *Dactylella* (s.str.) which are saprobic, though sometimes capable of invading oospores or nematode eggs, whereas they transferred six species with short conidiophores to the genera *Brachyphoris* (five spp.) and *Vermispora* (*V. spermatophaga*). The monotypic genera *Drechsleromyces* and *Gangliophragma*, which Subramanian (1978) separated from *Dactylella* because of sympodially proliferating conidiophores, were considered to be synonyms of *Dactylella* by Zhang et al. (1995) and Chen et al. (2007b). According to Seifert et al. (2011), the genus *Paradactylella* Matsush. (1993) is a synonym of *Dactylella*. The shortness of the conidiophores would rather point to *Brachyphoris*, for which *Paradactylella* could provide an earlier name. However, in our opinion, on the original drawing of *P. peruviana* and on the drawing in Seifert et al. conidial secession seems to be rhexolytic, a feature which we have never observed in any of the orbiliaceous anamorphs reported here, so at present we hesitate to accept placement of *Paradactylella* in the *Orbiliomycetes*. An overview of ca. 30 *Dactylella* species accepted by us is given in Tab. 45 and Pls 5–6, see also Tab. S8. Yet, it cannot be excluded, that some of these species are anamorphs of *Hyalorbilia* (see above, under *Brachyphoris*).

D. zhongdianensis was described by Zhang et al. (2005) as a predacious fungus that forms three-dimensional adhesive networks. Chen et al (2007b), however, found this species unable of producing organs of capture when nematodes were added. This was supported by their neighbour-joining analysis (Chen et al. 2007a), in which the species clustered near *D. rhopalota* in the *Dactylella* clade. For the dubious *D. rhombica* Matsush. (1971) no type material was available (see Rubner 1996); the large fusiform conidia [50–70 × 14–20 µm, (5–)6(–8)-septate], with enlarged middle cell rather point to *Dactylellina*.

Some authors relied after 1999 on the traditional generic concept based on conidial morphology and placed new species with cylindric-clavate to fusoid, phragmosporous conidia and three-dimensional adhesive networks in the genus *Dactylella*. For instance, *D. shizishanana* (Liu & Zhang 2003) and *D. pseudoclavata* (Miao et al. 2003) belong to *Arthrobotrys*, where they were transferred by Chen et al. (2007b), and also *D. crassa* Miao et al. (1999) would better be placed in *Arthrobotrys.* The recently described South African *D. bolusanthi* (Crous 2019) with rather short conidiophores is not included in the plates.

Dactylella is reported several times as anamorph of *Orbilia* (see also Tab. 41): Thakur & Zachariah (1989) obtained apothecia of '*Orbilia* sp.' (possibly *O. cardui*) from a culture identified as *D. rhopalota* (see p. 1472). Pfister (1997) figured a *Dactylella* sp. obtained from an ascospore isolate of *O. dryadum* (as *O.* ?*alnea*). Yang & Liu (2005) described *D. coccinella* as anamorph of a teleomorph with unknown morphology but identified as '*O. coccinella*'. However, this anamorph is very different from *Dicranidion fragile*, the anamorph of *O. eucalypti* (= *O. coccinella* s.auct.). It agrees to Pfister's anamorph of *O. dryadum*, although the ITS-sequences are quite different (see p. 1389). Webster et al. (1998) reported *D.* (cf.) *oxyspora*, an isolate identified as *D. atractoides* by Zhang et al. (2011a), in pure culture of *O. fimicoloides* (= *O. oxyspora*). A report of *D. lignatilis* as anamorph of a *Hyalorbilia* sp. by Mo et al. (2005b) refers to a species of *Brachyphoris* (= *Hyalorbilia*, see p. 359), that of *D. dorsalis* as anamorph of *O. dorsalis* by Yu et al. (2007) is difficult to distinguish from *O. oxyspora* (see p. 1500), that of *D. alba* as anamorph of *O. alba* by Yu et al. (2009a) is referred here to *Gamsylella* (see p. 1615), and that of *D. pseudobrevistipitata* as anamorph of *Orbilia* sp. by Qin et al. (2011) is combined in *O. pseudobrevistipitata* by Zhang et al. (2015) (see p. 864). *O. tianmushanensis* with a dactylella-like anamorph was reported by Zhang et al. (2016). Zhang et al. (ined.) reported us two further species with dactylella-like anamorphs, *O. longquanensis* and *O. dehongensis* nom. prov.

Species of *Dactylella* probably have a worldwide distribution. They were isolated at wet habitats from decaying plant material and soil, and were found to be sometimes parasitic on oospores of oomycetes and eggs of nematodes, one also on rhizopods.

In the present study, dactylella-like anamorphs were mainly found in series *Neodactylella* of section *Arthrobotrys*, but also in series *Hyalinia* and *Xanthoguttulatae* (section *Aurantiorubrae*),

Table 45. Overview of the accepted species of the form genus *Dactylella* (nematophagous species and species with coloured conidia or conidiophores, or phialidic conidiogenesis are excluded; see also Rubner 1996: 105f. and Chen et al. 2007b); * = values corrected according to scale (published as 13.3–39 × 3.5–5.6 µm); ** = values corrected acccording to Z.F. Yu (pers. comm., published erroneously as 22–30.3 × 3.3–4 µm).

Species	Conidial size [µm]	Number of septa	Conidial shape	Habitat	Reference
D. polyctona (Drechsler) K.Q. Zhang et al.	12.7–21 × 2.3–2.8	1	clavate to ellipsoidal	on leaf mould, USA, parasitizing *Pythium* oospores, rhizopods, cysts of myxobacteria	Drechsler 1952
D. arrhenopa (Drechsler) K.Q. Zhang et al.	17–25 × 2.6–3.7	1	clavate to ellipsoid	in soil of a wood, USA, parasitc on *Pythium* oospores	Drechsler 1943a
D. tenuis Drechsler	25–41 × 6.3–8.2	(1–)3(–4)	cylindrical	on leaf mould in deciduous woods, USA, parasitic on *Pythium* oospores	Drechsler 1937a,
D. clavispora Juan Chen et al. (≡ *Orbilia clavispora*)	18–32.5 × 7.5–11	1–3	clavate or cylindrical to ellipsoid	living leaf of *Betula*, U.K.	Chen et al. 2007b
D. coccinella Y. Yang & Xing Z. Liu (Pfister as *Dactylella* sp.)	22.5–32.5 × 5–6.5	1–7	cylindrical	?	Yang & Liu 2005 Chen et al. 2007b
D. zhongdianensis J. Zhang & K.Q. Zhang (= *Orbilia zhongdianensis*)	17.5–37.5 × 5–8	(2–)3(–6)	cylindrical to clavate	soil, China	Zhang et al. 2005, Chen et al. 2007b
D. vermiformis Z.F. Yu et al. (≡ *Orbilia vermiformis*)	20–36.8 × 5.8–8.1	(0–)1	clavate	on rotten root of angiosperm tree, China	Yu et al. (2007a)
D. pseudobrevistipitata L. Qin et al.(≡ *Orbilia pseudobrevistipitata*)	18–39 × 3.8–6.7*	1–5	cylindrical	from bark of angiosperm tree, China	Qin et al. 2011
D. anisomeres Drechsler	20–43 × 3.5–4.5	(1–)3(–5)	± cylindrical	leaf mould, USA, parasitic on *Pythium* oospores	Drechsler 1962
D. cylindrospora (R.C. Cooke) A. Rubner	22.5–45 × 6.5–8.5	1–4	obconical to clavate to cylindrical	in soil, Western Samoa	Cooke 1969, Rubner 1996, Chen et al. 2007b
D. pulchra (Linder) de Hoog & Oorschot	(27–)34–45 × (7–)9–11	5–7	clavate to slightly fusiform	flower pots, from greenhouse lettuce seedlings, USA	Linder 1934, De Hoog & Van Oorschot 1985, Chen et al. 2007b
D. stenocrepis Drechsler	29–46 × 4.6–7.8	mainly 3	fusiform	decaying plant material, USA, parasitic on *Pythium* oospores	Drechsler 1962
D. heptameres Drechsler	29–52 × 8–10.8	3–7	mostly fusiform	on leaf mould, USA	Drechsler 1943b Chen et al. 2007b
D. ramosa Matsush.	32–54 × 4.2–6	3–9	cylindrical to clavate	on decaying *Ficus* leaf, Micronesia	Matsushima 1971, Chen et al. 2007b
D. xinjiangensis Juan Chen et al.(≡ *Orbilia xinjiangensis*)	39.5–54 × 7–12	4–7	clavate	soil, China	Chen et al. 2007b
D. clavata R.H. Gao et al.	20–64 × (4–)6–8	(1–)3–7	clavate	from soil, China	Gao et al. 1995, Chen et al. 2007b
D. strobilodes Drechsler	30–60 × 11–18	1–9	elongate ellipsoidal	on leaf mould in deciduous woods, USA	Drechsler 1950b
D. rhopalota Drechsler (≡ *Orbilia rhopalota*)	36–60 × 6.7–9.6	3–10	mostly clavate to cylindrical	on leaf mould, USA; decaying wood and leaf litter, Europe	Drechsler 1943b, Chen et al. 2007b
D. submersa (Ingold) Sv. Nilsson	35–65 × 6–9	1–6	cylindrical to clavate	decaying *Quercus* leaves in water, UK	Ingold 1944
D. nuorilangana X.F.Liu & K.Q.Zhang (= *Orbilia rectispora*)	42–62 × 4.5–7.5	1–7	cylindric (-fusoid)	from soil, China	Zhang & Mo 2006
[*D. rhombospora* Grove] *D. rhombospora* s.auct. (?= *O. dorsalis*)	[~52–70 × 14.5–19] 40–71 × 8.5–13	[7] 5–10	fusiform	[wood & bark], leaf litter, [U.K.], USA, Macaronesia	[Grove 1885], Drechsler 1937a, Chen et al. 2007b
D. minuta Grove **Type species**	60–70 × 14–15	6–8	clavate	on dead wood, England	Grove 1884 (Rubner 1996, Chen et al. 2007b)
D. attenuata R.H. Gao et al.	42–62 × 3–4	4–9	elongate-fusoid to cylindrical	in rainforest soil, China	Gao et al. 1997, Chen et al. 2007b
D. dorsalis Y. Zhang et al. (≡ *Orbilia dorsalis*)	51.8–75.5 × 7.8–12.3**	5–9	elongate fusoid	on dead bark, China	Yu et al. 2007b
D. atractoides Drechsler (= *D. oxyspora* fide Chen et al. 2007b)	26–76 × 7.2–10.2	3–13	mostly fusiform	decaying leaves of *Solanum lycopersicum*, USA	Drechsler 1943b
D. chichisimensis Ts. Watan.	20–78 × 5–8	3–9	clavate, cylindrical, or ellipsoid	from forest soil, Japan	Watanabe et al. 2001
D. bolusanthi Crous	42–75 × 5–6	5–11	elongate fusoid	leaf litter of *Bolusanthus speciosus*, South Africa	Crous 2019
D. intermedia T.F. Li et al.	40.5–82 × 8–13	5–8	fusiform	soil, litter of *Ziziphus spina-christi* and *Ficus religiosa*, China	Li et al. 1998, Chen et al. 2007b
D. panlongana X.F. Liu & K.Q. Zhang (Chen et al. as '*panlongna*')	42.5–97.5 × 4.5–8	3–12	oblong fusiform to cylindrical	soil, China	Zhang & Mo 2006, Chen et al. 2007b
D. oxyspora (Sacc. & Marchal) Matsush.	60–105 × 9–13	6–12	± elongate fusoid	dung, soil and plant debris, Germany, Netherlands, Tenerife, Ecuador, USA	Marchal 1885, Rubner 1996, Chen et al.2007b
= *D. arnaudii* Yadav (≡ *Orbilia oxyspora*)	29.5–92 × 3.3–9.9	3–12	fusiform, (partly rostrate)	on decaying stems of *Heracleum sphondylium*, U.K.	Yadav 1960, Chen et al. 2007b
D. yunnanensis K.Q. Zhang, Xing Z. Liu & L. Cao (= ?*D. oxyspora*)	66.5–106 × 8.5–13.5	7–10	elongate fusoid, somewhat rostrate	from forest soil, China	Zhang et al. 1995, Chen et al. 2007b
D. qiluensis H.Y. Su & M.H. Mo	89–143 × 8.7–11.2	5–9	elongate fusoid, rostrate	from waterlogged soil from a lake, China	Su et al. 2011a

and series *Orbilia* (section *Orbilia*). No sequence is available for the type of *Dactylella*, *D. minuta*. From its morphology, this species could either belong to series *Neodactylella* or in series *Hyalinia*. The type species of *Gangliophragma* (*D. rhopalota*) and *Drechsleromyces* (*Drm. atractoides*, = *D. oxyspora* fide Chen et al. 2007b) are assumed to belong to series *Neodactylella*. Species delimitation within *Dactylella* is problematic in several cases. Based on molecular analyses by Chen et al. (2007a) and the present study we conclude that *D. arnaudii*, *D. yunnanensis*, and *D. atractoides* s. Li et al. (2006) are conspecific with *D. oxyspora*. *D. rhombospora* s. Chen et al. (2007b) and *D. dorsalis* are morphologically similar to *D. oxyspora*, but form a separate clade.

Dactylellina M. Morelet – (Tab. 46, Pls 7–9, see also Tab. S9)

Mekhtieva (1967) proposed the genus *Dactylosporium* as a segregate of *Dactylella* for a single species (*D. leptospora*) because of its nematophagy by means of stalked adhesive knobs and non-constricting rings, and denticulate conidiophores. Eleven years later, Mekhtieva (1978) erected *Kafiaddinia* for a new taxon, *K. fusariispora*, with fusarium-like conidia with

(1998), **i**. from Barron (1990), **j**. from Liou et al. (1995) (= *D. leptospora*), **k**. from Drechsler (1937a). * = The size of conidia and conidiophores is somewhat modified in reference to the size given in the description.

Table 46. Overview of the accepted species of *Dactylellina*.

Species	Conidial size [µm]	Number of septa	Conidial shape	Noncon-stricting rings	Habitat	Reference
'*Arthrobotrys*' *paucus* J.S. McCulloch	12–19 × 4–7	1	(cylindric-) ellipsoid		soil around strawberry, Australia, nematophagous	McCulloch 1977
D. hertziana (M. Scholler & A. Rubner) M. Scholler et al.	(16–)16.5–27.5(–28.5) × 7.5–11.5(–12)	(0–)3(–4)	obovoid to ellipsoid-cylindrical		plant debris, Canary Islands, nematophagous	Scholler & Rubner 1999
D. huisuniana (J.L. Chen et al.) M. Scholler et al.	29.5–41 × 4.5–7.5	3	mostly fusiform		decaying leaves of a dicot tree, Taiwan, nematophagous	Chen et al. 1998
D. quercus Bin Liu, Xing-Z. Liu & Zhuang (≡ *Orbilia quercus*)	25–40(–50) × 8–12	3	fusiform		on rotten *Quercus*-wood, China, nematophagous	Liu et al. 2005a
'*Monacrosporium*' *ullum* D.G. Kim et al.	17–44 × 7–10	(1–)2(–4)	fusiform		decaying plant material in soil, Korea, nematophagous	Kim et al. 2006
D. drechsleri (Tarjan) M. Scholler et al.	29.5–48.7 × 10.7–15.4	3	somewhat fusiform		from soil, USA, nematophagous	Tarjan 1961, Rubner 1996
D. mammillata (S.M. Dixon) M. Scholler et al. (≡ *Orbilia mammilata*)	29–44 × 9–14	3–4	ellipsoid to fusiform		decaying wood, soil, leaf litter, Canada, Germany, UK, nematophagous	Dixon 1952, Rubner 1996
D. asthenopaga (Drechsler) M. Scholler et al.	20–46 × 6.5–9.5	(1–)3(–5)	obconical or (fusoid-) clavate		forest soil, leaf mould, decaying wood and acorns, Australia, Netherlands, UK, USA, nematophagous	Drechsler 1937a, Rubner 1996
D. parvicollis (Drechsler) Y. Li (as '*parvicolle*', = *D. phymatopaga*)	35–45 × 8–14	4	fusiform		leaf litter, dead grass, soil, horse dung, Ecuador, Germany, Sweden, USA, nematophagous	Drechsler 1962, Rubner 1996
D. ellipsospora (Preuss) M. Scholler et al. (≡ *Orbilia ellipsospora*)	(24–)35–52(–65) × (7.5–)12–17(–19)	(2–)4	fusiform		soil, wood, leaf-litter, Germany, Spain, UK, nematophagous	Drechsler 1937a, Rubner 1996
D. daliensis H.Y. Su	28.7–51.5 × 3.2–5.2	(1–)6–8(–13)	elongate fusoid	+	from soil, China, nematophagous	Su et al. 2008
D. candida s. Drechsler (= *D. haptotyla* s.l.)	26–52 × 5.5–11.5	(2–)4(–6)	fusiform	+	from leaf mould, USA, nematophagous	Drechsler 1937a
D. haptotyla (Drechsler) M. Scholler et al.	(29–)33–56 × (7–)8–13.3	(3–)4(–5)	fusiform		soil, decaying leaves and culms of *Poa pratense*, wood, France, Germany, Sweden, UK, USA, nematophagous	Drechsler 1950a, Rubner 1996
D. lysipaga (Drechsler) M. Scholler et al. (≡ *Orbilia lysipaga*)	28–55 × 9–14	(2–)4	fusiform	+	on leaf mould in deciduous woods, USA, nematophagous	Drechsler 1937a, Rubner 1996
D. haptospora (Drechsler) M. Scholler et al.	35–60 × 2.2–3.2	4	cylindrical		woody remnants of *Ambrosia trifida*, USA, nematophagous	Drechsler 1940
D. varietas Y. Li et al.	25–61.5 × 6.5–10	(1–)7–8(–9)	fusoid	+	from forest soil, China, nematophagous	Li et al. 2006
D. mutabilis (R.C. Cooke) M. Scholler et al.	37.5–60 × 12.5–17.5	(3–)4(–5)	ellipsoidal to fusiform		in soil, Samoa, nematophagous	Cooke 1969, Rubner 1996
D. phymatopaga (Drechsler) Y. Li	40–60 × 11–18	4	fusiform		from soil, from mosses, Germany, Ecuador, Sweden, nematophagous	Drechsler 1954, Rubner 1996
D. formosana (J.Y. Liou et al.) M. Scholler et al. (= *D. leptospora*)	30–70 × 5–7.5	(2–)4–7(–8)	fusoid – cylindrical		decaying leaves of dicot tree, Taiwan, nematophagous	Liou et al. 1995
D. yunnanensis (K.Q. Zhang et al.) M. Scholler et al. (= *D. hyptotyla* s.l.)	34–81 × 8.5–12.5	(3–)4–6(–9)	fusiform	+	from forest soil, China, nematophagous	Zhang et al. 1996
D. sichuanensis Y. Li, K.D. Hyde & K.Q. Zhang (= *D. lysipaga*)	(35–)47–74(–82.5) × (7.5–)12.5–15.5(–17.5)	(3–)4(–6)	fusiform	+	from forest soil, China, nematophagous	Li et al. 2006
D. copepodii (G.L. Barron) M. Scholler et al.	56–97 × 8.5–16	(1–)4(–6)	fusiform		composted manure, New Zealand, capturing copepods	Barron 1990, Rubner 1996
D. leptospora (Drechsler) M. Morelet **Type species**	40–105 × 4–5.8 (primary conidia)	5–15	elongate fusoid, also cylindrical	+	soil, leaf mould in deciduous woods, USA, nematophagous	Drechsler 1937a, Rubner 1996
D. appendiculata (Anastasiou) M. Scholler et al.	57–108 × 9.3–14.5	4–7	fusiform, with lateral arms		from leaves in water, Hawaii, nematophagous	Anastasiou 1964, Rubner 1996
D. illaqueata D.S. Yang & M.H. Mo (?= *D. lysipaga*)	25.5–117.5 × 5.5–15.2	3–8	elongate fusiform	+	from soil, China, nematophagous	Yang et al. 2006
D. multiseptata (H.Y. Su & K.Q. Zhang) Z.F. Yu	67.5–132.5 × 13.8–17.5	4–9	fusiform to clavate		from soil, China, nematophagous	Su et al. 2005

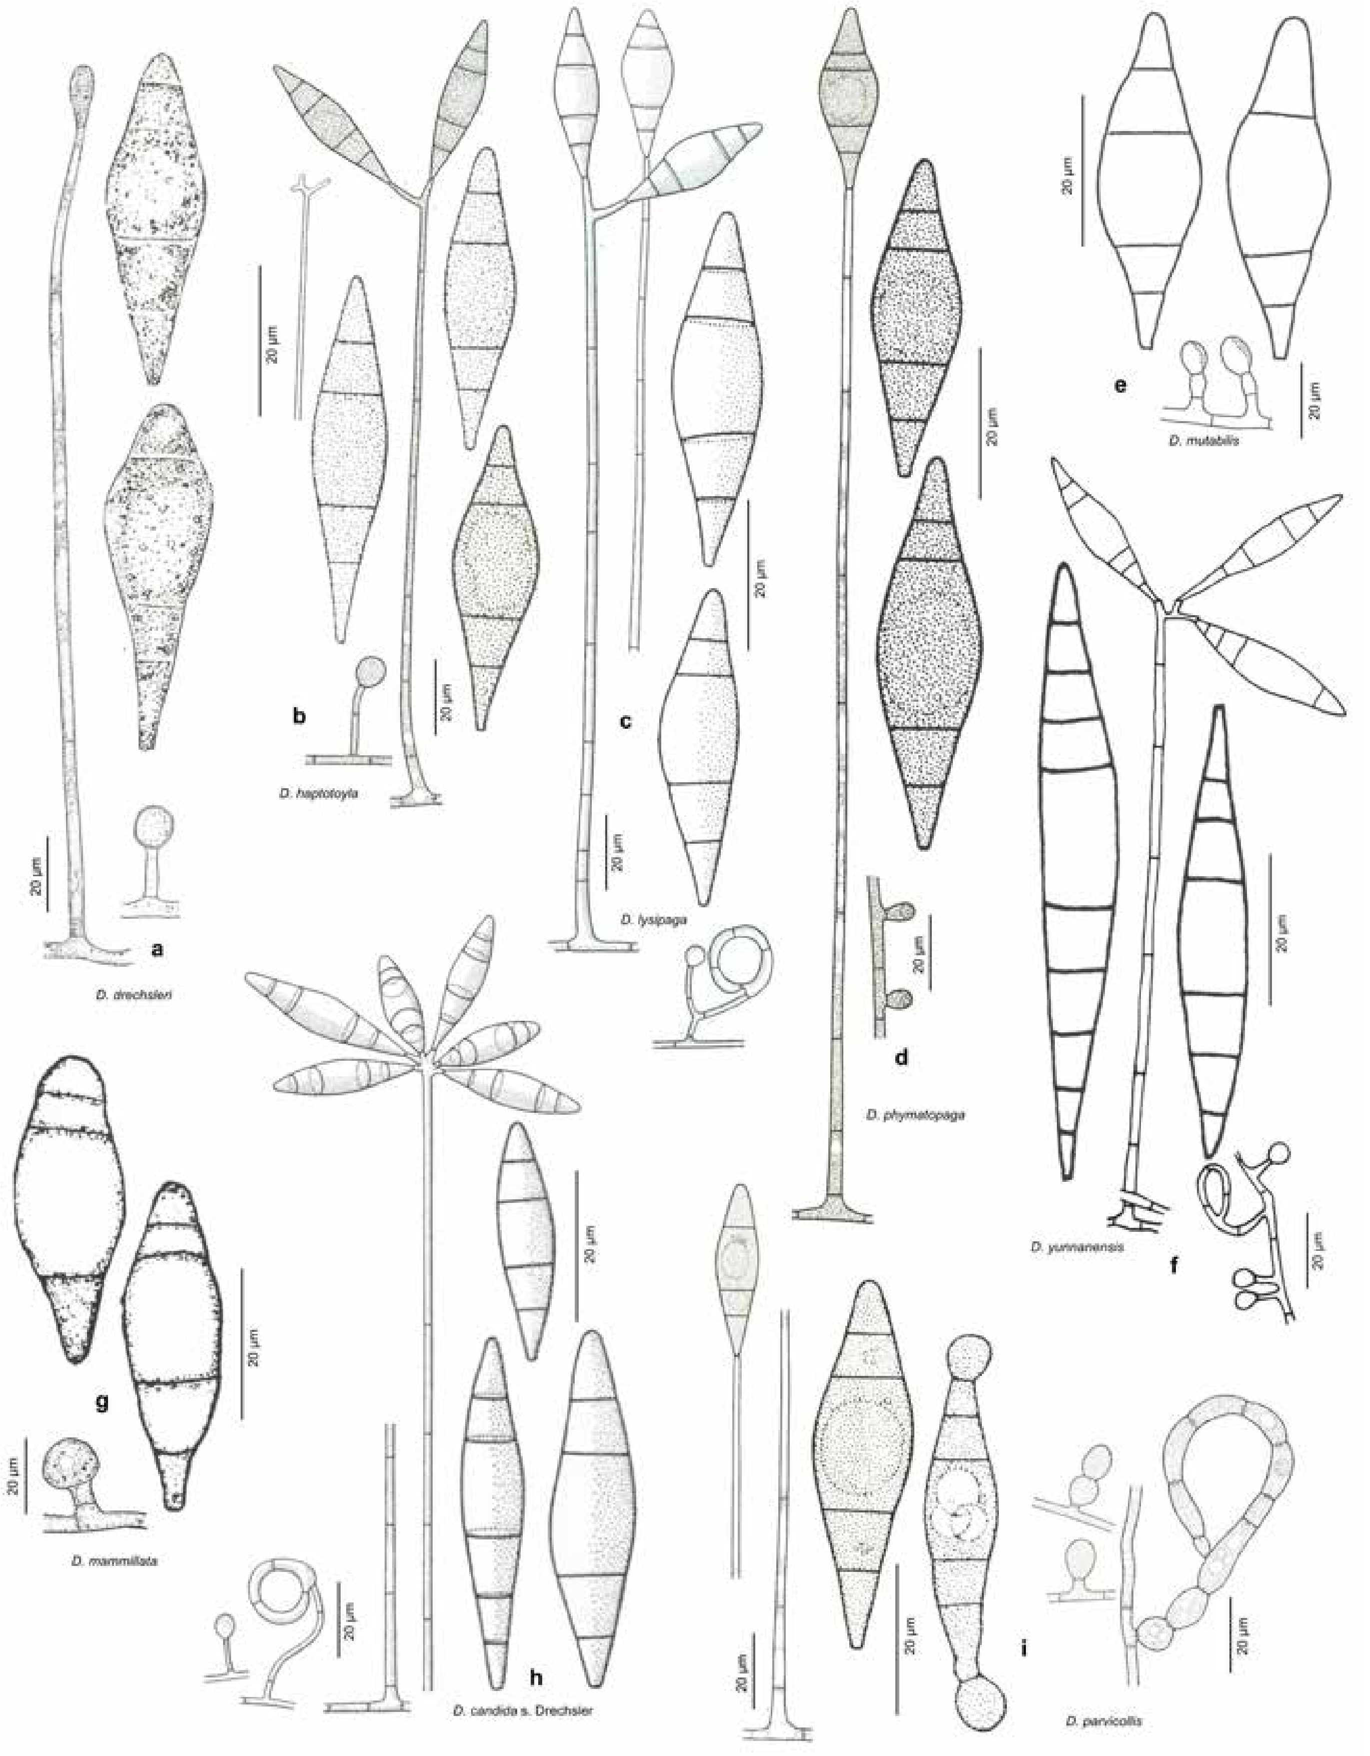

Plate 8. The accepted, hitherto known species of *Dactylellina* II (*D. candida* s. Drechsler = *D. yunnanensis* ?= *D. haptotyla*, *D. parvicollis* = *D. phymatopaga*) (conidiophores, conidia, adhesive knobs and non-constricting rings). — **a**. from Tarjan (1961), **b**. from Drechsler (1950a), **c**. from Drechsler (1937a), **d**. from Drechsler (1954), **e**. from Cooke (1969), **f**. from Zhang et al. (1996), **g**. from Dixon (1952), **h**. from Drechsler (1937a), **i**. from Drechsler (1962).

sometimes an adhesive knob at one end, along with the characters mentioned for *Dactylosporium*. This species was considered as synonymous with *D. leptospora* by Rubner (1996). Because of the illegitimacy of *Dactylosporium*, Morelet (1968) proposed

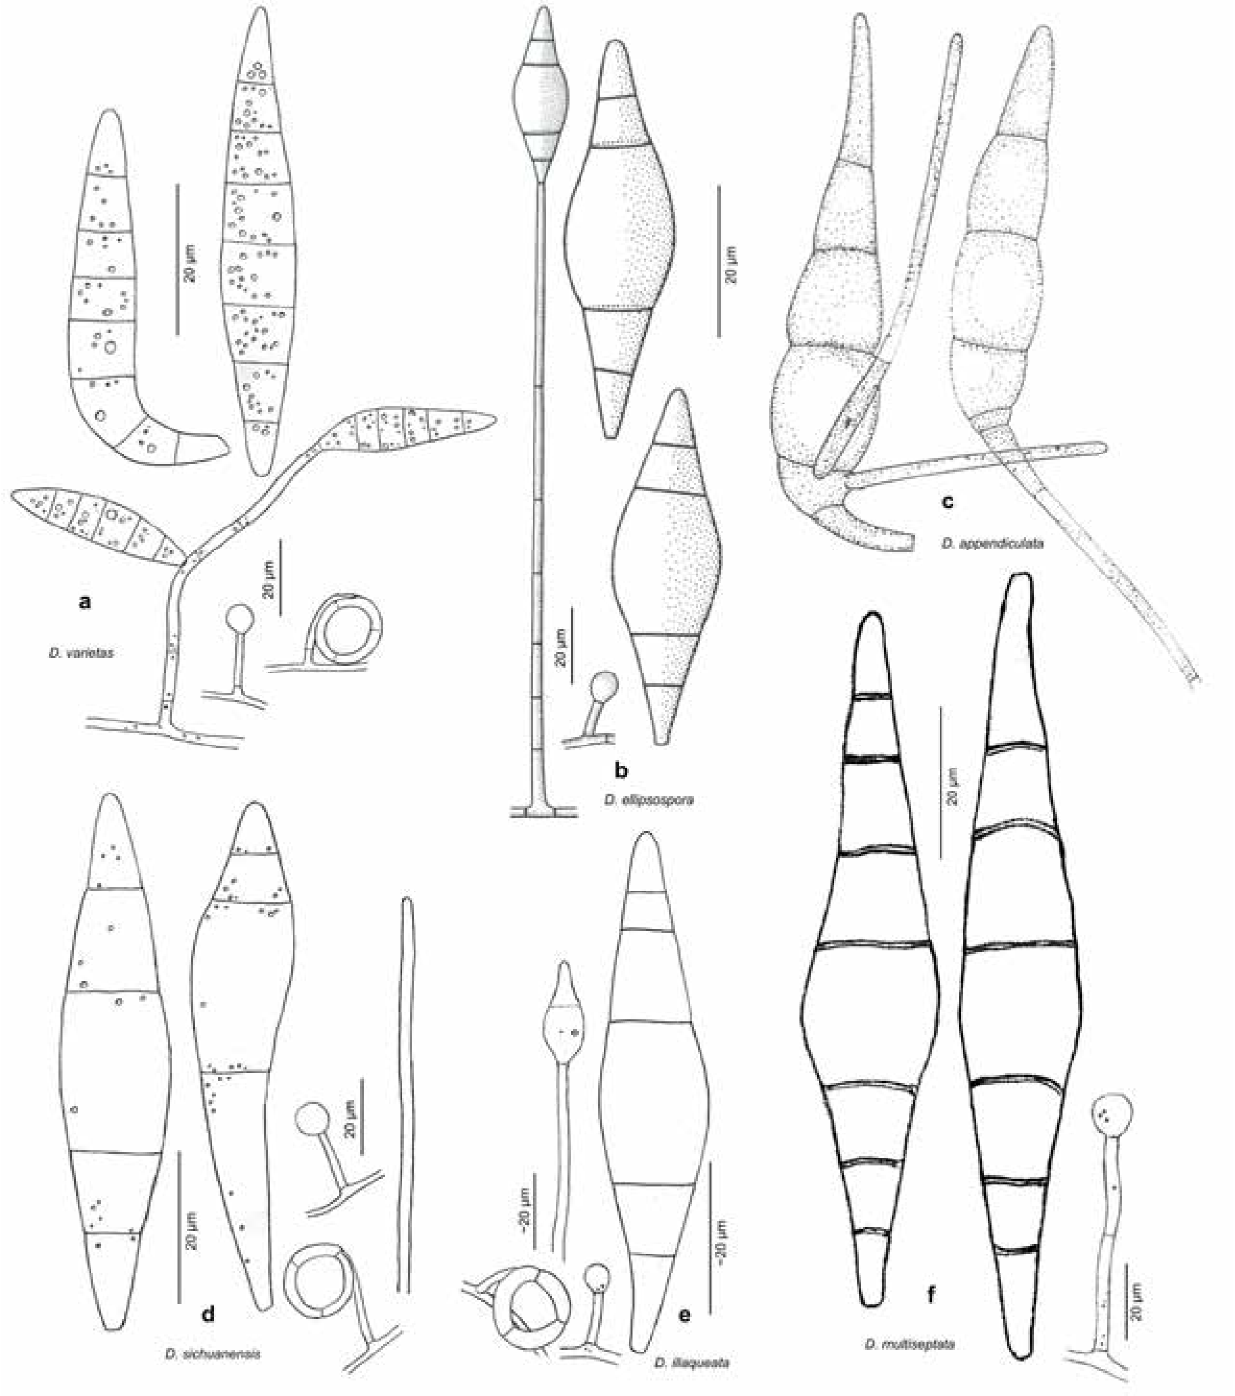

Plate 9. The accepted, hitherto known species of *Dactylellina* III (*D. sichuanensis* = *D. lysipaga*) (conidiophores, conidia, adhesive knobs and non-constricting rings). — **a**. from Li et al. (2006), **b**. from Drechsler (1937a), **c**. from Anastasiou (1964), **d**. from Li et al. (2006), **e**. from Yang et al. (2006)*, **f**. from Su et al. (2005). * = The scale is estimated in reference to the conidial size given in the description (the scale bar in the protologue seems to be 8 µm rather than 10 µm long).

the new name *Dactylellina*. In 1979, Mekhtieva considered her genus *Kafiaddinia* as a replacement name for the illegitimate *Dactylosporium*, unaware of the new name *Dactylellina* proposed by Morelet. The later synonym *Laridospora* was erected by Nawawi (1976a) with the type species *Dactylella appendiculata* based on long and filiform conidial branches that resemble appendages, also because of the semiaquatic habitat and being non-predacious when adding nematodes and rotifers (Anastasiou 1964, Nawawi 1976a). Yet, Rubner (1996: 98) obtained stalked adhesive knobs in a syntype culture of this species, but no conidia.

Dactylellina was emended by Scholler et al. (1999) who combined 16 species to the genus. Li et al. (2005) and Yang & Liu (2006) transferred further eight species to *Dactylellina*, which mainly comprise those previously assigned to *Gamsylella* by Scholler et al.

An overview of the 22 species of *Dactylellina* accepted in the new circumscription is given in Tab. 46, and Pls 7–9 (see also Tab. S9). The main characteristics are the nematode-trapping organs: stalked adhesive knobs which sometimes occur in combination with non-constricting rings, but also sessile adhesive knobs or two- to multicelled superimposed knobs or rarely adhesive columns or loops occur (*Dactylellina phymatopaga*). Conidia are hyaline, one- to multiseptate, predominantly fusoid to fusiform, formed singly or in clusters on the tip of long conidiophores. Scholler et al. (1999) listed *Kafiaddinia*, and *Laridospora* as synonyms of *Dactylellina*, and *Anulosporium* and *Dactylium* as possible synonyms. Also *Monacrosporium ullum* Kim et al. (2006) and *Arthrobotrys paucus* McCulloch (1977) with stalked adhesive knobs should be regarded as belonging to *Dactylellina*.

The genus *Anulosporium* with the single species *A. nematogenum* was described by Sherbakoff (1933) from a moist chamber culture with strawberry plants from Tennessee, with stalked adhesive knobs and non-constricting rings. The author misinterpreted the stalks as conidiophores, the rings as conidia, and the knobs as early stages of the rings. Because no authentic conidia were observed, the identity of the fungus at the species level cannot be clarified, and Rubner (1996: 36) could not classify the species in her generic system which was based on conidiophore and conidial morphology. For this reason, Scholler et al. (1999: 109) considered the genus as doubtful, although it is a clear synonym of *Dactylellina* in their classification and would have priority over that genus. However, since the specific identity of *A. nematogenum* is uncertain, the genus should be rejected (see also Baral et al. 2017b).

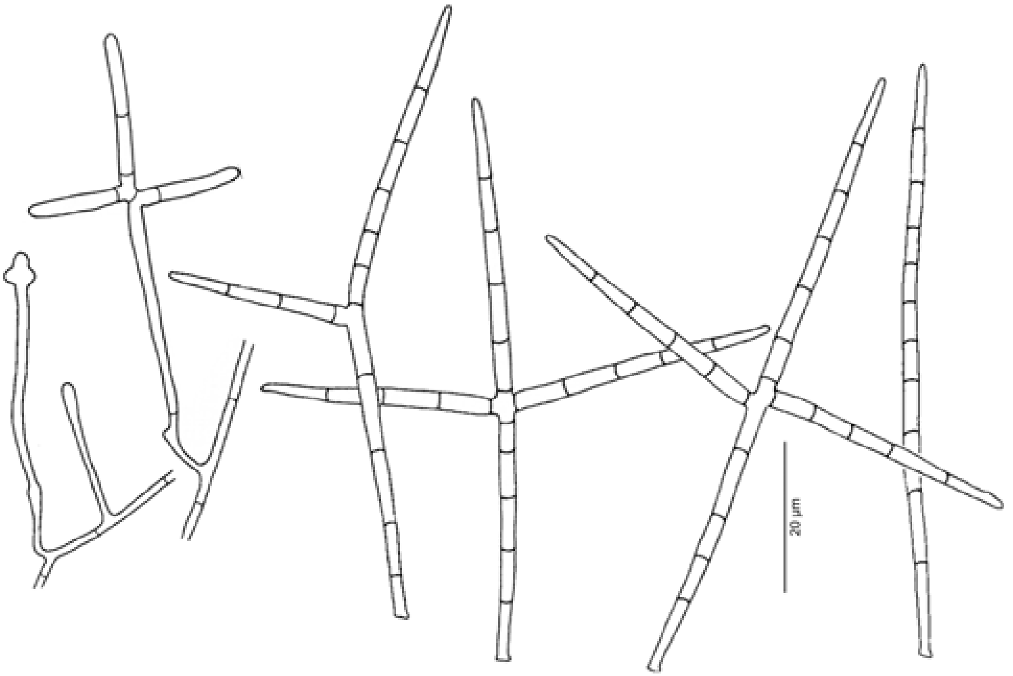

Plate 10: The single known species of the genus *Descalsia*, *D. cruciata* (conidiophores and conidia). From Roldán & Honrubia (1989).

'*Dactylellina*' *entomopaga* and '*D.*' *ferox* (Pl. 14: b–c) deviate from typical species of *Dactylellina* in adhesive knobs with voluminous mucilage which mainly trap insects. They are treated here under *Gamsylella* because of a close similarity in the trapping organ to *Orbilia alba* (Pl. 14: a), which we found to cluster in the *Gamsylella* clade.

The first connection of teleomorph and anamorph in *Dactylellina* was reported by Liu et al. (2005a): *Orbilia quercus* and *D. quercus* (both as *querci*). For two further taxa Liu (2006) reported connections to anamorphs: *O. quercus* var. *hunanensis* with *D. lysipaga* and *O. quercus* var. *hainanensis* with *D. ellipsospora*. In an abstract, Liu et al. (2002, cited in Mo et al. 2005a and Zhang & Mo 2006) reported *O. cunninghamii* as teleomorph of *Monacrosporium parvicolle*, but this refers to *O. quercus*/*D. quercus*, as B. Liu (pers. comm.) treated in that abstract his new species temporarily under those names. Zhang et al. (in prep.) described *O. apiculata* and *O. biforma* with anamorphs and teleomorphs. Species delimitation within *Dactylellina* is highly problematic, and various misidentifications and synonymies could be detected based on rDNA sequences (see p. 1584 ff.).

Dactylellina species have been collected in wet habitats like soil, decaying herbal material and wood, or on bryophytes. They prey on nematodes or arthropods and are distributed worldwide.

In the present study, *Dactylellina* was reduced to a series of section *Arthrobotrys* of *Orbilia*. New reports of connections between anamorphs and teleomorphs are given for *O. rubrovacuolata* and *O. mammillata*. The genus *Gamsylella* is accepted in a modified sense based on molecular as well as morphological reasons (see p. 235).

Descalsia A. Roldán & Honrubia – (Pl. 10)

The name of the genus refers to the mycologist Enrique Descals. Roldán & Honrubia (1989) described the only known species, *Descalsia cruciata*, a hyphomycete isolated from foam in a Spanish stream, with branched, septate conidia formed on short conidiophores. Conidia are mainly tetraradiate (┼-shaped), with a stipe and three arms, more rarely with only two arms or unbranched. Usually, the arms emerge from a single central cell, but sometimes there are two contiguous cells separated by an oblique septum (Pl. 10 left), which is a key character of the similar genus *Curucispora*. A sequence of this species was not available.

Roldán & Honrubia compared their genus with *Curucispora, Isthmotricladia* Matsush.*, Enantioptera* Descals*, Hexacladium* D.L. Olivier, and *Articulospora* Ingold.

Articulospora inflata Ingold (1944) has very similar though much larger conidia. In addition, in *Articulospora* the third and fourth arm is constricted at the point of insertion (see also under *Tridentaria*, p. 242).

In the present study we consider *Descalsia* as a possible synonym of *Orbilia*, particularly of series *Hemiorbilia*. We observed descalsia-like conidia in *O. aristata* and some related further species of series *Hemiorbilia* which closely resemble *D. cruciata* but occurred on xeric branches.

Dicranidion Harkn. – (Tab. 47, Pl. 11)

The name of the genus, which was erected for the single species *Dicranidion fragile* (Harkness 1885), refers to the shape of conidia resembling a tuning fork (from Greek 'dikranos'). Peek & Solheim (1958) emended the description of *Dicranidion* and synonymised *Pedilospora* Höhn. The genus is characterized by branched, U- to V- or Y-shaped, septate, hyaline conidia, borne on usually short conidiophores. Typically, the two arms are parallel, often touching each other, and the stipe is mostly short or ± absent. Young conidia are heart-shaped. In addition, unbranched phragmoconidia were observed in association with the bilobed conidia (Tubaki & Yokoyama, 1971, Butterfield

1973, Matsushima 1981), and also tri- or tetralobed conidia occurred (Ando & Tubaki 1984b, Bubák 1916, Butterfield 1973, Matsushima 1971, 1975, 1981, 1993). As an exception within *Dicranidion*, *D. incarnatum* forms conidia with regularly 3–8 arms (Martin 1948, as *Tetracrium incarnatum*). Conidia of *Dicranidion* with more than two arms are formed by repeated dichotomous branching (Pl. 11: a, l). In *D. fragile* and its possible synonym *D. argentinense* the conidiophores may be aggregated in sporodochia-like structures (Peek & Solheim l.c., Spegazzini 1911).

Twelve species of *Dicranidion* are tentatively accepted here (see Tab. 47), differing mainly in the length of conidial arms and stipes and in the number of septa, also in the number of arms. The two most often reported species are *D. fragile* and *D. gracile*. Peek & Solheim (1958) synonymised *Pedilospora ramularioides* Bubák with *D. fragile.* Furthermore, they assumed that *P. parasitans* Höhn. (the type species of *Pedilospora*) and *P. episphaeria* Höhn. are synonyms of *D. fragile*. Another possible synonym of that species is *D. argentinense* Speg. fide Matsushima (1981). *D. dactylopagum* deviates in extraordinarily long conidiophores, and in its ability to trap testaceous rhizopods similar as in *Brachyphoris* (= *Hyalorbilia*). The conidia of *D. macrosporum* closely resemble those of *D. amazonense* except for the higher number of septa. We consider *D. tenue* and *D. dactylopagum* as possible synonyms of *D. gracile* by reducing the number of accepted species to ten.

According to Matsushima (1987), *Dicranidion* species vary strongly in conidial morhology depending on the substrate: on the natural substrate, e.g., *D. ontariense* formed longer conidia (24–28 µm) than on PDA (14–18 µm). Likewise, Butterfield (1973) reported for *D. fragile* that different agar media caused an extensive variation in conidial morphology, for which reason he synonymised *D. inaequale* with *D. fragile*. Variation is also observed concerning diverging of the arms: in *O. xanthostigma* we observed dicranidion gracile-like conidia with strongly diverging arms only on the natural substrate, whereas in our culture the arms mostly did not diverge at all. Yet, Matsushima (1971, 1975, as *D. gracile*) and Pfister (1997: fig. 7, *Dicranidion* sp. of the gracile type) obtained conidia with diverging arms in culture. Especially if such V-shaped conidia possess an elongate 1-septate stipe, they are hardly separable from the form genus *Trinacrium*.

So far it has been known that *Dicranidion* anamorphs were connected with two *Orbilia* species. For *O. eucalypti* (as *O. coccinella*), anamorphs referable to *D. fragile* were reported by Brefeld (1891) and Liu (2006). Reports by Korf (1992) and Pfister (1997: fig. 8) under the name *O. alnea* (= *O. eucalypti*) rather resemble *D. gracile* and might relate to *O.* cf. *xanthoflexa*, *O. cejpii*, or *O. renispora*. For *O.* cf. *xanthostigma* (as *O. delicatula*) Pfister (1997) and Liu (2006) observed a dicranidion-like morph which Pfister referred to *D. gracile* and Liu to *D. tenue* (note that Pfister erroneously applied on p. 13 the epithets '*fragile*' and '*gracile*' in contradiction to what he wrote in the legends to his figs 7 and 8). Berthet (1964a) figured as anamorph of '*O. xanthostigma*' conidia (9–12 × 6–7 µm) with somewhat asymmetrical septation (i.e., without distinct basal cell) reminiscent of *D. inaequale*, and a sequence of this strain confirmed that the collection was *O. tremulae*, a species closely related to *D. inaequale.* Shao et al. (2018) reported *O. renispora* with dicranidion fragile- and *O.* (cf.) *xanthoguttulata* with dicranidion-like anamorph.

Species of *Dicranidion* were usually isolated from decaying plant material (wood, leaves etc.). The morphology of the staurosporous conidia led Pfister (1997) to speculate about an aquatic habitat. However, with the exception of *D. fissile* which was isolated from rainwater draining from intact trees (Ando & Tubaki 1984b), no reports of *Diranidion* species from water or foam came to our attention. Only for one species (*D. dactylopagum*, Drechsler 1934) the ability of capturing and

Table 47. Overview of the accepted species of the form genus *Dicranidion* (values partly corrected or completed acccording to the author's illustrations).

Species	Conidial total size [µm]	Stipe [µm]	Arms [µm]	Habitat	Reference
D. inaequale Tubaki & T. Yokoyama	9–17 × 6–7	—	~(5–)8–13.5 × 2.4–3.3	on decaying *Diaporthe*-like fungus, Japan	Berthet 1964a, Tubaki & Yokoyama, 1971

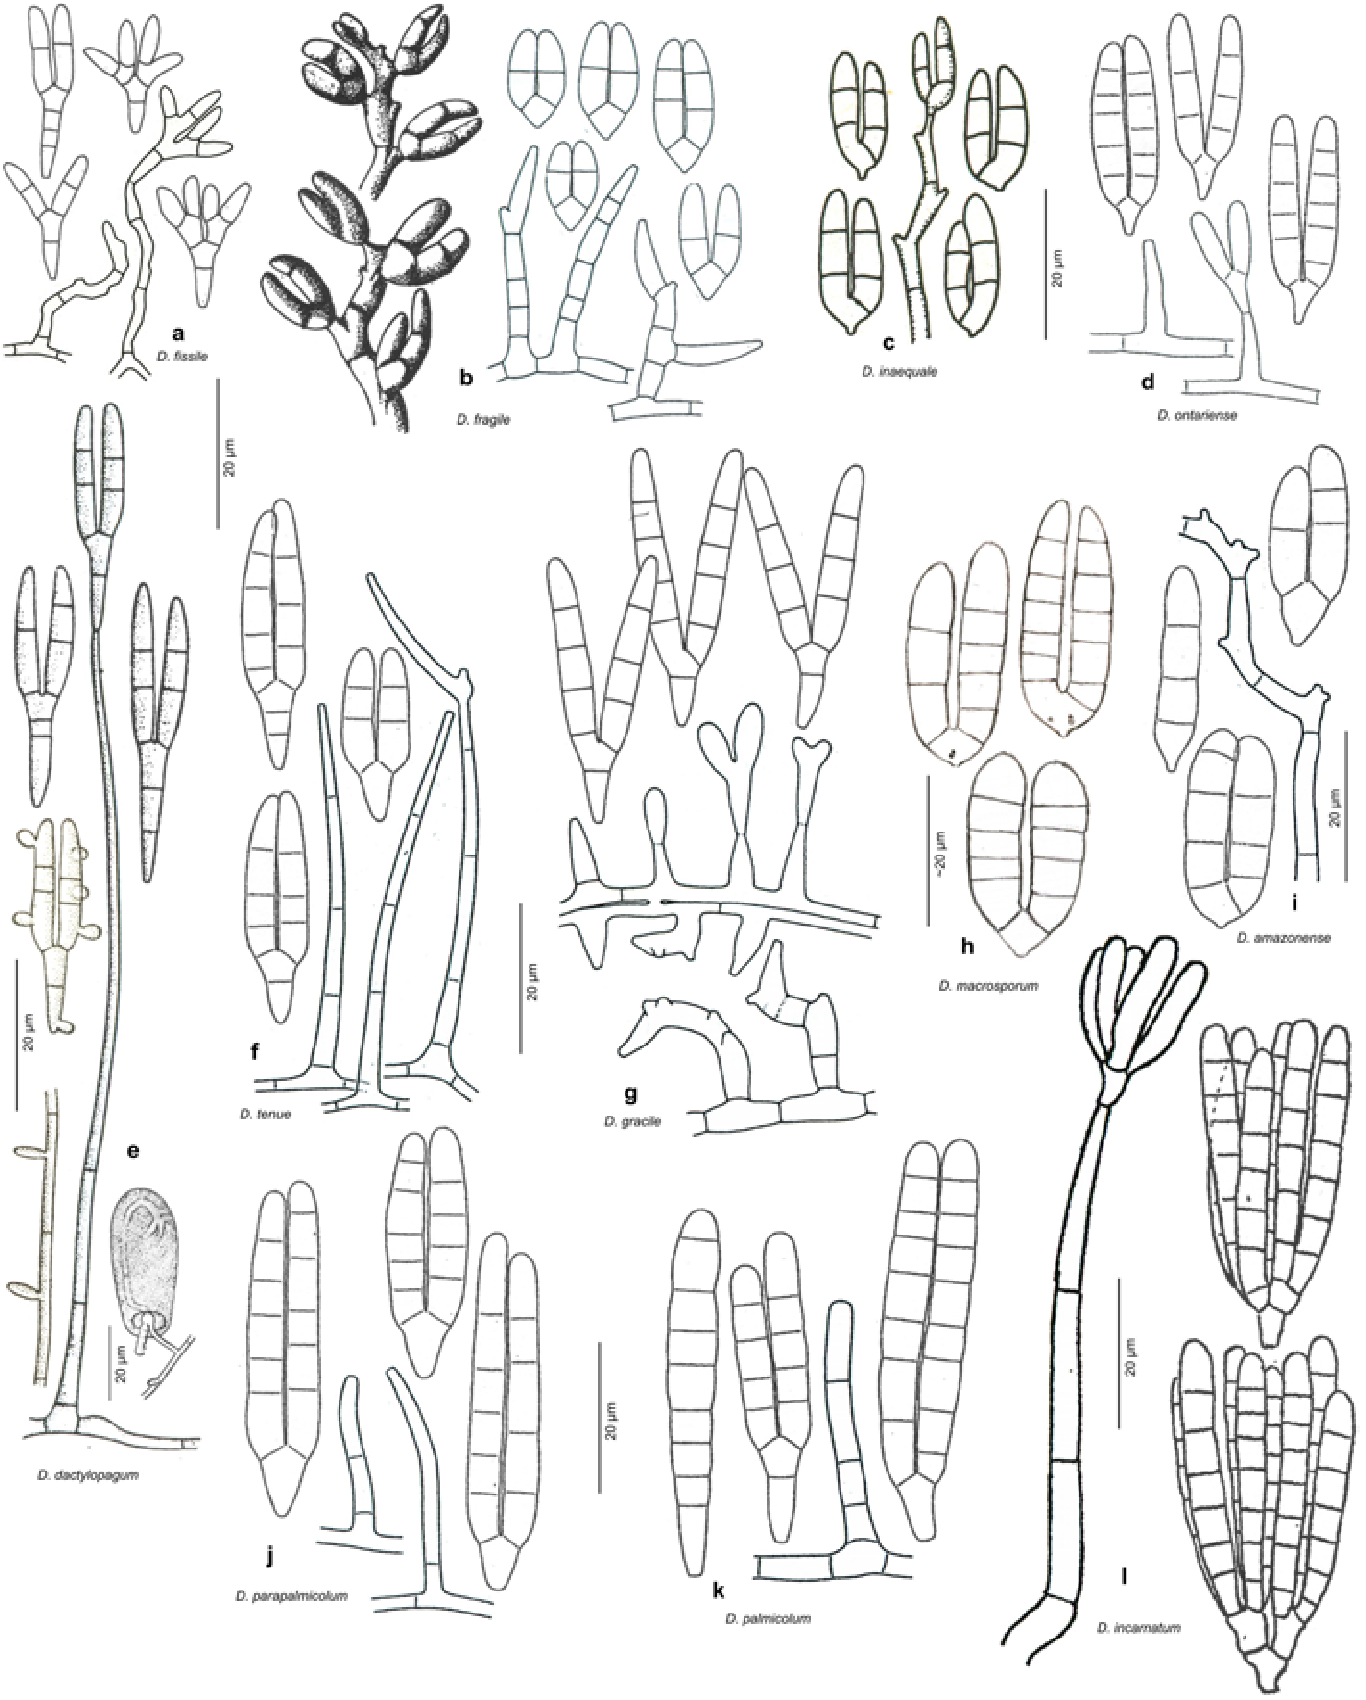

Plate 11: The accepted, hitherto known species of the form genus *Dicranidion* (conidiophores and conidia, **e**. with captured rhizopod). — **a**. from Ando & Tubaki (1984b), **b**. left from Harkness (1885), right from Matsushima (1975), **c**. from Tubaki & Yokoyama (1971), **d**. from Matsushima (1987), **e**. from Drechsler (1934), **f**. from Matsushima (1993), **g**. from Matsushima (1971), **h**. from Prasher et al. (2008, scale estimated), **i**. from Matsushima (1981), **j–k**. from Matsushima (1981), **l**. from Martin (1948).

consuming invertebrates (testaceous rhizopods) is proved. *Dicranidion* species were reported from Asia, North and South America, Oceania, and Europe.

In the present study we treat *Dicranidion* as a synonym of *Orbilia* section *Orbilia* series *Orbilia*, and the type species *D. fragile* as a synonym of *O. eucalypti*. Dicranidion-like anamorphs mainly occur in series *Orbilia*, but also in sections *Lentiformes* (*O. ovalis*) and *Aurantiorubrae* (*O. xanthoguttulata*, *O. siculispora*). Judging from their morphology alone, *D. gracile* and *D. tenue* might be conspecific. On the other hand, *O. xanthostigma*, *O. leucostigma*, *O. battenii*, *O. cejpii*, and *O. renispora* all have anamorphs referable to *D. gracile*, and the *xanthostigma-leucostigma* complex is comprised of various cryptic taxa. We accept *D. inaequale* as a species different from *D. fragile* based on its frequently asymmetrical basal cell (see also under *O. tremulae* p. 1377).

Drechslerella Subram. – (Tab. 48, Pl. 12, see also Tab. S10)

Subramanian (1964) erected *Drechslerella* for the single species *Dactylella acrochaeta* based on a long, filiform apical appendage of its conidia, and named the genus after the author of the species, Charles Drechsler. Liu and Zhang (1994) treated *Drechslerella* as a synonym of *Monacrosporium* Oudem. Scholler et al. (1999) resurrected and emended the genus, accepted 13 species, and synonymised the genera *Dactylariopsis* and *Golovinia* under *Drechslerella*. Another species, '*Monacrosporium*' *obtrulloides*, is close to *D. bembicodes* (see Castaner 1968, Rubner 1996) but was never combined in *Drechslerella*. The present survey tentatively accepts 16 species (see Tabs 48 & S10), but further, mainly cryptic taxa without a name for the anamorph are accepted in the taxonomic part of this study. The genus is characterized by three-celled constricting rings that trap nematodes by active and sudden swelling of the cells, and by hyaline, one- to four-septate, cylindric, ellipsoid, obovoid, fusiform, or top-shaped conidia, formed singly or, more rarely, in clusters at the tip of long conidiophores. Only in one species a mucilaginous sheath around the conidia is reported (*D. polybrocha*). Many of the species were found to produce microconidia (see p. 113).

Pfister (1997) reported the anamorph-teleomorph connection between *D. polybrocha* and *Patinella tenebricosa* and between *D. ?doedycoides* and *Orbilia* sp. (= *O. pilosa*). Yu et al. (2006) reported *D. brochopaga* as anamorph of *O. orientalis*, and Yu et al. (2009b) *D. yunnanensis* as anamorph of *O. ?orientalis*. Zhang et al. (2020a) described *O. tonghaiensis* and *O. pseudopolybrocha* with anamorphs and teleomorphs. Species delimitation within *Drechslerella* is very difficult, and different cryptic taxa need to be separated based mainly on their rDNA sequences, particularly in the *D. brochopaga* complex (see p. 1624).

Species of *Drechslerella* were isolated from decaying herbal material, mainly leaf mould, and from soil. They were reported from North America, Asia, and Europe. From western Australia no *Drechslerella* could be found among 37 isolates of fungi referable to section *Arthrobotrys* (Park et al. 2002).

In the present study, the genus *Drechslerella* was reduced to a series of section *Arthrobotrys*. A further connection of anamorph and teleomorph is reported for *O. naumburgensis*.

Table 48. Overview of the accepted species of *Drechslerella*. – §: larger (1–)3-septate conidia of (16–)20–32 × 5.0–6.5 µm occurred in another isolate of this species (HMAS 139691), indicating that the small conidia are microconidia.

Species	Conidial size [µm]	Number of septa	Conidial shape	Habitat	Reference
D. yunnanensis Z.F. Yu & K.Q. Zhang (≡ *Orbilia yunnanensis*)	7.8–12.9(–17.8) × 3.3–4.2(–5.5) §	(0–)1	cylindric-ellipsoid	on decaying bark of broad-leaved tree, China, nematophagous	Yu et al. 2009b

Dwayaangam Subram. – (Tab. 49, Pl. 13)

Species of *Dwayaangam* are characterized by staurosporous, hyaline conidia arising from short conidiophores, with normally four arms formed by repeated dichotomous branching (the name is derived from Sanskrit: *dwaya* = two, *angam* = branch, Subramanian 1978). Eight species have to date been validly described, with *D. quadridens* (Drechsler) Subram. as type species (see Tab. 49). *D. quadridens* was combined into

Table 49. Overview of the accepted species of the form genus *Dwayaangam*; **D. colodena* is phylogenetically related to *Arachnopezizaceae* (*Helotiales*).

Species	Total size of conidia (length × width at the widest part) [µm]	Habitat	Reference
D. yakuensis (Matsush.) Matsush.	~20–34 × 12–20	from soil and leaf mould, decaying leaves of *Machilus*, *Quercus*, *Archontophoenix*, *Fagus* bark, Australia, Japan, USA	Matsushima 1975, 1981, 1989, Kitz & Embree 1980, Ando & Tubaki 1984a
D. heterospora G.L. Barron	~36–39 × 16–22	organic debris, New Zealand, parasitic on eggs of rotifers and nematodes	Barron 1991c

D. quadridens (Drechsler) Subram. **Type species** (= *Hyalorbilia quadridens*)	~80–90 × 62–80	organic material, USA, parasitic on testaceous rhizopods (*Euglypha levis*)	Drechsler 1962
D. cornuta Descals	~50–90 × 35–70	decaying twig in water, Great Britain	Descals & Webster 1982
D. colodena Sokolski & Bérubé*	~80–110 × 80–110	needles of *Picea mariana* in water, Canada	Sokolski et al. 2006

Hyalorbilia recently (Baral et al. 2017b). Cazau et al. (1993) and Kohlmeyer et al. (1998) provided an overview of five and seven species, respectively. Several authors (e.g., Ingold 1942, 1958, 1959; Sinclair et al. 1983) have published dwayaangam-like conidia from streams in Africa and Great Britain, some of which they regarded as belonging to the genera *Tripospermum* Speg. or *Triposporina* Höhn.

Matsushima (1993) figured a collection from Ecuador under the name *D. cornuta* (Pl. 13: c) which represents, in our opinion, an undescribed species resembling *D. junci* (see also under *O. junci*, p. 767).

Drechsler (1937a, 1962) described *Triposporina aphanopaga* and *T. quadridens.* When Deighton & Pirozynski (1972) examined the type species of *Triposporina*, *T. uredinicola* Höhn., a hyperparasite with short bilabiate arms growing on uredospores of a rust fungus, they found that the conidiogenesis is annellidic, whereas it is not annellidic in Drechsler's two *Triposporina* species. Based on this and on differences in conidial shape, Subramanian (1978) erected two new genera, *Dwayaangam* with *D. quadridens* as type species, and *Tripoconidium* with *T. aphanopagum* (Drechsler) Subram. (see p. 246).

The type species of the genus *Retiarius*, *R. superficiaris* D.L. Olivier (Pl. 20: a) has dwayaangam-like conidia though the number of arms varies

The conidia of *Dwayaangam* normally branch twice dichotomously at the tip of the main axis, thus resulting in four arms, but this feature varies in some species. *D. heterospora* (Barron 1991c) and *D. yakuensis* (Matsushima 1981, Ando & Tubaki 1984a) show intraspecific variation in producing morphologically different types of conidia: typical conidia with four arms (dwayaangam-like), conidia with two arms (trinacrium-like), and unbranched phragmoconidia (Barron 1991c). *D. cornuta* develops up to eight arms (Descals & Webster 1982), and *D. colodena* has usually six arms (Sokolski et al. 2006). That the limits between the form genera *Dwayaangam* and *Trinacrium* are rather artificial is also shown in the reports of Drechsler (1938) and Ando (1992) (see under *Trinacrium*, p. 243–245).

Only for one *Dwayaangam* species, *D. junci*, an *Orbilia* teleomorph was reported up to now: *O. junci* (Kohlmeyer et al. 1998). For *D. colodena* (with 5–6 arms) Sokolski et al. (2006) demonstrated by molecular analysis that this species is phylogenetically remotely related to *Arachnopeziza* (*Helotiales*), although conidial morphology strongly resembles other species of *Dwayaangam*, like *D. dichotoma*. Possibly, further species of the form genus *Dwayaangam* will turn out to belong to classes other than *Orbiliomycetes*.

Matsushima (1993) mentioned a similarity to *Hydrometrospora* Gönczöl & Révay (1984). In the single species *H. symmetrica* Gönczöl & Révay a large H-shaped part of the conidium emerges laterally from the main axis, whereas in *Dwayaangam* the apex of the main axis divides dichotomously. *Monogrammia* F. Stevens (1918) with the single species *M. miconiae* F. Stevens resembles *Dwayaangam* but was considered to be the anamorph of *Paranectriella miconiae* (F. Stevens) Rossman (*Pleosporales*), with which it was found to co-occur on the natural substrate (Rossman 1987).

Some species of *Dwayaangam* were isolated from water or foam, some from decaying plant material. Because of the staurosporous form of the conidia, the habitat of *D. junci* at the sea shore, and the occurrence of other *Dwayaangam* species in freshwater, Kohlmeyer et al. (1998) considered this species as an Ingoldian fungus adapted to water dispersal. Yet, later research (Kohlmeyer & Volkmann-Kohlmeyer 2001) indicated that *O. junci* forms its conidia on recently dead dry tips of standing culms, where later the apothecia occur (see p. 767). Gönczöl & Révay (2006) reported nine different species (*D. cornuta*, *D. dichotoma*, *D. yakuensis*, and *Dwayaangam* spp. 1–6) from rainwater collected from different trees. *D. heterospora* was found to grow parasitically on eggs of rotifers and nematodes (Barron 1991c) and *D. quadridens* as predacious on a rhizopod (Drechsler 1962). *Dwayaangam* species have been collected in North and South America, Asia, Africa, New Zealand, and Europe.

In the present study we consider the genus *Dwayaangam* in a very narrow sense, restricted to its type species *D. quadridens*, as synonym of *Hyalorbilia* (see below). We obtained dwayaangam-like anamorphs in pure culture of three species in two different sections of *Orbilia* (*O. aristata* and *O. subvinosa* in section *Hemiorbilia*, *O. albidorosea* in section *Aurantiorubrae*). But also *O. subaristata*, *O. flagellispora*, and *O. arachnovinosa* (section *Hemiorbilia*) are presumably connected to dwayaangam-like anamorphs. In section *Hemiorbilia* the dwayaangam-like conidia frequently occur mixed with trinacrium- and descalsia-like conidia. All this indicates that *Dwayaangam* is a form genus when defined merely by conidial shape. Actually, the predacious capability of the type species of *Dwayaangam*, *D. quadridens*, points to a relationship with *Hyalorbilia*, in which rhizopod traps occur in *Brachyphoris tenuifusaria* and '*Dactylella*' *passalopaga*

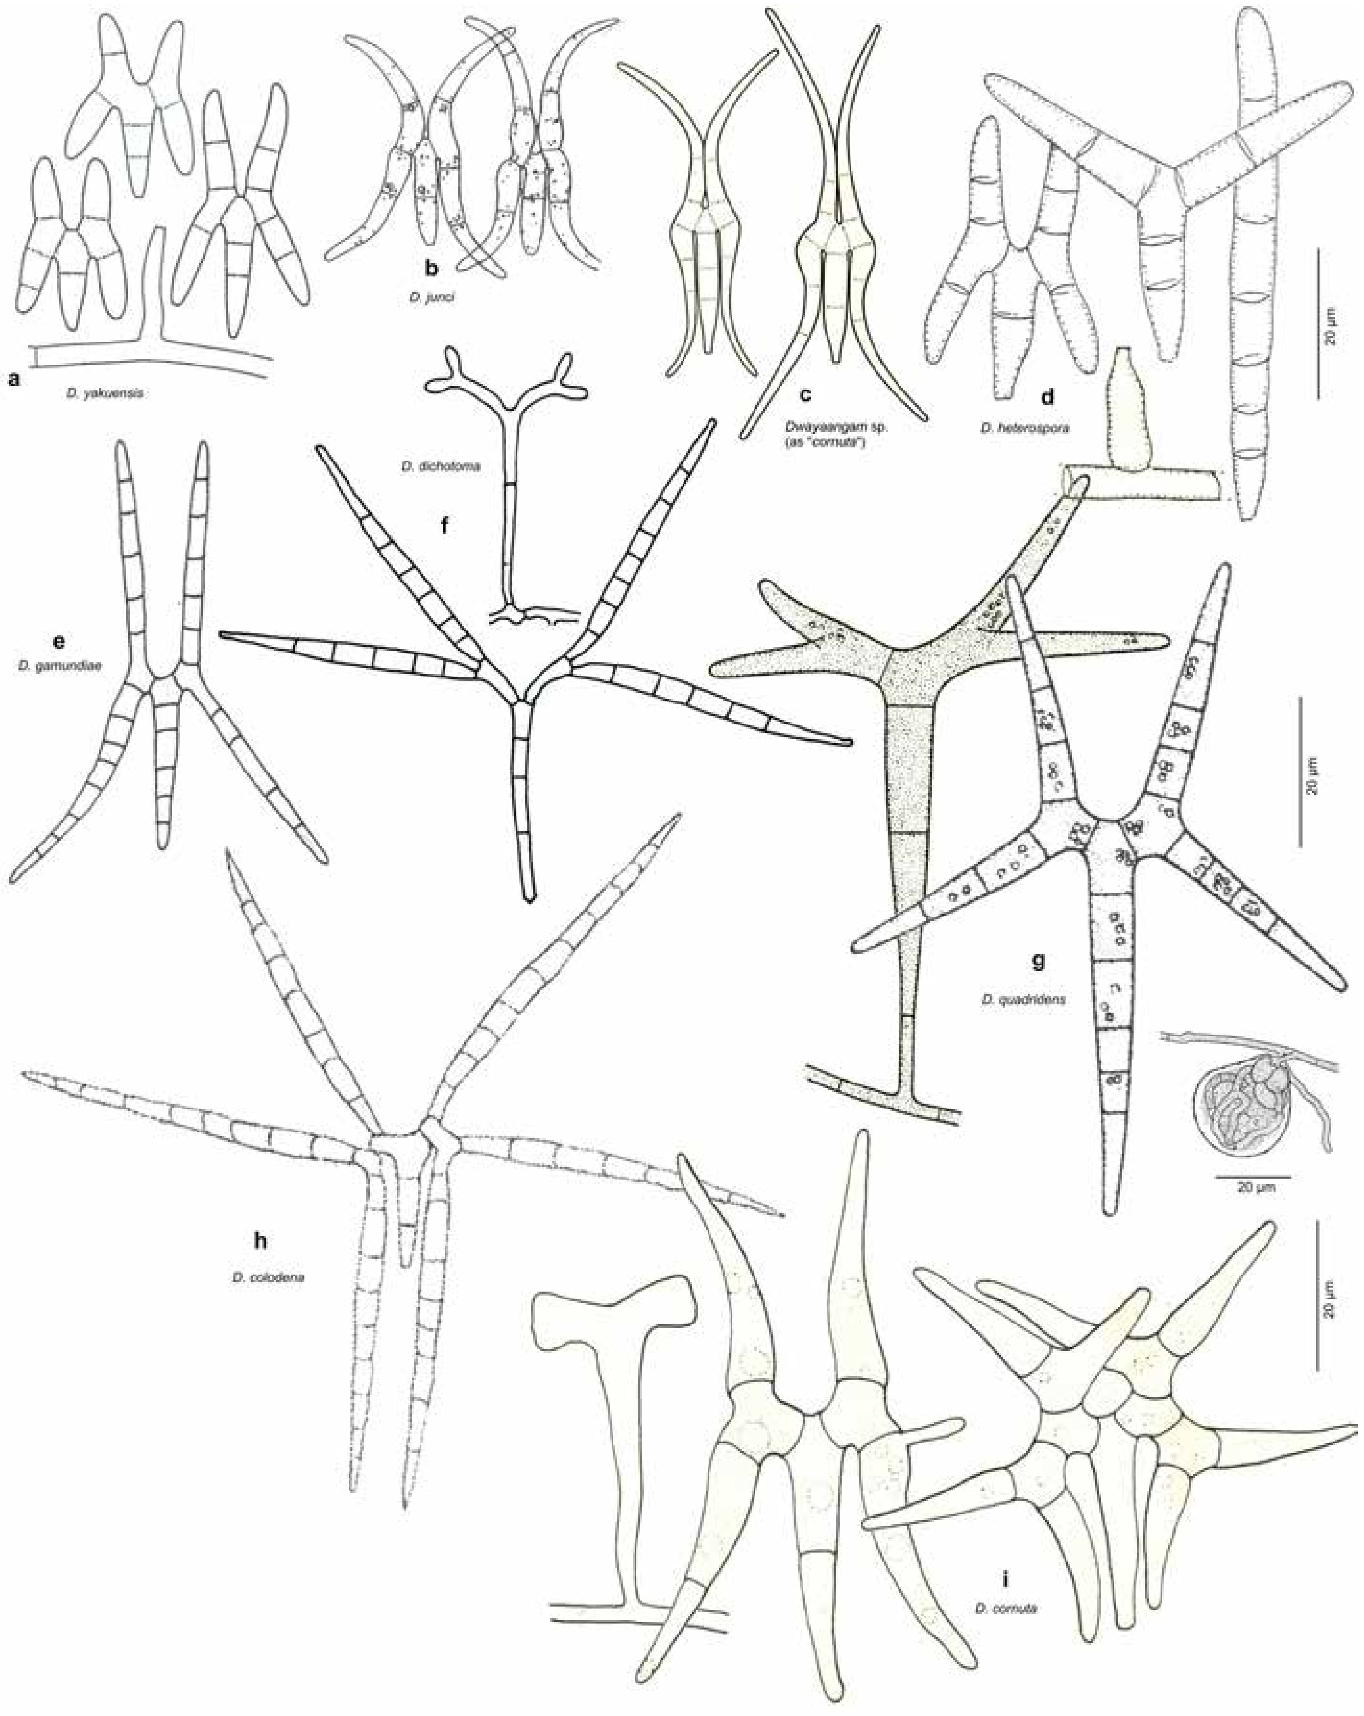

Plate 13. The accepted, hitherto known species of the form genus *Dwayaangam* (conidiophores and conidia, **g**. trapped rhizopod). — **a**. from Matsushima (1975), **b**. from Kohlmeyer et al. (1998), **c**. from Matsushima (1993), **d**. from Barron (1991c), **e**. from Cazau et al. (1993), **f**. from Nawawi (1985a), **g**. from Drechsler (1962), **h**. from Sokolski et al. (2006), **i**. from Descals & Webster (1982).

(see under *Brachyphoris*, p. 218). Moreover, the droplets in the rather broad cells of the living conidia of *D. quadridens* as drawn by Drechsler should be of non-lipidic nature and point to a relationship with *Hyalorbilia*, in which these droplets were found to be characteristic and branched conidia occur in some species.

Gamsylella M. Scholler, Hagedorn & A. Rubner – (Tab. 50, Pl. 14, see also Tab. S11)

This genus was erected by Scholler et al. (1999) for six species that trap nematodes by means of sessile adhesive knobs or two- to multicelled columns which tend to form arches or scalariform bridges: *G. arcuata* (type species), *G. gephyropaga*, *G. lobata*, *G. parvicollis*, *G. phymatopaga*, and *G. robusta*. According to Rubner (1996) and Scholler et al. (1999), '*Dactylella*' *cionopaga* is a synonym of *G. gephyropaga*, but this synonymy is questioned by molecular data. The generic name was chosen in honour of the famous mycologist Walter Gams.

The circumscription of the genus is problematic because of a high diversity in the trapping organs. The limits between sessile and stalked adhesive knobs are gradual, and strong variation in the constriction of sessile knobs and columns complicate their classification. As a consequence, trapping organs with a strong constriction, i. e., globose sessile knobs that occur one above another (Fig. 106: h, i), could be treated as a modification of either stalked adhesive knobs (by proliferation) or adhesive columns. One species (*G./D. parvicollis*, Pl. 8: i) forms different types of trapping organs, some of which are reminiscent of *Gamsylella* and others of *Dactylellina*. Scholler et al. (l.c.) placed it in *Gamsylella* because of sessile adhesive knobs that proliferate to form adhesive columns of roundish cells similar to *G. lobata*, or adhesive arches of elongate cells with only slight constrictions at the septa similar as in *G. arcuata*. However, *D. parvicollis* predominantly forms very short- to long-stalked adhesive knobs (see Drechsler 1962, pls 4–5; Jarowaja 1968a; Rubner 1996: fig. 44). This feature was not mentioned when Scholler et al. placed *D. parvicollis* in *Gamsylella*, whereas Yang et al. (2007: fig. 3), who classified it in *Dactylellina*, listed for this species only stalked, sessile, and superimposed (proliferating) knobs in their table of trapping organ types, but no adhesive columns. For more details about the different phylogenetic concepts of the genus see under series *Gamsylella*, p. 1610 ff.

No teleomorph is known for any of the anamorphic states here accepted in *Gamsylella*, with exception of '*Dactylella*' *alba*, described by Yu et al. (2009a) as anamorph of *O. alba* (Pl. 14: a). The authors misinterpreted the stalked adhesive knobs as a new type of spores similar to chlamydospores, and placed the species in *Dactylella*, although their phylogenetic analysis rather suggested placement in *Dactylellina*. In their elongate shape the heads of the adhesive knobs resemble those of '*Dactylellina*' *entomopaga* (Pl. 14: b) which, besides '*D.*' *ferox* (Pl. 14: c), deviates from all other species recognized in *Dactylellina* in a thick adhesive mucilage around the heads. Adhesive knobs with a thick mucilage represent an adaptation to the trapping of small arthropods. We observed this type of adhesive knob in two European collections referred to *O. alba*, and the presence of larger amounts of gel could also be demonstrated for the Chinese type of *Dactylella alba* (see p. 1615).

Gamsylella species have been collected in moist habitats like soil, decaying herbal material and wood, or on bryophytes. They are predatory by trapping nematodes as a rule; Drechsler observed once in *G. gephyropaga* also captured rhizopods. Abiko et al. (2005) reported mites and rotifers as additional prey of that species. Our new concept includes the capture of arthropods. *Gamsylella* species are probably worldwide distributed.

In the present study we reduce the genus *Gamsylella* with eight accepted species (Tabs 50 & S11) to a series of section *Arthrobotrys* and retain it as separate from series *Dactylellina*. The previous circumscription is changed, with *Dactylellina phymatopaga* (= *D. parvicollis*) and *Orbilia quercus* remaining in series *Dactylellina*, and with '*D.*' *entomopaga* and '*D.*' *ferox* newly included in series *Gamsylella*. This concept is, however, predominantly based on molecular results, which place also *O. alba* and *O. anigozanthi* (the latter without anamorph) in this clade. The arthropod-trapping taxa might deserve a separate series because of their special trapping organs.

Haptocara Drechsler – (Pl. 53)

The nematophagous genus *Haptocara* was erected by Drechsler (1975) with *H. latirostrum* as type species. The hitherto only described species is characterized by broad, 2–4-septate conidia with a hyphal, filiform, subapically emerging nonseptate appendage and a later developing subglobose adhesive knob at the apex (see Pl. 53: 3). Molecular data do not exist and a connection to a teleomorph is unknown. Drechsler (1975) demonstrated that not only the conidial knobs are able to capture

Table 50. Overview of the accepted species of *Gamsylella*.

Species	Conidial size [µm]	Number of septa	Conidial shape	Habitat	Reference
'*Dactylellina*' *ferox* (Onofri & Tosi) M. Scholler et al.	(13–)15–18(–24.5) × (5–)6–8(–9)	1	obovoidal to clavate	on mosses (*Bryum algens*, *Ceratodon purpureus*), continental Antarctica, predatory on springtails	Onofri & Tosi 1992
'*Dactylella*' *alba* Z.F. Yu & K.Q. Zhang (= *Orbilia alba*)	18–26(–34) × 5–7(–8)	1(–3)	cylindric (-ellipsoid)	on decaying bark of a broad-leaved tree, China, capturing springtails, flies, mites	Yu et al. 2009a, present study
'*Dactylellina*' *entomopaga* (Drechsler) M. Scholler et al.	15–28 × 4.5–5.5	1	cylindrical to clavate	decaying roots of *Polygonum pennsylvanicum*, USA, capturing springtails (and nematodes)	Drechsler 1944b
G. arcuata (Scheuer & J. Webster) M. Scholler et al. **Type species**	30–45 × 4.5–6	3	fusiform	decaying leaves of *Ammophila arenaria*, UK, nematophagous	Scheuer & Webster 1990
G. gephyropaga (Drechsler) M. Scholler et al.	27–46 × 16–21	(2–)3–4	top-shaped, fusiform	decaying leaves and wood, from soil, Germany, Sweden, Italy, Spain, UK, USA, nematodes, mites, rotifers, rhizopods	Drechsler 1937a, Rubner 1996, Abiko et al. 2005*
G. lobata (Dudd.) M. Scholler et al.	38–55 × 8–12	3	cylindrical to clavate	from *Dicranella heteromalla*, rabbit dung, Germany, UK, nematophagous	Duddington 1951b, Rubner 1996
G. cionopaga (Drechsler) Yang et al.	35–60 × 13–21	(2–)3–4(–6)	fusiform	decaying culms of *Triticum aestivum*, USA, nematophagous	Drechsler 1950a
G. robusta (J.S. McCulloch) M. Scholler et al.	68–85 × 20–30	3–5	fusiform	from soil, Australia, nematophagous	McCulloch 1977, Rubner 1996

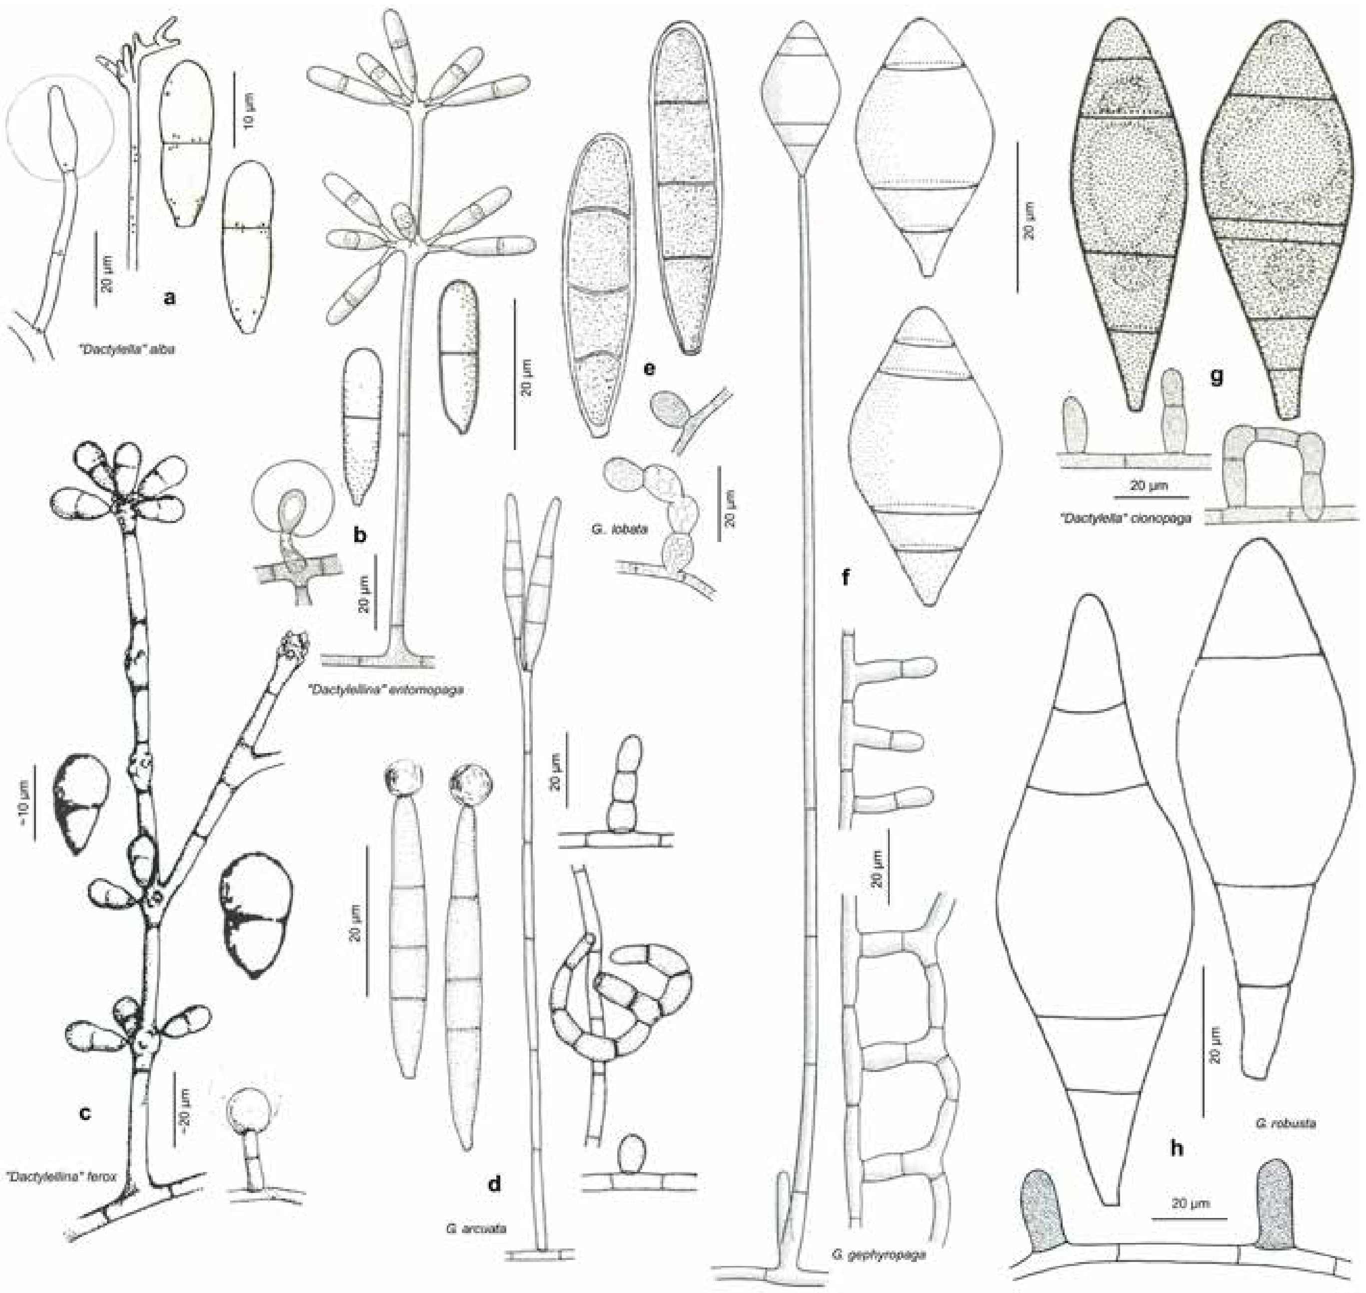

Plate 14. The accepted, hitherto known species of *Gamsylella* (conidiophores, conidia and trapping organs). — **a**. from Yu et al. (2009a) but adhesive knob from H.B. 9051a, **b**. from Drechsler (1944b), **c**. from Onofri & Tosi (1992), **d**. from Scheuer & Webster (1990), **e**. from Duddington (1951b), **f**. from Drechsler (1937a), **g**. from Drechsler (1950a), **h**. left conidium from Rubner (1996), right conidium and adhesive peg-like knobs from McCulloch (1977). The scale for conidia and conidiophores of *Dactylellina ferox* in Onofri & Tosi's (1992) illustration is modified by the factor ~1.45 in order to match the measurements given in their description.

nematodes with their adhesive surface, but also smaller knobs formed on short lateral branches of the mycelium.

In the present study, *Haptocara* is considered as probably orbiliaceous and closely related to *Lecophagus* based on very similar trapping organs and broad mycelial hyphae, also because of similar cubical bodies observed in an unnamed further member of *Haptocara* (see Pl. 53: 1–2).

Helicoon Morgan – (Pl. 15)

The genus was erected by Morgan (1892) with *H. sessile* Morgan as type species. The main characteristics of the genus in later circumscriptions are filiform, multiseptate, strongly coiled (helicosporous), barrel-shaped, hyaline to fuscous conidia, coiled more tightly towards the poles, produced on short to long, hyaline to brown conidiophores (Goos et al. 1986). Moore (1955) presented in his key to *Helicoon* nine and Goos et al. (l.c.) eight species. Among these, *H. sessile* and *H. farinosum* Linder deviate from the others in hyaline conidia and conidiophores.

Voglmayr (1994, 2000) found that the sense of rotation of the helicoid conidia in *Helicoon* represents a species-specific marker. As an exception, however, conidia of *H. sessile* were twisted either like a left-hand or a right-hand thread, and for a given strain this feature was consistent on the natural substrate as well as in culture (Pl. 15: b). Therefore, he assumed that two species are involved, according to the sense of rotation. Regrettably, molecular data could only be gained from a single strain which showed left-handed rotation. Reports in the older

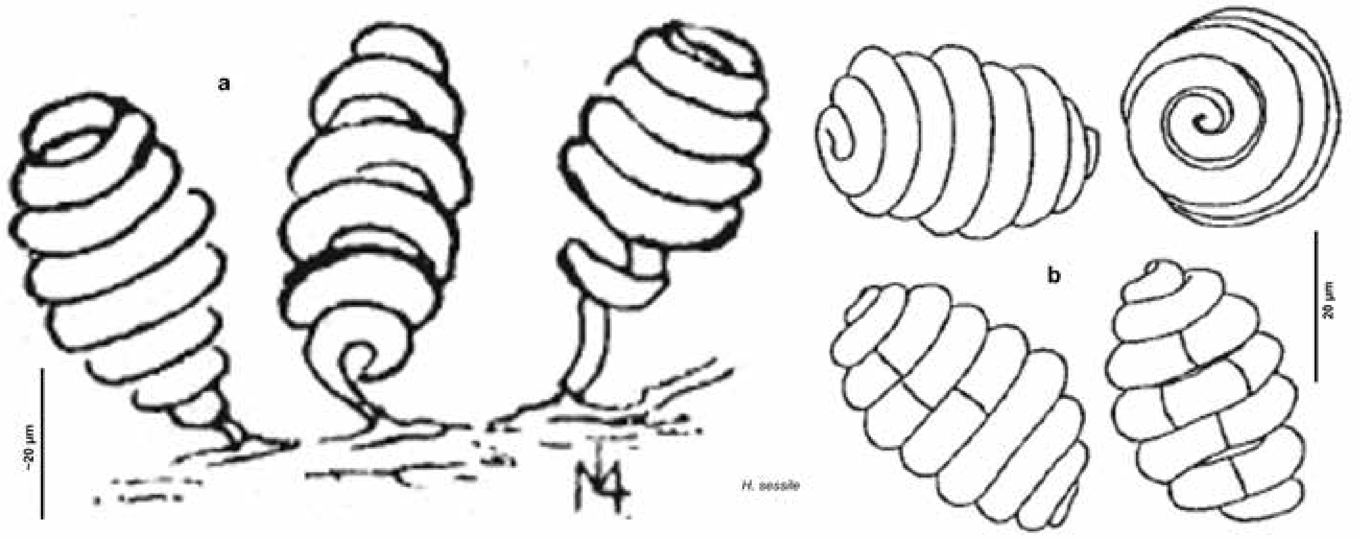

Plate 15. *Helicoon sessile* (conidia and conidiophores). — **a**. conidia twisted as right-handed helix (from Morgan 1892, type, but see in text), **b**. conidia from two different collections from the same geographic area, the above twisted left-handed, the below right-handed (from Voglmayr 2000).

literature usually do not stress this character, however, and illustrations may be misleading. For instance, Morgan (1892) figured the conidia of *H. sessile* as a right-handed helix but Voglmayr (1994) found them left-handed in the type material. Therefore, he assumed that the conidia in Morgan's sketch might have changed their chirality during reproduction.

Genera with similarly coiled conidia, such as *Helicoma* Corda, *Helicomyces* Link, and *Helicosporium* Nees, are anamorphs of *Tubeufia* Penz. & Sacc. and allied genera in the *Tubeufiaceae*, *Dothideomycetes* (Goos 1987). Most species of *Helicodendron* Peyronel so far sequenced belong to the *Leotiomycetes* (Tsui & Berbee 2006), although conidial morphology sometimes closely matches that of *Helicoon*, particularly *H. sessile*.

Tsui & Berbee (2006) found that *Helicoon* species, despite their distinctive, barrel-shaped conidia, have evolved polyphyletically in different ascomycete orders. They analysed three species and found in their phylogram *H. fuscosporum* Linder in a clade with *Botryosphaeria rhodina* Berk. & M.A. Curtis (*Dothideomycetes*), *H. gigantisporum* Goh & K.D. Hyde within the *Tubeufiaceae* (*Dothideomycetes*), and *H. richonis* (Boud.) Linder within the *Pleosporales*. *H. farinosum* was found to be the anamorph of *Ascotaiwania hughesii* Fallah, J.L. Crane & Shearer in the *Sordariomycetes* (Fallah et al. 1999). The type species *H. sessile* was not studied, however. Tsui & Berbee refer to Pfister (1997) who found *H. sessile* to be the anamorph of *Orbilia luteorubella*. However, Pfister's (1997) result was doubted by Hagedorn & Scholler (1999), because Pfister's sequences fall in the *Hypocreales*.

Helicoid conidia that form barrel-shaped bodies trap air in their interior which enables them to float on the water surface (aero-aquatic hyphomycetes). The mentioned molecular results show that such conidia, which represent an adaptation to dispersal in aquatic environments, arose convergently from very different classes in the *Ascomycota* (Tsui & Berbee l.c.).

In the present study, Pfister's finding of *H. sessile* as anamorph of *O. luteorubella* in North America is affirmed by our European and a Chinese ascospore isolate of *O. luteorubella* which also produced *H. sessile*. This indicates that Pfister's sequences belong to a hypocrealean contaminant (see p. 976). Among the known species of *Helicoon*, only the type species is connected to *Orbiliomycetes*, to the present knowledge, but a more simplified conidial type with just one turn occurs in the closely related *O. sarraziniana*. The conidia of *H. sessile* measure 30–59 × 17–30 µm, with 4–16 turns, and records are known from North America, Europe and Asia, on periodically submerged leaves and wood, mainly at standing water bodies.

The genus *Helicoon* is reduced here to a series of *Orbilia*, which belongs together with the closely related series *Pseudotripoconidium* to section *Helicoon*. Series *Helicoon* includes also closely related taxa with anguillospora-like anamorphs.

Lecophagus M.W. Dick – (Tab. 51, Pl. 16)

When investigating the systematic position of the rotifer-trapping *Zoophagus insidians* Sommerst. (*Zoopagales*), Dick (1990) stated that two distinct fungi were reported under this binomial. When studying an isolate deposited by H.C. Whisler

Table 51. Overview of the accepted species of *Lecophagus*.

Species	Conidial size [µm]	Number of septa	Habitat	Reference
L. navicularis (Tzean & G.L. Barron) M.W. Dick	28–34 × 6–9	(2–)3	from old manure, Ontario (Canada), predatory on bdelloid rotifers	Tzean & Barron 1983
L. muscicola (G.L. Barron et al.) Tanabe et al. (= *L. fasciculatus*) **Type species**	125–200 × 6.2–11 73–145 × 6–8 112.5–135 × 7.5–8.7	9–11 4–11 ~8	from organic debris or mossy soil in forests, water-filled tree-holes, New Zea-land, Japan, Hungary, capturing tardigrades and bdelloid or ploimoid rotifers	Barron et al. 1990 Dick 1990 (as *L. fasciculatus*) Magyar 2006
L. longisporus (G.L. Barron et al.) Tanabe et al.	125–228 × 8.5–10	(9–)10	from mossy soil, New Zealand, Ontario (Canada), capturing tardigrades and bdelloid rotifers	Barron et al. 1990
L. vermicola D. Magyar et al.	(45–)50–80(–86) × (8–)10.5–16.5(–18)	(3–)7(–8)	from xeric bark, Luxembourg, France, Hungary, capturing nematodes	Magyar et al. 2016

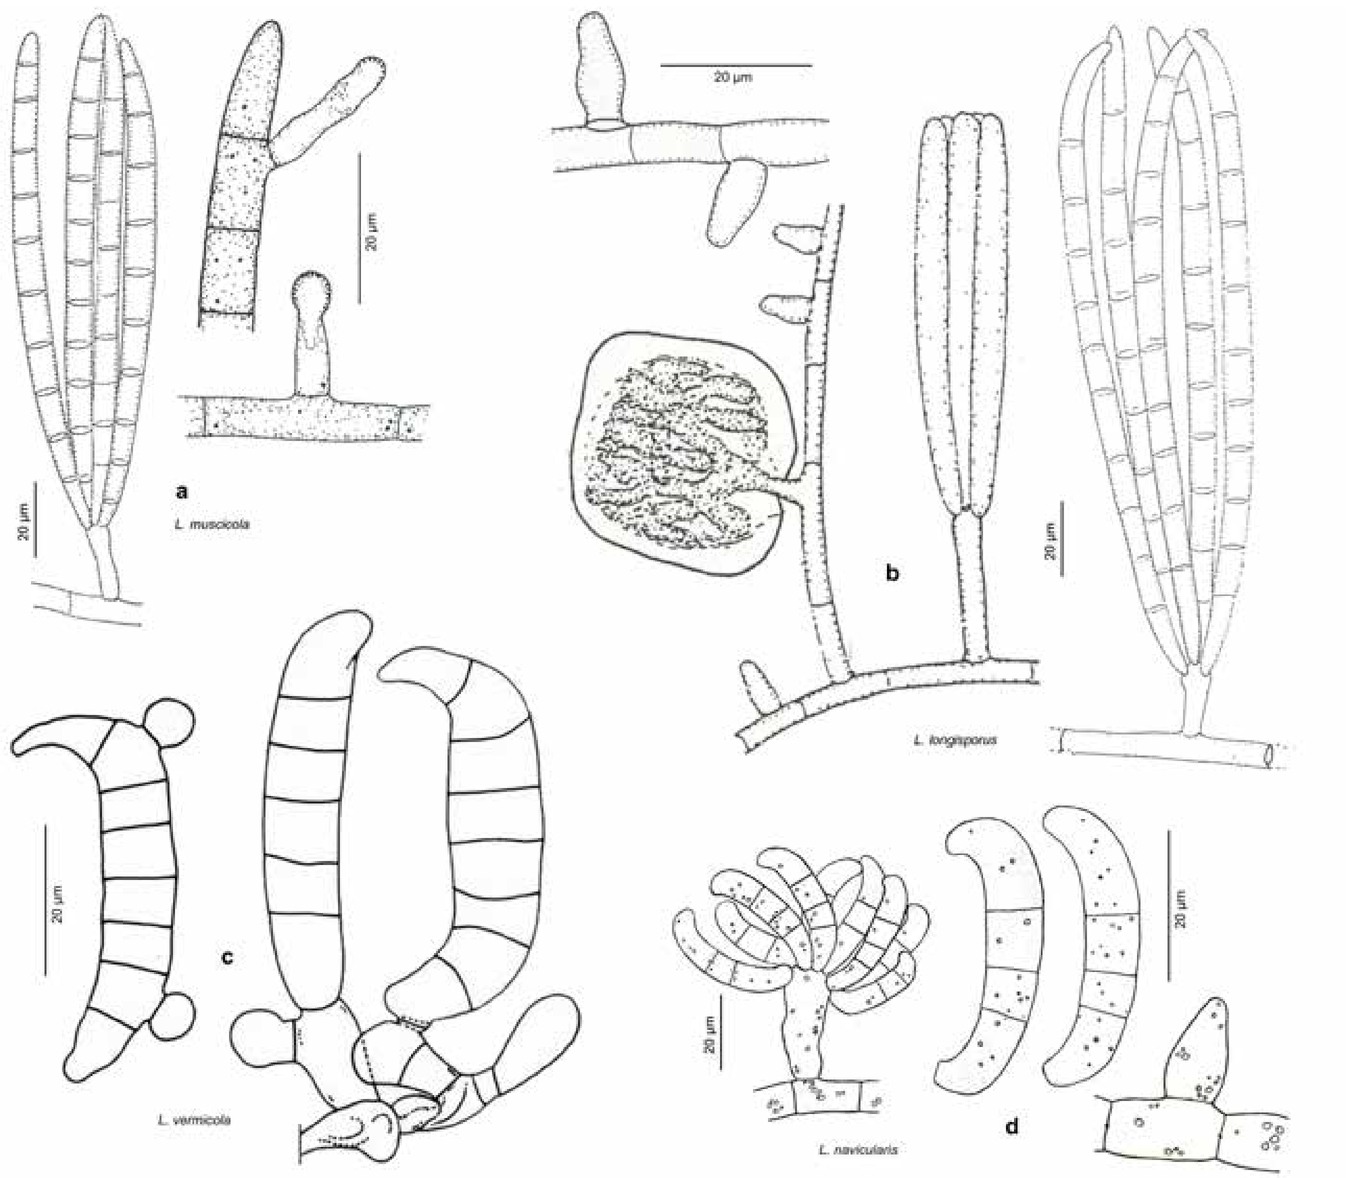

Plate 16. The accepted, hitherto known species of *Lecophagus* (conidiophores, conidia, and adhesive pegs). — **a**. from Barron et al. (1990), **b**. from Tzean & Barron (1983), **c**. from Magyar et al. (2016), **d**. from Barron et al. (1990).

as *Z. insidians* (APCC 9000), Dick found that this was not *Z. insidians* but an undescribed species, for which he proposed the new genus *Lecophagus* and the new species *L. fasciculatus* M.W. Dick. However, while Dick believed that APCC 9000 was the axenic culture which Whisler & Travland (1974) used for their ultrastructural studies (see also Morikawa et al. 1993), we assume that different strains were isolated by Whisler & Travland. Actually, their photographs show non-septate hyphae and cylindrical, basally non-septate pegs of varying length typical of *Z. insidians*.

Besides the new species *L. fasciculatus* (= *Z. insidians* s.auct.), Dick included *Cephaliophora navicularis* Tzean & G.L. Barron in the genus. The name of the new genus is derived from the rotifer genus *Lecane*, which Whisler & Travland 1974 used in their studies, and *phagus* (from Greek *phageín* = to eat), and indicates the ability to prey on rotifers. According to Dick, the main characteristics are: multinucleate mycelial cells, short lateral adhesive pegs of zoopagalean form, and blastic conidiogenesis on simple, short, lateral conidiogenous cells. Dick described the conidia as fusiform (although in the two included species they are drawn by him more cylindrical than fusoid), septate, slightly to strongly falcate. *L. fasciculatus* has very long conidia, whereas those of *L. navicularis* are much shorter and more canoe-shaped (claw-like). A possible relationship to the *Zoopagales* (earlier referred to the zygomycetes, today classified in *Zoopagomycotina*) was assumed.

In the same year, Barron et al. (1990) described two new species in *Cephaliophora* Thaxt. that produce large, slightly falcate conidia and capture rotifers and tardigrades, *C. muscicola* G.L. Barron et al. and *C. longispora* G.L. Barron et al. The genus *Cephaliophora* was erected by Thaxter (1903) with *C. tropica* Thaxt. as type species and *C. irregularis* Thaxt. (both isolated from animal dung, the latter preying on nematodes, see Barron et al. 1990). Based on morphological criteria, Morikawa et al. (1993) stated that *C. muscicola* and *L. fasciculatus* were conspecific. Because Barron et al.'s (1990) publication appeared one month earlier than that of Dick, *C. muscicola* has priority over *L. fasciculatus.* Morikawa et al. did not accept Dick's new genus *Lecophagus* but retained the species in *Cephaliophora*. They compared *Cephaliophora* with *Zoophagus insidians* and found by TEM that the central pore structure of hyphal and conidial septa of *C. muscicola* and *C. longispora* resembles those of ascomycetes rather than of zygomycetes which lack perforated septa and pore plug mechanisms. Further, *Cephaliophora* formed anastomoses between hyphae or conidia, a feature unknown in zygomycetes.

Tanabe et al. (1999) conducted molecular studies (18S rDNA) with four *Cephaliophora* species in comparison with nematophagous hyphomycetes. In their neighbour-joining tree *C. tropica* and *C. irregularis* are situated near *Ascodesmis sphaerospora* W. Obrist (*Pezizales*), whereas *C. muscicola* and *C. longispora* clustered in a monophyletic group with nematophagous hyphomycetes of the genera *Arthrobotrys*, *Monacrosporium*, and *Dactylella* (*L. navicularis* was not sequenced until now). Therefore, Tanabe et al. resurrected the genus *Lecophagus*, to which they transferred the two rotifer capturing species *C. muscicola* and *C. longispora.* This genus was emended by these authors in some points and transferred from the zygomycetes to the ascomycetes, with probable placement within the 'discomycetes'.

Three of the four species accepted in *Lecophagus* were collected in soil, moss, manure, treeholes and at shores of freshwater lakes in Canada, Japan, New Zealand, Europe, and Antarctica. They are predatory on rotifers and tardigrades. A fourth, recently described *Lecophagus* species, *L. vermicola* Magyar et al. (2016), is somewhat aberrant in growing on xeric branches and trunks, where it captures nematodes by sessile adhesive knobs formed on mycelial hyphae and on the large conidia (see Pl. 16: c and p. 300). Similar broad hyphae are described for *Haptocara* Drechsler, a nematophagous genus which, in our opinion, appears to be closely related to *Lecophagus*. *Haptocara* differs from *Lecophagus* mainly in morphology of conidia, showing a ± globose, sessile adhesive knob at their apex and a long, filiform hypha emerging laterally at their subapex (see Pl. 53). *L. vermicola* shares with *Haptocara* the nematophagy by means of sessile adhesive knobs, which are, however, formed in *L. vermicola* at the dorsal side of conidia.

McInnes (2003) described *L. antarcticus* from benthic cyanobacterial mats and sediments at the margin of lakes on maritime Antarctic Signy Island, capturing tardigrades and bdelloid rotifers. Apart from being invalid, the distinguishing features of this taxon against *L. muscicola* and *L. longisporus* are doubtful (see under *Lecophagus*, p. 297).

In the present study, *Lecophagus* is accepted as a separate genus within the *Orbiliaceae*. Teleomorphs of described anamorph taxa are unknown, but the connection between an undescribed anamorph and teleomorph exploiting dead rotifer bodies on xeric substrate is reported under the new name *L. ellipsoideus*. This connection was assumed based on strikingly similar, very broad mycelial hyphae containing extraordinary cubical bodies (see p. 94), and placement in *Lecophagus* was verified by molecular data gained from apothecia. The generic name *Lecophagus* is adopted here for the holomorph of these fungi. Some further observations support that the ecological range of *Lecophagus* encompasses also xeric substrate (see p. 290).

Microdochiella M. Hern.-Restr. & Crous – (Pl. 17)

Hernández-Restrepo et al. (2015) proposed this genus as different from *Microdochium* Syd. (*Sordariomycetes*) based on a single atypical species, *Microdochium fusarioides* D.C. Harris, growing on oospores of *Phytophthora syringae*. The three CBS cultures examined by these authors include the type strain. They remained sterile, therefore, the anamorph could not be redescribed. The gained sequences clustered in their phylogenetic analysis (LSU) highly supported as a sister clade of *Vermispora*.

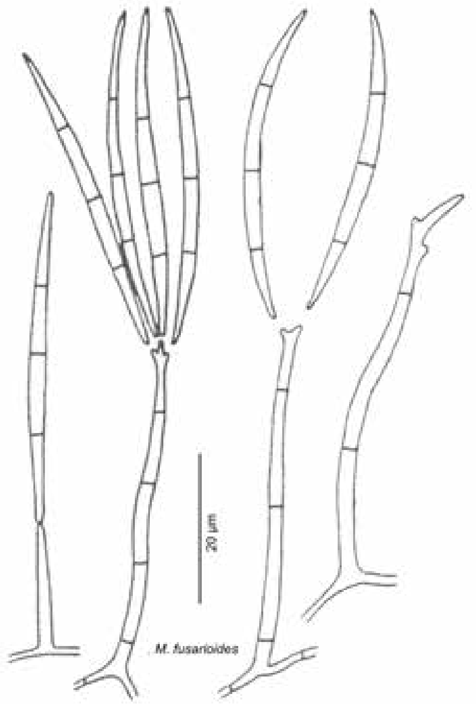

Plate 17. Conidiophores and conidia of *Microdochiella fusarioides* (from Harris 1985).

Morphologically, *Vermispora* and *Microdochiella* are very similar, and their main difference was thought to be an ecological one, parasitism on oospores in *Microdochiella* as reported by Harris (1985). However, spores of oomycetes are also invaded by *V. spermatophaga* (Drechsler 1938), and a strain of this species isolated from *Phytophthora megasperma* var. *sojae* (CBS 255.76) clustered in the *Vermispora* clade in the phylogenetic analyses of Chen et al. (2006a) and Hernández-Restrepo et al. (l.c.).

Microdochiella fusarioides (D.C. Harris) M. Hern.-Restr. & Crous was isolated during an experiment on the survival of *Phytophthora* oospores, which were buried for 8 months in soil of an apple orchard in Kent, U.K., together with the apple leaves which contained them. The species is characterized by narrowly fusiform, slightly curved (falcate), (1–)3(–5)-septate conidia of 30–60 × 2–3 µm, formed singly or in clusters of 2–3(–4) on short denticles at the tip (or sometimes at the sides or in whorls one above another) of very short to medium long, 0–7-septate conidiophores. From *Vermispora* it seems to differ merely in the rather narrow conidia with a drop of moisture at their mid-point, and presence of chlamydospores.

In the present study, *Microdochiella* is considered to be congeneric with *Vermispora* based on its close morphological and molecular similarity, but also *Vermispora* is included in *Hyalorbilia* despite a high molecular distance to the core clade of *Hyalorbilia* (see under *Vermispora*, p. 246–247).

Mycoceros D. Magyar & Z. Merényi – (Pl. 18)

Mycoceros was introduced by Magyar et al. (2017b) for a single species, *M. antennatissimus*. It is named after the shape of the conidia resembling horns with thin and often long branches, preying on wind-borne pollen grains which it apparently captures by erect hyphae. Its conidia resemble those of *Dwayaangam*

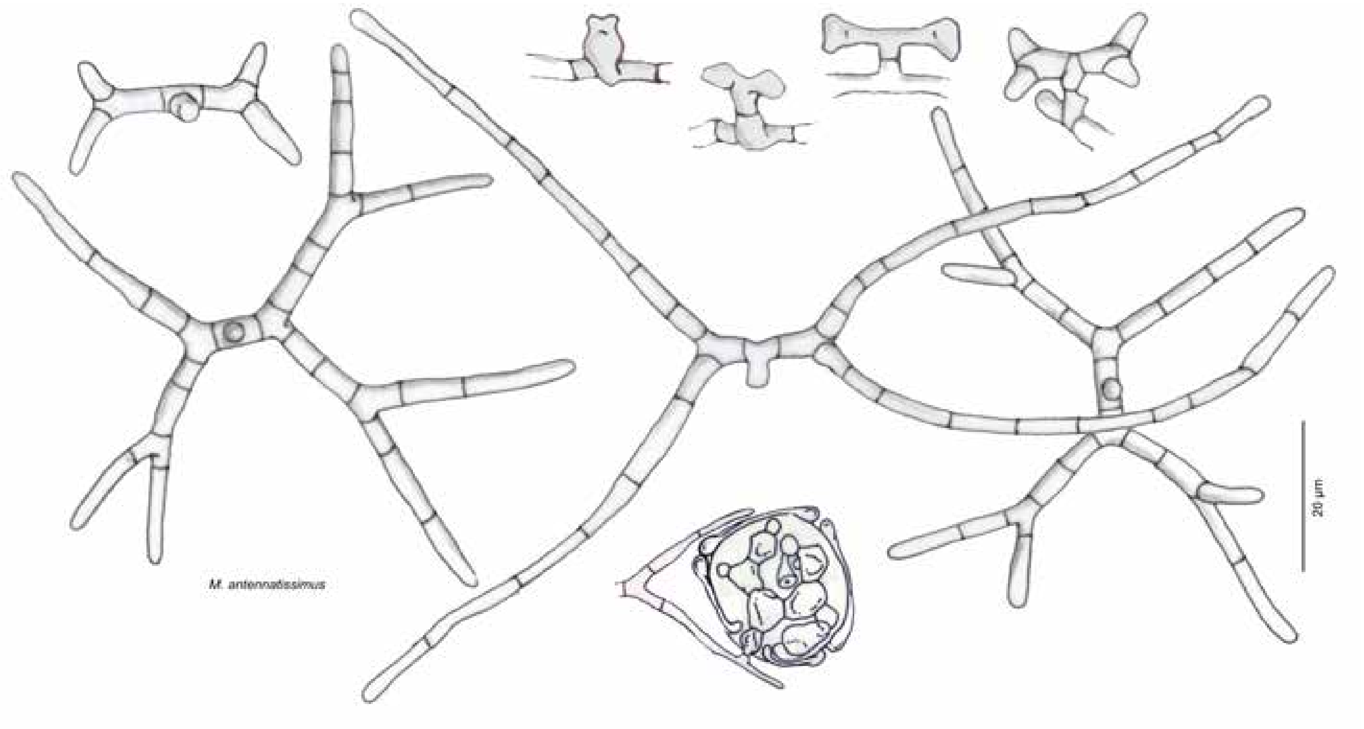

Plate 18. Conidiophores and conidia of *Mycoceros antennatissimus*, with infected pollen (from Magyar et al. 2017b).

but the primary arms are longer than the non-septate main axis, and the conidia are often three times dichotomously branched. No teleomorph is known. The similar pollen-capturing genus *Retiarius* differs by trinacrium-, curucispora-, or dwayaangam-like conidia, the latter with primary arms shorter than the septate main axis, but mainly by molecular data. In Magyar et al.'s (2017b) molecular phylogenetic analysis of different classes of ascomycetes, *Mycoceros* nested with high support as a sister clade to all the remaining *Orbiliomycetes*, nevertheless, it was considered to belong to this class.

M. antennatissimus was so far reported from xeric bark of *Elaeagnus angustifolia*, *Platanus* × *acerifolia*, and *Taxus baccata* in Budapest, Hungary, on which it parasitizes on pollen of *Pinaceae*.

In the present study, *Mycoceros* is accepted as a separate genus based on its isolated basal placement in phylogenetic analyses. Two samples possibly belonging to *M. antennatissimus* were observed by us on the natural substrate (see p. 287).

Pseudotripoconidium Z.F. Yu & K.Q. Zhang – (Pl. 19)

Yu et al. (2011) introduced the genus *Pseudotripoconidium* to accomodate an anamorph, *P. sinense* Z.F. Yu & K.Q. Zhang, which they obtained in four ascospore isolates from apothecia identified as *Orbilia* aff. *luteorubella* (= *O. sinensis*). The characters are: conidiophores 110–140 µm long, simple or occasionally branched, with prominent denticles near the apex, conidia non-septate, inversely pyramidal, slightly laterally compressed and with ± distinct nipple-shaped protuberances at their broad distal end, containing one or several large oil drops. The generic name refers to the conidial shape which resembles that in *Tripoconidium* (see p. 246).

Su et al. (2011c) reported and figured a *Pseudotripoconidium* anamorph from pure culture of *O. acicularis*, and H.Y. Su (pers. comm.) obtained such anamorphs in several further isolates here described as *O. fusiformis*, *O. jinguangsiensis*, and *O. tenuispora*. All these samples originate from montane, subtropical humid (winter-dry) southern China. They were isolated from ascospores from apothecia on decaying fallen branches. No trapping devices are known. A phylogenetic analysis of ITS rDNA by Yu et al. (l.c.) showed that the four investigated isolates clustered in a clade with two sequences in GenBank under the name *O.* cf. *luteorubella* (U72607 = D.H.P. 146, FJ719770). The former strain is a non-sporulating ascospore isolate from a temperate North American collection genetically connected to *Pseudotripoconidium* and described as *O. tenuispora* in the present monograph, the latter a Chinese isolate with a *Helicoon* anamorph falling in the scope of European *O. luteorubella*.

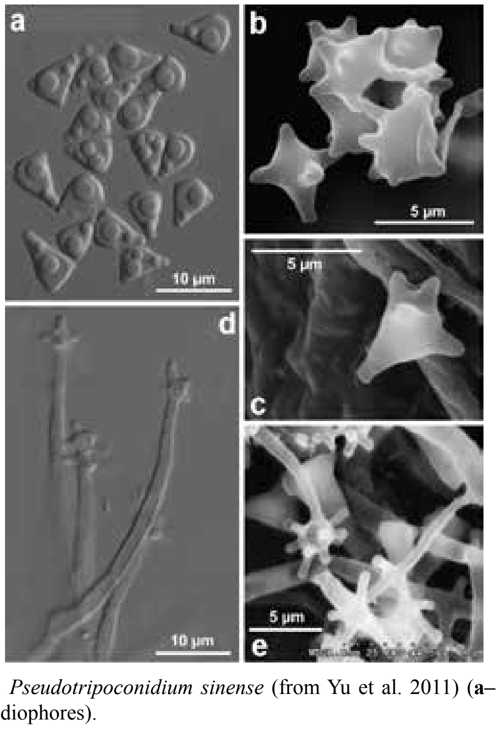

Plate 19. *Pseudotripoconidium sinense* (from Yu et al. 2011) (**a–c**. conidia, **d–e**. conidiophores).

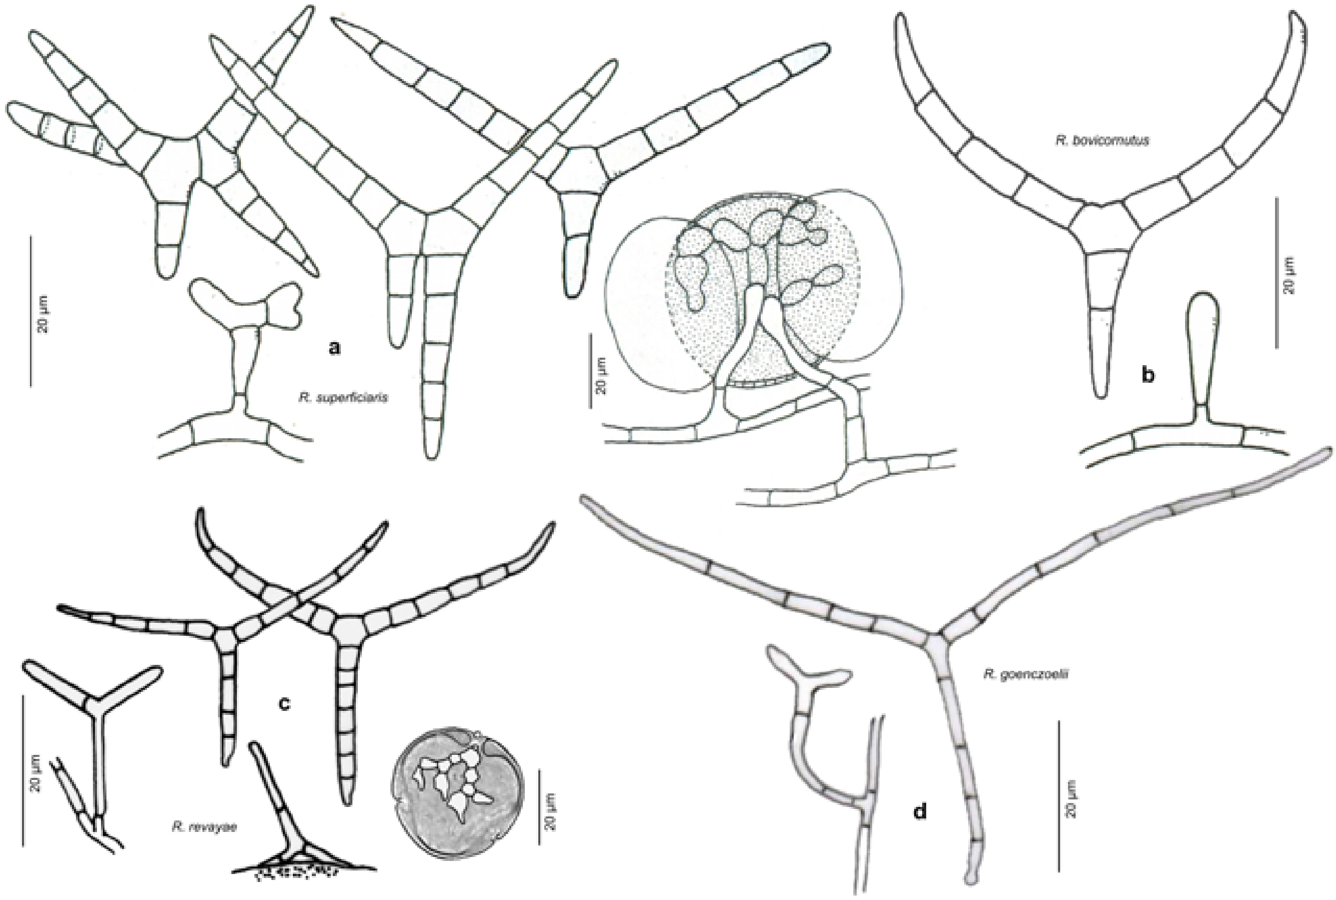

Plate 20. The accepted species of the genus *Retiarius* (conidiophores, conidia, and infected *Tilia* pollen). — **a** and **b**. from Olivier (1978), **c** and **d**. from Magyar et al. (2017a).

Similarly shaped conidia are found in the genus *Heliscella* Marvanová, but here conidiogenesis is phialidic. Conidia are also similar in *Clavatospora* Marvanová & Sv. Nilsson, *Clavariopsis* De Wild., *Heliscina* Marvanová, and *Coronospora* M.B. Ellis, but they differ in being septate and larger, and no oil drops are mentioned. In none of these genera conidiophores with denticulate apices occur.

In the present study, the genus *Pseudotripoconidium* is reduced to a series of *Orbilia* subgenus *Habrostictis* section *Helicoon* which comprises also series *Helicoon* with scolecosporous conidia currently referred to *Anguillospora* and *Helicoon* (see p. 214 and p. 236). Although we have never observed a pseudotripoconidium-like anamorph in European samples, there is a possibility for the occurrence of this series in Spain (*O.* cf. *sinensis*, Pl. 561: 5–6). The lack of both cultural and molecular data in most of the samples complicates recognition at the series level, because the teleomorphs hardly differ between the two series (see p. 953).

Retiarius D.L. Olivier **–** (Tab. 52, Pl. 20)

The genus *Retiarius*, named after a Roman gladiator armed with a cast net (which he threw over his rival), a trident, and a dagger, was introduced by Olivier (1978) for two species that capture wind-borne pollen grains of *Pinaceae* by means of erect hyphae (Pl. 20: a–b). The type species *R. superficiaris* has dwayaangam- to trinacrium- or curucispora-like conidia; Olivier compared it with the genus *Tripospermum*. The second included species, *R. bovicornutus*, was considered to belong to *Trinacrium* by Matsushima (1993: 30). Two further species with

Table 52. Overview of the accepted species of *Retiarius* (*total size, arm and stipe width evaluated from Olivier's and Magyar et al.'s drawings).

Species	Total size of conidia (height × width) * [µm]	Stipe [µm]	Arms [µm]	Conidial shape	Habitat	References
R. bovicornutus D.L. Olivier*	~47–50 × 45–55	(12–)15–20(–25) × 3.5–4.5(–5.5)	(25–)30–45(–50) × 4–5	Y-shaped	on leaves of *Brabejum stellatifolium*, South Africa, parasitic on pollen grains	Olivier 1978
R. superficiaris D.L. Olivier* **Type species**	~37–60 × 44–66	(8–)10–15 × 4–4.5(–5.5)	(20–)25–35(–45) × 4.5–6	dwayaangam-like, also Y or +-shaped	on leaves of *Eryobotrya japonica*, South Africa, parasitic on pollen grains	Olivier 1978
R. revayae D. Magyar & Z. Merényi	~26–40 × 32–48	†14–22 × 2–3.5	†22–30 × 2–3(–3.5)	Y-shaped	bark of *Taxus baccata*, Hungary, parasitic on pollen grains	Magyar et al. 2017a
R. goenczoelii D. Magyar	~37–70 × 100–150	†19–33 × 1.7–2.5(–3)	†42–90 × 2–2.5	Y/T-shaped	bark of *Platanus* × *acerifolia*, Hungary, parasitic on pollen grains	Magyar et al. 2017a

trinacrium-like conidia were added to the genus by Magyar et al. (2017a). No teleomorph is known.

Magyar et al. (2017a, b) gained rDNA sequences from the ex-type cultures of Olivier's two *Retiarius* species (IMI 223459, 223460) and *R. revayae*, which formed in their phylogenetic analysis a separate group within the clade containing *Lecophagus*.

Retiarius species were reported from South Africa, Europe, and Asia (Magyar et al. l.c., see also Tab. 52). Matsushima (1993: fig. 717, 2005: fig. F574, P508) figured a collection of *R. bovicornutus* from Peru, on palm petioles. Magyar et al. (l.c.) reported *Picea* pollen as nutrient source of their two species, but observed also infected *Tilia* pollen (Pl. 20: c). Olivier (l.c.) used *Pinus radiata* pollen to examine the parasitic behaviour of *Retiarius*.

In the present study, *Retiarius* is accepted as a different genus though very close to our new genus *Amphosoma*, Several samples referable to *Retiarius* were examined, most of them resembling *R. bovicornutus* or *R. revayae* (see p. 283–285).

Tridentaria Preuss – (Tab. 53, Pl. 21)

In the unillustrated protologue of *Tridentaria* Preuss (1852) and its single species *T. alba* Preuss, the hyaline 'spores' are oblong to clavate, and were formed in whitish acervuli on *Brassica oleracea*. The generic name refers to the tridentate shape which originates from the connection of several 'spores' to form a three-armed structure. A later included species, the aquatic hyphomycete *T. setigera* Grove, was combined into *Tetracladium* De Wild. by Ingold (1942) and belongs to the *Helotiales* based on available molecular data. Drechsler (1937b, 1940, 1962, 1964) described four new hyphomycetous, nematode- or rhizopod-trapping species in *Tridentaria*. In spite of the absence of conidiomata, he placed them in this genus because of the staurosporous, normally three-pronged (trident-like) conidia. For a similar reason, two further species were described in *Tridentaria*: *T. fertilis* by Castañeda Ruíz (1988) and *T. subuliphora* by Matsushima (1989, Pl. 21).

Like Drechsler (l.c.), Van der Aa & Van Oorschot (1985) regarded the genus *Tridentaria* as doubtful because 'the type specimen did not bear a fungus which agreed with the very brief original description'. According to the latter authors, similar genera like *Tricornispora* Bonar, *Fumagopsis* Speg., and *Kazulia* Nag Raj with sporodochia and holoblastic conidiogenesis, and *Eriosporella* Höhn. with acervuli and phialidic conidiogenesis, are properly typified and can be regarded as distinct from those taxa described by Drechsler. They concluded that 'the nematode-trapping hyphomycetes formerly placed in *Tridentaria* should be reclassified'.

Numerous genera of aquatic hyphomycetes with similar staurosporous conidia do exist. The tetraradiate form is seen as an adaptation to water dispersal and is a polyphyletic character (Belliveau & Bärlocher 2005). The genera *Alatospora* Ingold, *Articulospora* Ingold, *Flabellocladia* Nawawi, *Flabellospora* Alas., *Fontanospora* Dyko, *Geniculospora* Sv. Nilsson, *Isthmotricladia* Matsush. (with arms at the base strongly attenuated), *Lemonniera* De Wild., *Quadricladium* Nawawi & Kuthub., and *Tetrachaetum* Ingold are to be mentioned here. In *Alatospora* and *Lemonniera*, however, conidiogenesis is phialidic. In *Quadricladium* and *Lemonniera* conidia are attached to the conidiophore at their central cell (i.e., they have no stipe or main axis), while in the other genera, including *Tridentaria*, they insert at the base of a septate stipe. For *Articulospora tetracladia* Ingold and *Geniculospora grandis* (Greathead) Nolan a connection to teleomorphs of *Hymenoscyphus* (*Helotiales*) were found in pure culture (Abdullah et al. 1981, Descals et al. 1984), for *Lemonniera* a relation to the *Helotiales* was indicated by DNA-sequence analysis (Campbell et al. 2006, Baschien et al. 2006), and for *Alatospora* one with *Leotia* (*Leotiales*, Baschien et al. 2006), although sequences of *Alatospora* show also affinities with *Helotiales*. The type of *Flabellocladia*, *F. gigantea* Nawawi (1985b), possibly belongs to *Tridentaria* in the sense of Drechsler, as does *Articulospora foliicola* Matsush., based on a very similar morphology. *Flabellocladia* should be sequenced from the holotype to clarify its possible relationship with *Orbiliomycetes*.

Tridentaria species were isolated from decaying plant material, some were found to capture nematodes and rhizopods by means of sessile adhesive knobs, or parasitize oospores. They have been reported from Asia, Australia, South Africa, Europe, Northern, Middle, and South America (see Tab. 53). Up to now, no teleomorphs were reported in the form genus *Tridentaria*.

In the present study, *Tridentaria* is considered to be a nomen dubium. Tridentaria-like anamorphs developed in pure culture of *Orbilia quaestiformis*, *O. septispora*, and *O. quercus-ilicis* (section *Habrostictis*). In our phylogenetical analyses two non-authentic CBS strains of *T. implicans* and *T. subuliphora* clustered in the clade of series *Orbilia*. Since the identity of the type species of *Tridentaria*, *T. alba*, is doubtful and very probably not orbiliaceous, we use the term 'tridentaria-like' for describing conidia of a shape similar as in those taxa illustrated in Pl. 21.

Table 53. Overview of the accepted species of the form genus *Tridentaria* (the type species *T. alba* is of uncertain identity).

Species	Main axis/stipe [µm]	Arms [µm]	Habitat	Reference
T. tylota Drechsler	19–30 × 3–4.7	13–24 × 2.3–3.7	decaying bean stem, USA, capturing testaceous rhizopods, parasitic on *Pythium* oospores	Drechsler 1964
T. subuliphora Matsush.	12–24 × 3–5	22–35 × 2.8–3.8	decaying leaves, Australia	Matsushima 1989
T. implicans Drechsler	7–20 × 2.5–5	12–55 × 3.5–5.5	decaying leaves and stems, dead banana leaves, rotten wood, Japan, Peru, South Africa, USA, Taiwan, capturing nematodes	Drechsler 1940, Matsushima 1975, 1981, 1987, 1993, 1996
T. glossopaga Drechsler	12–15 × 2.8–3.5	21–45 × 2.2–3	leaf mould, USA, capturing testaceous rhizopods	Drechsler 1962
T. carnivora Drechsler	12–21 × 2.8–3.8	17–44 35–45 × 3–4	leaf mould, USA, capturing testaceous rhizopods, rotten *Acacia* leaves, Taiwan	Drechsler 1937b Matsushima 1987
T. fertilis R.F. Castañeda	3–8 × 2–3	7–20 × 2–3	dead *Poaceae* stem, Cuba	Castañeda Ruíz 1988

Plate 21. Trinacrium Riess in Fresenius – (Tab. 54, Pl. 22)

The genus was erected in 1852 with the single species *Trinacrium subtile* Riess. The main characteristics are the triradiate (Y-shaped), hyaline conidia with one main axis and two divergent arms that arise by dichotomous branching (for the similar form genera *Dicranidion* and *Tridentaria* see there). The name *Trinacrium* refers to the fact that the two arms are hardly distinguishable from the main axis as soon as the conidia are detached. In some cases unbranched phragmoconidia, but also higher-branched conidia were reported to occur together with the typical triradiate conidia (*T. angamosense*, Matsushima 1995; *T. incurvum*, Matsushima 1993; *T. subtile*, Drechsler 1938, Ando 1992).

In the protologue of the type species, a slight uncertainty exists concerning the point of conidial attachment. The two conidia figured by Riess (in Fresenius 1852: pl. V figs 14 & 15) clearly show a scar-like protuberance at the tip of the main axis, reminiscent of *Trifurcospora* K. Ando & Tubaki (1987) where conidial attachment is indeed at the central cell. However, Riess reported and illustrated (l.c.: fig. 17) a very young conidium as being attached with the basal end of its short stipe to the short conidiophore (see Pl. 22: h).

Tzean & Chen (1989) gave an overview of six *Trinacrium* species. 16 species have to date been described, nine of which are listed and figured below (Tab. 54, Pl. 22), while another was transferred to *Arthrobotrys.* The remaining six species are only known from the short and mostly unillustrated type descriptions and are, therefore, doubtful. Three of them have triradiate conidia: *T. mycogenum* Tassi (conidial arms 15–20 × 4 µm, on *Nectria*, between *Fusarium*, Italy, Saccardo 1902), *T. torulosum* Sacc. & Malbr. (conidial arms 35–40 × 3–4 µm, on mycelium of *Sphaerulina boudieriana* on leaf of *Scabiosa sylvatica*, France, Saccardo 1886), and *T. minus* Speg. (conidial arms 20–25 × 2 µm, on *Fumago pannosa* on leaf of *Pernettya mucronata*, South America, Saccardo 1892). The other three taxa have 3–4- or 4-radiate conidia and, therefore, deviate from the form genus *Trinacrium* s.str.: *T. pulchellum* Speg., the presumed anamorph of *Paracapnodium pulchellum* Speg. (*Dothideomycetes*, with arms 10–15 × 2 µm, on leaf of *Ilex paraguariensis*, Java, Spegazzini 1909: 327, fig. 7), *T. subtropicale* Speg. (arms 30 × 5–6 µm, on 'subiculum' of *Symphaeophyma subtropicale* on leaf of *Lucuma neriifolia*, Argentina, Spegazzini 1912), and *T. tropicale* Speg.

(2001), **j**. from Drechsler (1938).

Table 54. Overview of the accepted species of the form genus *Trinacrium*.

Species	Main axis/stipe [µm]	Arms [µm]	Habitat	Reference
T. tothii Magyar (= *Orbilia aprilis*)	14.5–22 × 2.7–3.6(–5)	2.5–7.5 × (2–)2.3–2.7(–4)	bark of *Elaeagnus angustifolia*, Hungary	Magyar & Révay 2008
T. angamosense Matsush.	11–18 × 2.5–3.5	(3–)5–10 × 2–2.5	palm petioles, Peru	Matsushima 1995
T. parvisporum Matsush.	8–20 × 2–4	4–16 × 2–3	basidiocarps of *Tremella foliacea*, stems of *Bambus*, Japan, Taiwan	Matsushima 1987
T. incurvum Matsush.	18–36 × 3.5–6	6–14 × 3–5.5	plant material, decaying leaves and bark, Peru, Taiwan	Matsushima 1980, 1993, Tzean & Chen 1989
T. robustum Tzean & J.L. Chen	15–20 × 3.8–6.3	9.6–25 × 4.6–6.3	decaying stem, Taiwan	Tzean & Chen 1989
T. gracile Matsush.	13–18 × 1.6–2	18–30 × 1.8–2.2	decaying leaf, Japan, Peru	Matsushima 1975, 1993
T. inaequiramiferum Matsush.	13–20	23–36 × 1.8–2.8	decaying leaves, leaf litter, Australia, Japan	Matsushima 1989, 1995
T. subtile Riess **Type species**	30–47 × 2–3.5	20–46 × 3.5–4	on *Stilbospora*, insect eggs, on *Chloridium brunneum* on *Tilia*, *Berberis* twigs, *Fagus sylvatica* bark, decaying *Quercus* wood, Austria, Germany, Italy, Japan	Fresenius 1852, Saccardo 1886, Lindau 1907, Matsushima 1975
T. indicum Soosamma et al. (as *T. indica*)	28–56 × 1.2–2.5	23–35 / 46–65 × 1.2–2.5 (short / long arm)	on decaying *Coffea* leaves, India	Soosamma et al. 2001
Trinacrium sp. (as *T. subtile*)	52–65 × 6,7–8	21–42 × 3.3–7.5	decaying plant material of *Spinacia oleracea*, parasitizing oospores of *Pythium butleri* and rhizopods, USA	Drechsler 1938

(arms 15–20 × 3–4 µm, on various mycelia on leaves of various plants, Costa Rica, Spegazzini 1918). Another unillustrated taxon, *T. subtile* var. *tjibodense* Penz. & Sacc. (on rotten branch, associated with *Stictis pallidula*, Java), differs from *T. subtile* in the arms being curved upwards and with thicker bases (Saccardo & Saccardo 1906). *T. indicum* Soosamma et al. (2001), with the two slender arms differing in length and only one of them being curved, does not fit well in *Trinacrium*. *T. iridis* Ts. Watan. from *Iris* roots in Japan was described by Watanabe (1992) and, after several transfers, was later called *Arthrobotrys iridis* (Ts. Watan.) M. Scholler et al. (1999) because of its capability of trapping nematodes by means of adhesive networks.

Drechsler (1938) reported and figured an isolate identified as *T. subtile*, which parasitizes oospores of *Pythium* (Pl. 22: j) but also testaceous rhizopods. This isolate shows a high variability in conidial shape: with typical trinacrium- and descalsia-like (┼-shaped) conidia in majority, but also with unbranched and higher-branched ones. Because of a greater width of the conidial main axis we consider Drechsler's isolate as not conspecific with *T. subtile.* Drechsler's species is also figured in Carmichael et al. (1980) and Seifert et al. (2011) as *T. subtile*. Similarly, Ando (1992) reported six different conidial types in a Japanese isolate named *T. subtile*. Here a majority of conidia (97%) were two-armed, trinacrium-like and fit quite well typical *T. subtile*, the remaining being unbranched or higher-branched. According to Tzean & Chen's (1989) protologue, curucispora/descalsia-like or dwayaangam-like conidia with 3–4 arms rarely occurred in *T. robustum* in addition to triradiate conidia.

The two-armed *Trinacrium inaequiramiferum* has one or two arms basally constricted, and this is apparently why the species was considered to be congeneric with the three-armed *Tridentaria carnivora* Drechsler (Matsushima 1989). Matsushima (1987) considered the genus *Retiarius* (Pl. 20) as a possible synonym of *Trinacrium*. Three of the four included species have trinacrium-like conidia, whereas the type species *R. superficiaris* shows more resemblance to *Dwayaangam* (see there).

In five cases a proved connection to an orbiliaceous teleomorph has been reported: in a culture of an unidentified *Trinacrium*, Matsushima (1995) obtained apothecia referable to *Hyalorbilia erythrostigma* s.l. (as *Orbilia trinacriifera* Matsush., but see p. 421); Liu (2006) reported in an ascospore isolate of '*O. brasiliensis*' (= *O.* aff. *pilifera*) an anamorph identified as *Trinacrium incurvum*; Guo et al. (2013) obtained the trinacrium-like anamorph of a not mentioned *Orbilia* here referred to as *O.* aff. *bannaensis* based on unpublished photos; Ren et al. (2014b) obtained the trinacrium-like anamorph of *O. corculispora*, and Shao et al. (2018) that of *O. occulta*.

Besides *Dicranidion*, *Dwayaangam*, and *Tridentaria*, similar trinacrium-like staurosporous conidia were described in *Trifurcospora* (see above), *Ypsilinia* Descals et al. (1999) with an additional phialidic microconidial state (Marvanová & Bärlocher 2001), and *Lambdasporium* Matsush. (1971). Within the genus *Tripospermum* Speg. similar conidial forms occur, but here the conidia are more or less pigmented.

Most of the known *Trinacrium* species were isolated from decaying plant material, whereas some collections originate from fungal substrates. Gönczöl & Révay (2006) found seven species in rainwater collected from different trees. *Trinacrium* species have been reported from Asia, South Africa, Europe, North and South America.

In the present study we treat *Trinacrium* as a synonym of *Orbilia* and, at the series level, as a possible synonym of series *Hemiorbilia* of section *Hemiorbilia*. We frequently observed trinacrium-like anamorphs, particularly in *Orbilia* but also in *Hyalorbilia* and *Amphosoma*, often in pure culture. Within *Orbilia*, mainly sections *Habrostictis* and *Hemiorbilia*, but also *Lentiformes*, *Aurantiorubrae* (series *Albovinosae* and *Piliferae*), and *Orbilia* (series *Microsomates*) are connected to trinacrium-like anamorphs. Among the described *Trinacrium* species only *T. tothii* can be assigned with high probability to a teleomorph (*O. aprilis*). Anamorphs referable to *T. robustum* were observed in about 30 *Orbilia* species of sections *Habrostictis* and *Hemiorbilia*, while for the teleomorph of *T. incurvum* members of series *Piliferae*, but also of section *Lentiformes* come into question, and several members of series *Hemiorbilia* form conidia similar to those of *T. subtile*. Without molecular data gained from a holo- or epitype, reliable assignments of these anamorph names to a teleomorph are impossible.

Tripoconidium Subram. – (Pl. 23)

The genus was erected in 1978 with a single species, *Tripoconidium aphanopagum* (Drechsler) Subram. It is mainly characterized by hyaline, septate, twice dichotomously branched conidia formed on long conidiophores. The conidia consist of a large triangular central cell, a short obconical stipe, and four short conical arms.

Drechsler (1937a, 1962) described two species in *Triposporina* Höhn., *T. aphanopaga* and *T. quadridens*. However, the type species of that genus, *T. uredinicola*, differs in the annellidic mode of conidiogenesis (see under *Dwayaangam*, p. 233). Therefore, Subramanian (l.c.) proposed new genera for Drechsler's species: *Tripoconidium* for *Triposporina aphanopaga*, and *Dwayaangam* for *Triposporina quadridens*. The name *Triposporina* was derived from the Greek 'tripos' or 'tripodo' = tripod (referring to conidial shape), after which Subramanian named his genus *Tripoconidium*. Drechsler mentioned the similarity of conidia of *Triposporina aphanopaga* with those of the broadly fusiform type found in *Drechslerella bembicodes* (as *Dactylella*), 'modified by two successive bifurcations'.

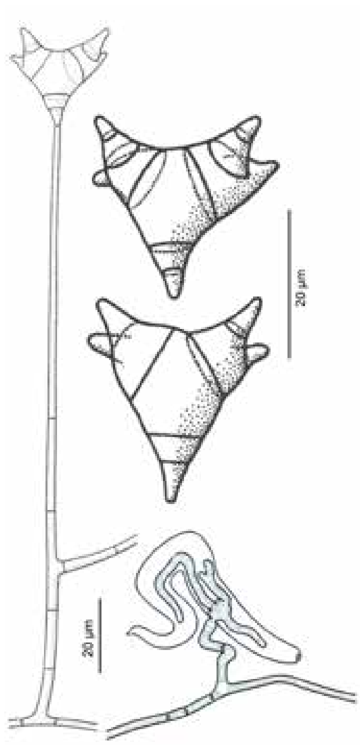

Plate 23. *Tripoconidium aphanopagum* (conidiophore, conidia, and captured nematode). From Drechsler (1937a).

Tripoconidium aphanopagum was isolated from leaf mould from North America. It is weakly predacious on nematodes but does not form conspicuously differentiated trapping organs (Drechsler 1937a: 534).

In the present study we did not observe anamorphs of this type of conidia. Yet, judging from the morphology of conidia and conidiophores, this species seems to belong to *Orbilia* section *Arthrobotrys*.

Vermispora Deighton & Piroz. – (Tab. 55, Pl. 24)

Vermispora was erected in 1972 with the single species *Vermispora grandispora* Deighton & Piroz., and five species were later added to the genus. According to Chen et al. (2007a, c) the genus is characterized by hyaline, simple, short to long conidiophores with sympodial conidiogenesis, slightly geniculate above the older conidiogenous scars, and conidia elongate (cylindric-)fusoid to fusiform, slightly curved and usually slightly sigmoid (possibly slightly helicoid). The name *Vermispora* is derived from the worm-shaped conidia. Chen et al. obtained in their molecular analysis of several isolates of *Brachyphoris*, *Dactylella*, and *Vermispora* a well-supported clade (*Vermispora* group) comprising *V. leguminacea*, *V. fusarina*, and *V. spermatophaga* (≡ *Dactylella spermatophaga*). The authors accepted five species in *Vermispora* (see Tab. 55), and excluded *V. obclavata* V. Rao & de Hoog, which was added to the genus in 1986, by morphology (e. g., faintly pigmented conidiophores). No teleomorphs are reported for any of these five accepted species. The phylogenetic analysis by Chen et al. (l.c.) suggests that the three included species are members of *Orbiliomycetes*.

However, no sequence data were available for the type species of *Vermispora*, *V. grandispora*, which was not taken into culture (Burghouts & Gams 1989), and *V. cauveriana*. The latter deviates from the remaining species in having the longest conidiophores (up to 170 µm) and the largest conidia which produce microconidia on long and thin germ tubes emerging from the macroconidia (Pl. 24: f). Rajashekhar et al. (1991) compared *V. cauveriana* with nematophagous orbiliaceous taxa but did not mention to have tested their cultures with nematodes. A relation to *Arthrobotrys* or *Drechslerella*, in which microconidia are frequent, cannot be excluded.

The genus *Microdochiella* is very similar to *Vermispora* (see p. 239), and also *Lecophagus* resembles *Vermispora* in conidial shape, but differs in conidiophore shape, very broad mycelial hyphae containing cubical bodies, and in the capture of invertebrates by adhesive pegs. Anamorphs in *Brachyphoris* mainly differ in ± straight conidia.

Similar phragmosporous conidia with holoblastic conidiogenesis can be found in *Dactylaria* Sacc., with mostly straight conidia and brownish conidiophores, or in *Neta* Shearer & Crane where conidiogenous cells develop in an arachnoid mat of setose (thick-walled), brown, dichotomously branched hyphae, and the conidia may contain very large lipid bodies. The type species of *Dactylaria*, *D. purpurella* (Sacc.) Sacc., was described from Italy with a pale purple pigmentation of conidia and lower part of conidiophores, whereas other species

Table 55. Overview of the accepted species of the form genus *Vermispora*.

Species	Conidial size [µm]	Septa	Conidial shape	Habitat	References
V. leguminacea Juan Chen et al.	20–34 × 4–5	(1–)3(–5)	cylindric-fusoid	soil, China, Fujian	Chen et al. 2007a, c

V. cauveriana Rajash et al.	160–180 × 10–22	6–9	elongate fusiform	decaying leaves of *Ficus religiosa*, India	Rajashekhar et al. 1991

of *Dactylaria* section *Dactylaria* have hyaline or pale brown pigmented conidiophores (De Hoog 1985). With its denticulate sympodial conidiophores, *Dactylaria* resembles orbiliaceous anamorphs in the genera *Brachyphoris* and *Vermispora*. However, a molecular study by Bhilabutra (2009) shows that a Japanese strain of *D. purpurella* and strains of some other species of *Dactylaria* show affinities with *Herpotrichiellaceae* (*Chaetothyriales*).

For *Aquaphila albicans* Goh et al. (1998) with similar conidia, Tsui et al. (2007) reported *Tubeufia asiana* Sivichai & K. M. Tsui (*Pleosporales*) as teleomorph. The genus *Trichoconis* Clem. (e.g., *T. sigmoidea* Deighton & Piroz.) is somewhat similar to *Vermispora*, but here conidial secession is rhexolytic: the denticles on which the conidia are produced are narrow tubular separating cells cut off from both conidiophore and conidium by a septum. A BLAST search based on a sequence of *T. echinophila* (C. Massal.) de Hoog & Oorschot in GenBank did not show any relation to *Orbiliomycetes*. In the genus *Sigmoidea* J.L. Crane the teleomorph is said to be *Corollospora* Werderm. (*Halosphaeriales*, Jones et al. 2009). However, *S. aurantiaca* Descals (in Descals & Webster 1982) shows similarities to anamorphs of *Orbilia*. *Chionomyces* Deighton & Piroz. (*Pezizomycotina* incertae sedis) deviates in more or less thick-walled conidiophores with a percurrent proliferation. Yet, the later added *C. ponapensis* (Matsushima 1983, as '*Chinomyces*') is very probably an anamorph of *Orbilia*, judging from its conidial morphology (conidia 17–32 × 3–4 µm, 3–6-septate, cylindric-fusoid, on decaying bark, Micronesia; Pl. 24: e) which especially resembles that reported here in *Orbilia* section *Aurantiorubrae*. Finally, the phragmoconidia of *Fusarium* Link and *Cylindrocarpon* Wollenw. resemble *Vermispora* but originate from phialides, their teleomorphs belonging to *Nectriaceae* (*Hypocreales*).

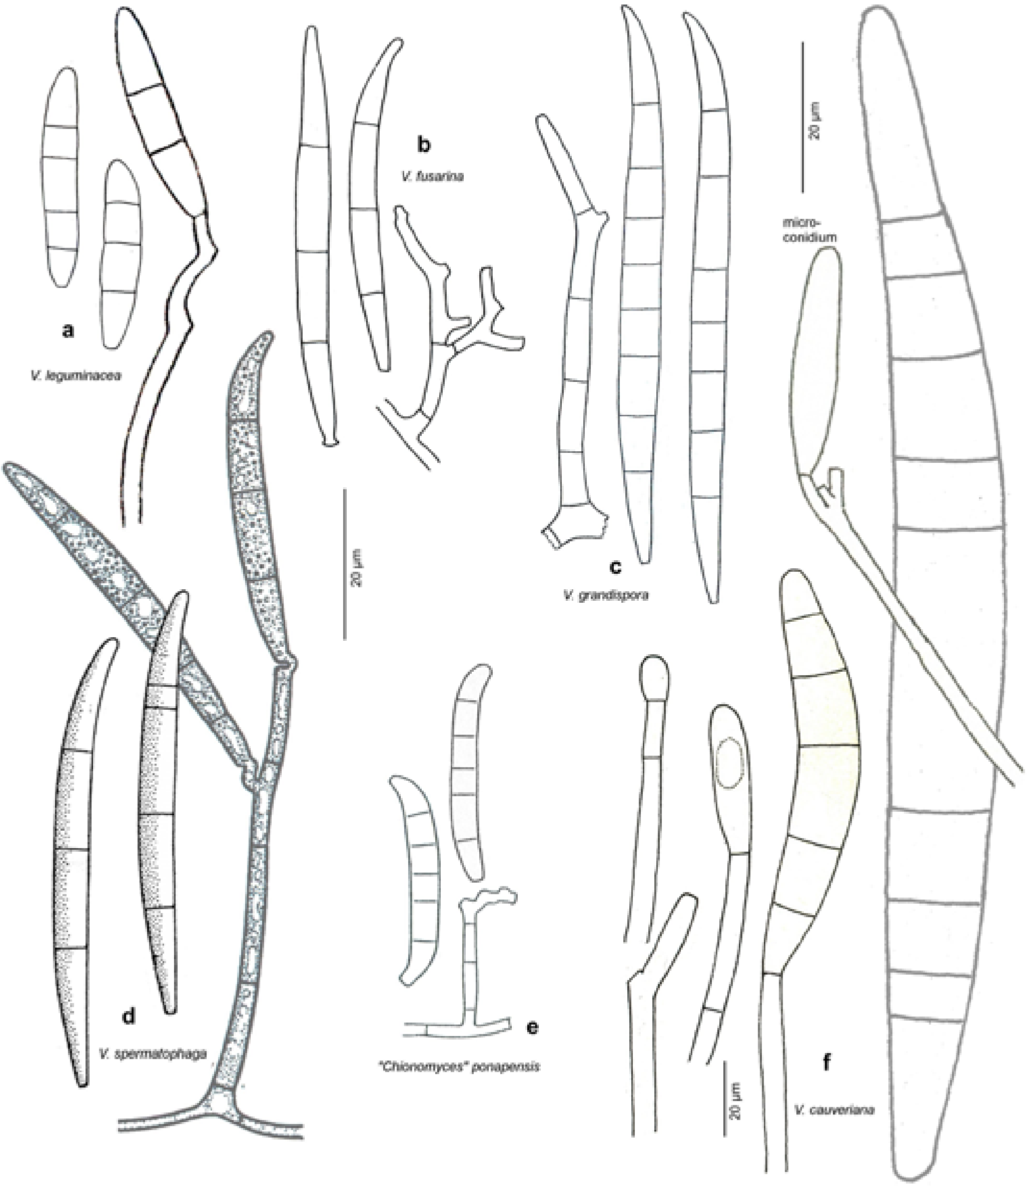

Plate 24. The accepted, hitherto known species of *Vermispora*, and '*Chionomyces*' *ponapensis*, a potential anamorph of *Orbilia* with a similar conidial shape (conidiophores and conidia). — **a**. from Chen et al. (2007a, c), **b**. from Burghouts & Gams (1989), **c**. from Deighton & Pirozynski (1972), **d**. from Drechsler (1938), **e**. from Matsushima (1983), **f**. from Rajashekhar et al. (1991).

The five *Vermispora* species were isolated from decaying herbal material, from living leaves overgrown with *Irenopsis* (*Meliolaceae*), from soil, and from nematode eggs. They have been collected in Asia, Oceania, Africa, North America, and Europe.

In the present study, *Vermispora* is tentatively considered as a synonym of *Hyalorbilia*. *Vermispora fusarina*, *V. leguminacea*, and *V. spermatophaga* are regarded as unquestionable members of *Hyalorbilia*, based on a sequence gained from apothecia of *H. rotifera* with the typical morphology of a *Hyalorbilia*, which formed together with the three *Vermispora* species and *Microdochiella fusarioides* a strongly supported clade. Because of lacking molecular data for *V. grandispora*, the synonymy of *Vermispora* remains at present uncertain. In our combined analysis of rDNA (Phyl. 2), *Hyalorbilia* formed a weakly supported clade distant from *Orbilia* and other orbiliaceous genera. Because slightly to strongly curved phragmoconidia reminiscent of *Vermispora* occur in most sections of *Orbilia*, particularly in section *Aurantiorubrae*, we refer to such anamorphs as 'vermispora-like'.

TAXONOMIC PART

Orbiliomycetes O.E. Erikss. & Baral, in Eriksson et al., Myconet 9: 96 (2003) – Type: *Orbilia* Fr. (series *Orbilia*)

1 order: ***Orbiliales*** Baral, O.E. Erikss., G. Marson & E. Weber, in Eriksson et al., Myconet 9: 96 (2003)

1 family: ***Orbiliaceae*** Nannf., Nova Acta Regiae Soc. Sci. Ups., ser. 4, 8: 250 (1932) [= *Orbiliaceae* Velen., Monogr. Discom. Bohem.: 90 (1934), nom. illegit., ICN Art. 52.1 (nomenclaturally superfluous)]

= *Trinacriaceae* Nann., Repert. mic. uomo: 473 (1934) – Type: *Trinacrium* Riess [= *Orbilia* (?series *Hemiorbilia*)]

= *Monacrosporiaceae* Locq., Mycol. gén. struct. (Paris): 207 (1984), nom. inval., ICN Art. 39.1 (Latin diagnosis missing) – Type: *Monacrosporium* Oudem. [= *Orbilia* (series *Arthrobotrys*)]

= *Helicoonaceae* Locq., Mycol. gén. struct. (Paris): 201 (1984), nom. inval., ICN Art. 39.1 – Type: *Helicoon* Morgan [= *Orbilia* (series *Helicoon*)]

Description of the class, **order and family**: — **TELEOMORPH**: **Apothecia** round to undulating, cupulate to flat or convex, sessile or sometimes distinctly stalked (stalk rarely and only a bit longer than wide), with a gymnohymenial, sometimes cleistohymenial development, superficial to erumpent, not or sometimes medium gelatinous, hyaline to bright, rarely dark-coloured, exterior smooth or with short to long prolongations being frequently agglutinated as teeth, rarely with protruding teeth-like excipular tissue. **Asci** ± cylindrical in the region of the pars sporifera, apex of dead asci either hemispherical to subconical (irrespective of the viewing direction), or ± saddle-shaped (± truncate or hemispherical depending on the viewing direction), thin- or thick-walled, never with a ring structure in the apical wall, 8–128-spored, usually some of the spores inversely oriented (if spores heteropolar), at maturity spores generally glued together to form a compact body being ejected as a single entity, arising from croziers or simple septa (then base often furcate). **Ascospores** hyaline at all development stages, almost always non-septate when mature but sometimes septate prior to germination, thin-walled, smooth or rarely warted by minute cell wall protrusions, never with sheaths or appendages, sporoplasm at maturity generally containing one or several variously shaped refractive **spore bodies** (**SBs**, visible only in living state) and a few small **lipid bodies** (LBs), rarely also **glycogen bodies**. **Paraphyses** septate, apically inflated or not, with anastomoses at the base, branched below or also above. **Excipulum** sharply or indistinctly divided into a compact ectal tissue of angular to prismatic cells and a dense or loose medullary tissue of usually a mixture of slender hyphae and inflated cells. Cortical cells at margin and flanks sometimes terminated in short to very long, solid prolongations (**glassy processes**) or septate **hairs**. Cells of paraphyses and ectal excipulum often containing globose or elongate **vacuolar bodies** (VBs), globose or crystalloid **cytoplasmic bodies** (SCBs), or globose **lipid bodies** (LBs), the former two visible only in living state, the latter often containing **carotenoids**; exterior of apothecium usually covered by a granular to cloddy, hyaline to yellowish (rarely dark-coloured) **exudate**. — **ANAMORPH**: **Mycelium** hyaline, septate, smooth, very slow- to moderately fast-growing. **Conidiophores** hyaline, thin-walled, smooth, unbranched or branched, mononematous or reduced, rarely synnematous, with holoblastic conidiogenesis, never included in a peridium. **Conidiogenous cells** monoblastic or sympodial, rarely synchronous; conidial secession schizolytic. **Conidia** hyaline, smooth, thin-walled, either unbranched (amero-, didymo-, phragmo- or scolecosporous), straight or curved (falcate to canoe-shaped, rarely helicoid), sometimes with protuberances, or variously branched (staurosporous), with straight or curved arms, 2- or 3-dimensional, lipid content low to sometimes high. **Trapping organs** known in some groups: adhesive pegs capturing rotifers in *Lecophagus*, peg-like knobs capturing rhizopods in *Hyalorbilia*, or various, mainly nematode-trapping organs (adhesive knobs, columns or networks, constricting and non-constricting rings) in 4 of the 5 series of *Orbilia* section *Arthrobotrys* (*Arthrobotrys*, *Dactylellina*, *Gamsylella*, *Drechslerella*). — **Chemical characteristics**: **IKI/MLZ**: apical and lateral ascus wall consistently inamyloid (with or without KOH-pretreatment), rarely the thickened apical endoascal wall faintly dextrinoid; glassy processes always unstained; carotenoids staining blue-green. $\mathrm{CR}_{\mathrm{SDS}}$: ascus apical thickenings and glassy processes stain rose-red, ectotunica negative. **CRB**: a very thin or sometimes thick gel layer over the walls of all kinds of cells (except ascospores) staining lilac; light-coloured exudate staining bright turquoise-blue; SBs and VBs selectively staining turquoise-blue or blue-violet, SCBs unstained. **KOH**: SBs, VBs and SCBs irreversibly disappearing; LBs, glassy processes and exudate unaltered.

Habitat: saprobiontic on various plant and fungal substrates, often invading pollen, some species preying on spores of oomycetes, eggs of nematodes, or capturing various invertebrates. **Desiccation tolerance**: hygro- to xerobiotic. **Distribution**: worldwide.

Recognized genera: *Amphosoma*, *Bryorbilia*, *Hyalorbilia* (incl. *Microdochiella* and *Vermispora*), *Lecophagus* (?incl. *Haptocara*), *Liladisca*, *Lilapila*, *Mycoceros*, *Orbilia*, *Pseudorbilia*, and *Retiarius*. with 470 recognized species plus 8 provisional names and ~83 unnamed species. For a survey on the various aspects of the class see Pfister (2015).

Characteristics of the teleomorph. Among taxa with a known teleomorph, about 470 species have been accepted in the class *Orbiliomycetes* in the present monograph, 331 of which being here described as new species. Circa 90 more or less distinctive further taxa are at present without a valid name. For ca. 50 of these roughly 560 taxa no vital characters are known because they have never been studied and documented in the living state.

Besides ascus inamyloidity, three previously frequently overlooked and therefore rarely reported features are emphasized here as most diagnostic of the class: (1) the transient spore bodies within the ascospores (being typical of all eight genera with a known teleomorph as recognized here), (2) the inverse orientation of some of the spores within the asci (typical of three of these eight genera – the other five genera lack the prerequisite for this: elongate spores with one polar spore body), and (3) the existence of unique transient plasmatic inclusions (crystalloid SCBs) in the vegetative cells (present in about 25 % of the species).

Among the teleomorph characteristics of *Orbiliomycetes*, the spore body (SB), a refractive organelle that is usually clearly visible in living spores but often undiscernible in dead spores, represents the most important key character, as it is unknown from any other group of ascomycetes. Further remarkable though not consistent characteristics of the class are: a saddle-shaped (shouldered) type of ascus apex (dead state), present in *Pseudorbilia* and in many species of *Orbilia*, and a simple-septate ascus base that is often furcate with two legs, a feature occurring throughout *Orbilia*, but also in *Amphosoma* and *Bryorbilia*.

Although the group was often characterized as having exceptionally small asci and ascospores, the at present known species diversity comprises also comparatively large asci and/or ascospores. Polyspory of asci at four different levels (16- up to 128-spored) was observed in about 34 % of *Orbiliomycetes* (ca. 140 species), although being previously only known in one species (*O. polyspora*). Large spores and/or polysporous asci are exclusively observed in desiccation-tolerant species (with exception of *Bryorbilia* which has rather large spores in 8-spored asci), whereas small spores and 8-spored asci are not only found in desiccation-sensitive species. A considerable number of desiccation-tolerant taxa have asci with an apical thickening with apical chamber, a feature completely unknown to the whole group until reported by Baral (1994). Likewise, croziers were previously not reported although consistently present in the genus *Hyalorbilia*. The inverse spore orientation is characteristic of almost all taxa in which elongate spores are heteropolar in regard to their sporoplasm (presence of a single SB near the spore apex). The morphological spectrum of characters within the *Orbiliomycetes* is enlarged to include also some species with dark-coloured, blackish-olivaceous or dark purple-lilac apothecia.

None of the many species of *Orbiliomycetes* tested with IKI showed an amyloid (eu- or hemiamyloid) reaction of the ascal walls, with or without KOH-pretreatment. This is astonishing because members of most other classes of ascomycetes, e. g., *Pezizomycetes*, *Leotiomycetes*, *Lecanoromycetes*, *Arthoniomycetes*, *Sordariomycetes*, and even *Neolectomycetes*, possess an amyloid ascus wall and/or amyloid apical ring in some or many of its members. Also the vegetative elements of *Orbiliomycetes* (paraphyses, excipular cells, hairs, anchoring hyphae) never displayed an amyloid or dextrinoid reaction of the cell wall or its gelatinous sheath. Only in a few species of subgenus *Hemiorbilia* a faint dextrinoid reaction of the internal thickenings of the ascus apical wall could be noted. Remarkable ecological characters include the frequent desiccation tolerance of both teleomorphs and anamorphs, and the ability of some groups to prey on invertebrates by means of various types of trapping organs.

Confusion with other classes. Although the *Orbiliomycetes* appear to form a natural group with sharp limits against other classes of *Ascomycota*, cases of confusion, mainly against *Leotiomycetes*, quite often happened, particularly in the older literature. Authors have included helotialean species in the family *Orbiliaceae* because of characters such as translucent, waxy-gelatinous apothecia, or capitate paraphyses, but were usually unaware of the characteristic vital characters of the class, and included even species with amyloid asci.

Spore bodies provide the most convincing morphological trait to accept *Liladisca*, *Lilapila*, *Lecophagus*, *Pseudorbilia*, and *Amphosoma* as phylogenetically related to *Orbilia* and *Hyalorbilia*. For example, *Lilapila* possesses a lens-shaped spore body very similar to that in *Orbilia* series *Lentiformes*. The prominent hair vesture of *Lilapila* recalls hairy members of the *Helotiales*, such as *Perrotia* Boud., in which genus a herbarium taxonomist would have placed this species, but thick-walled hairs similar to *Lilapila*, though hyaline, also occur in a few *Orbilia* species (e.g., *O. phragmotricha*, *O. pilosa*). Teleomorphs here referred to the genus *Lecophagus* are recognizable as orbiliaceous mainly on account of a distinct spore body and asci with inversely oriented spores. *Hyalorbilia erythrostigma* was transferred by Baral & Marson (2001) from *Pithyella* (*Helotiales*) to the *Orbiliomycetes* based on the presence of a spore body and a trinacrium-like anamorph.

Spore bodies are usually only visible in living material, therefore, studying dead herbarium specimens of such teleomorphs hardly allows to recognize the class. As an exception, SBs could be discerned in, e.g., *Liladisca acicola*, which is only known from the old type specimen. Without living spores, a member of *Lecophagus* may easily be mistaken as belonging to *Leotiomycetes*, e.g., to *Gelatinopsis* Rambold & Triebel or *Parorbiliopsis* Spooner & Dennis (= *Hyaloscypha* Boud.), and in the older literature it might have been described in genera such as *Pezizella* Fuckel or *Helotium* Pers.

Because of capitate paraphyses, Nannfeldt (1932) treated the dark-coloured *Patinella hyalophaea*, the type species of *Patinella* Sacc., in the *Orbiliaceae*. This taxon was correctly excluded from the family by Spooner (1987, see p. 208). Nevertheless, six here described orbiliaceous species with black apothecia may easily be mistaken as belonging in the *Leotiomycetes*, e.g., in *Patinella*, *Durella* Tul. & C. Tul., or *Claussenomyces* s.auct. regarding both macro- and microscopy, though only when studied in the dead state by overlooking the spore bodies and the inverse spore orientation. Only the bifurcate ascus bases would argue for a relationship with the *Orbiliomycetes*.

Our molecular data support the high diagnostic value of spore bodies as a morphological marker to place a species in the *Orbiliomycetes*. Available sequences from taxa with dark apothecia (*Lilapila* spp., *Amphosoma atroolivaceum*, *Orbilia patellarioides*) confirm their relationship within the class. Likewise, molecular data of *Hyalorbilia erythrostigma* confirm placement in *Hyalorbilia*. *Bryorbilia* strongly resembles *Orbiliomycetes* in having a bifurcate ascus base and globose SCBs in the inflated paraphysis apices, and molecular data confirmed its relationship with the class (the presence of SBs is not fully assured). Genera which lack SBs, such as *Claussenomyces* s.auct. and *Gelatinopsis*, or *Deltopyxis* clustered in the *Leotiomycetes* or *Lecanoromycetes*, respectively (Phyl. 1).

Characteristics of the anamorph. Although our monograph concentrated over a long time on the teleomorph and largely relies on the classical morphological method based on light microscopy, cultural work was later carried out on a fairly large number of species. During this study, roughly 120 species were taken into culture.

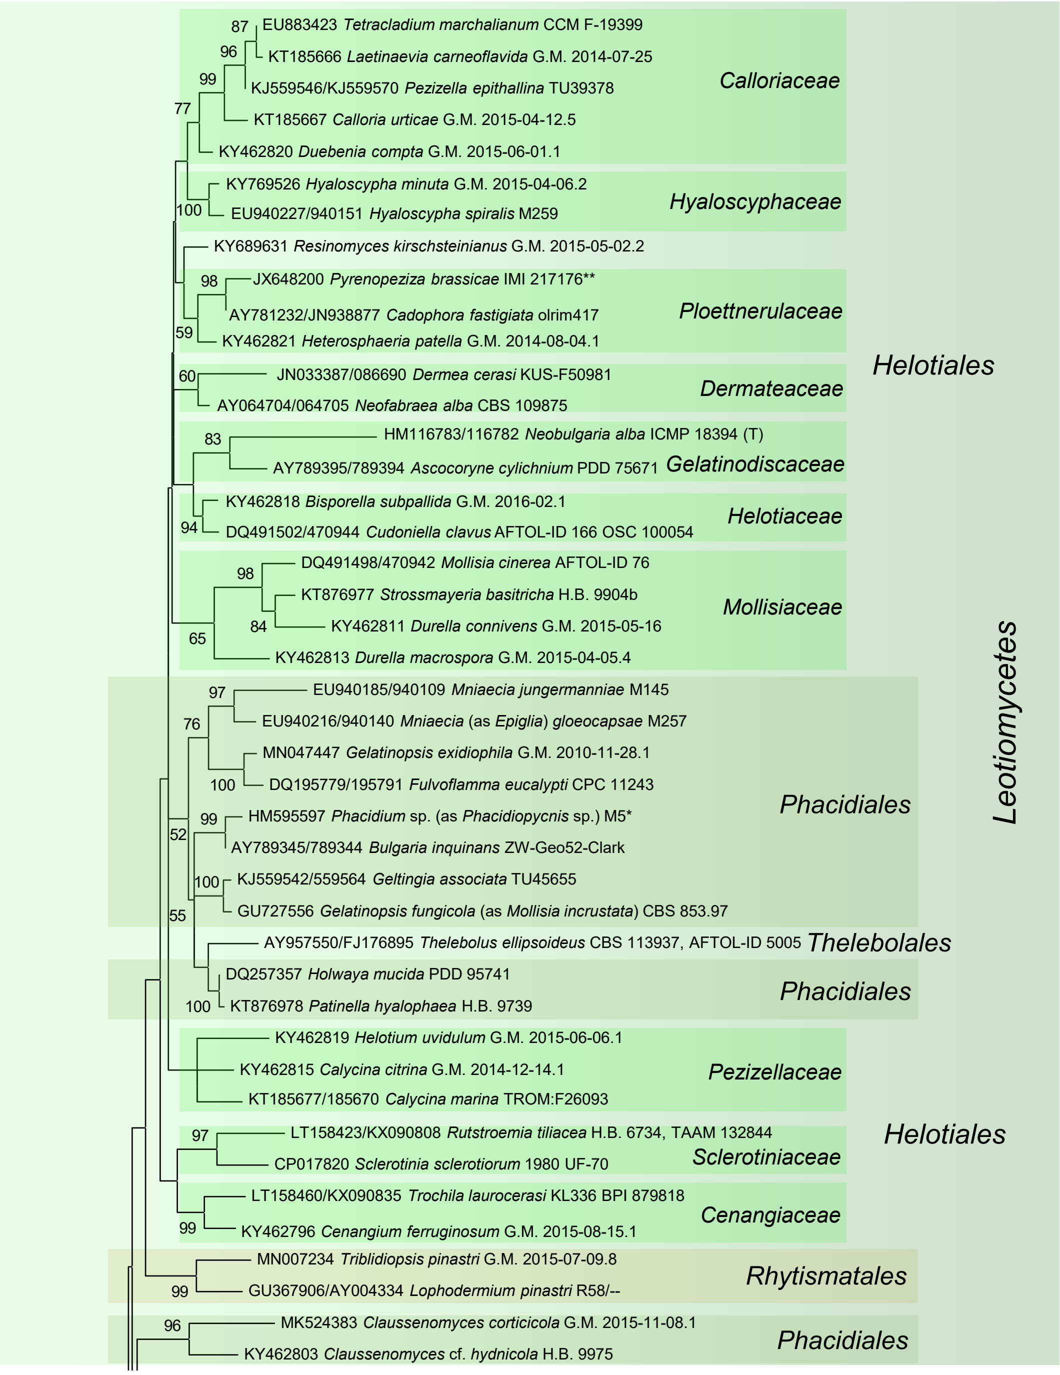
Anamorphs exist in probably all species of *Orbiliomycetes*. They exhibit a high diversity in conidial morphology, including so-called Ingoldian fungi with variously branched multicellular conidia. Such stauroconidia, though previously believed to represent an adaptation to an aquatic environment, belong to the life cycle of many desiccation-tolerant species, which occur with a vast species diversity in a largely unexplored ecological niche: substrate exposed to dry air. Despite growing under xeric conditions, often far from watercourses or lakes, their conidia are adapted to a periodically aquatic environment during rainy periods.

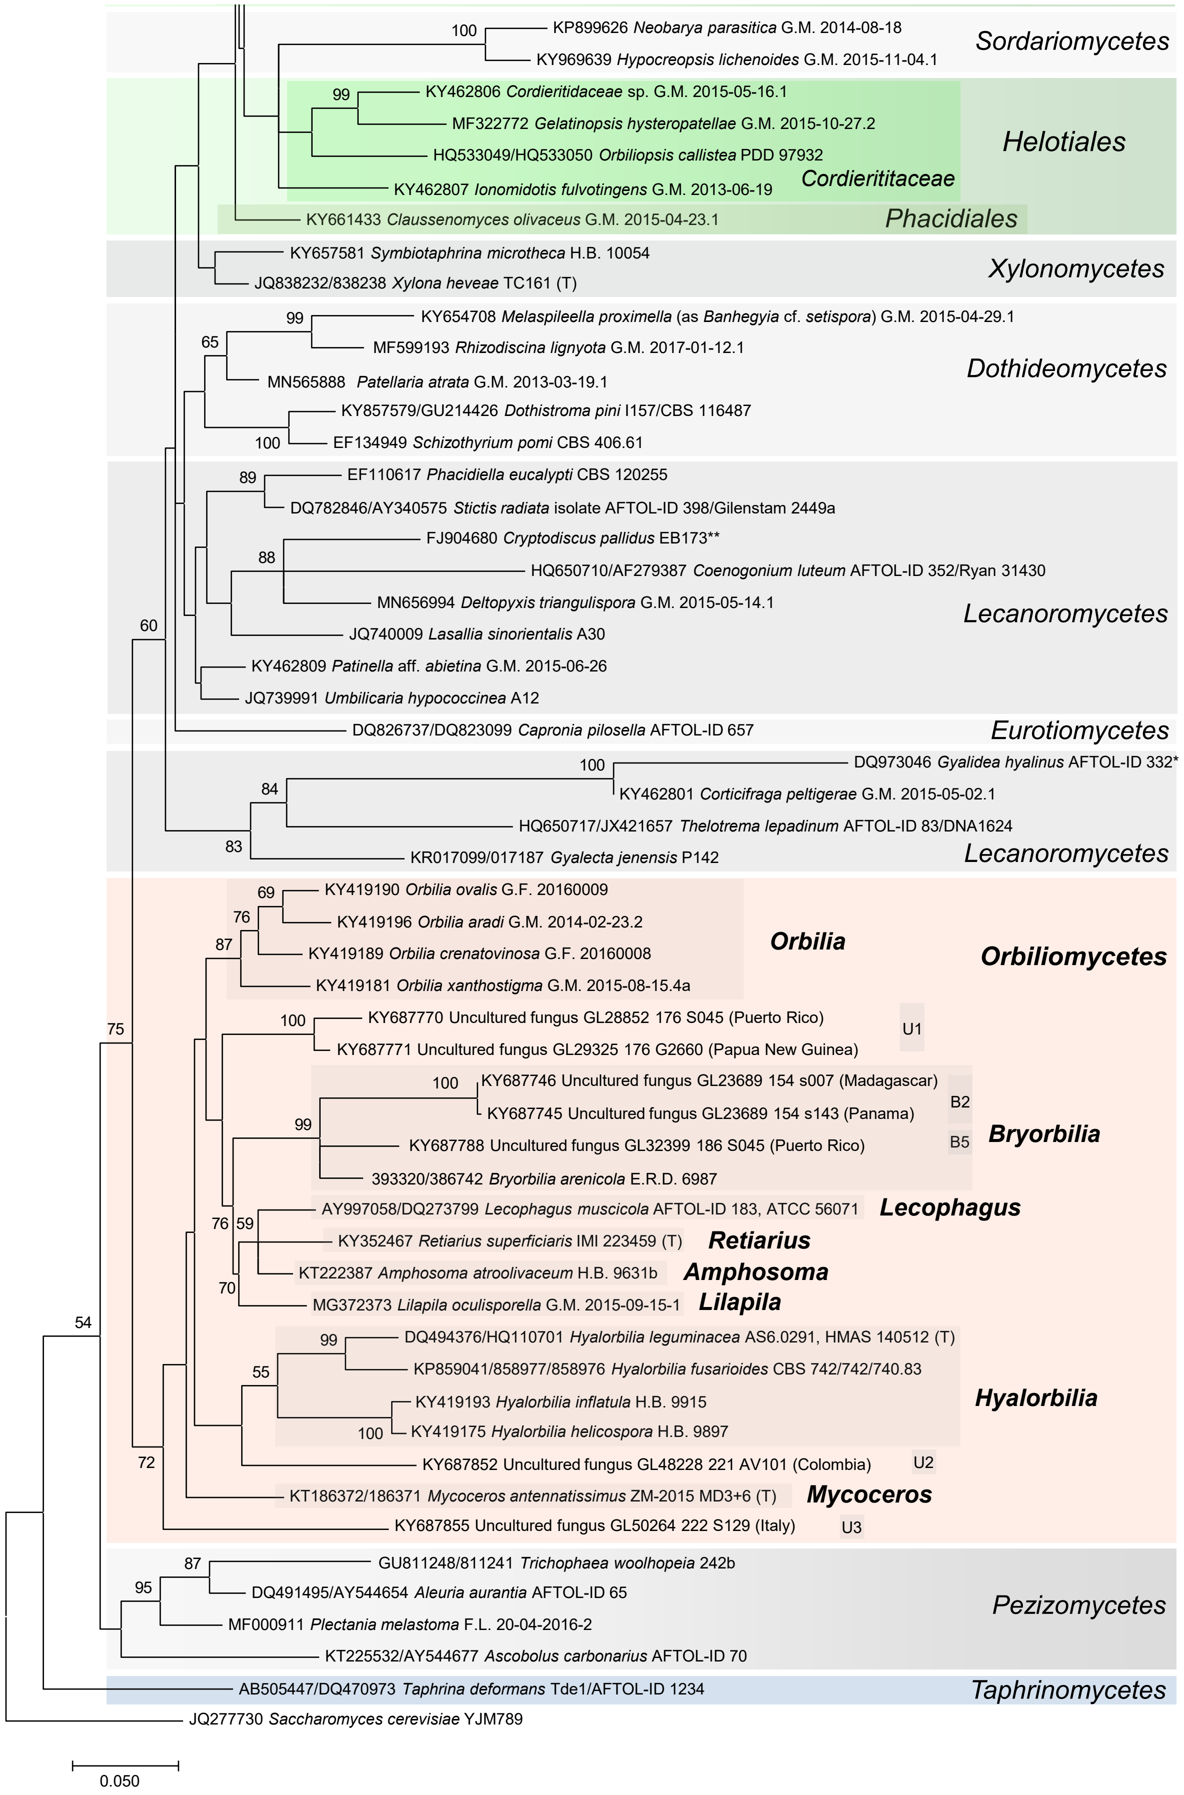
Up to the present, the connection between anamorph and teleomorph is known with certainty in 4 of the 10 recognized genera: *Lecophagus*, *Hyalorbilia*, *Amphosoma*, and *Orbilia*. Anamorphs are unknown in *Bryorbilia*, *Liladisca*, *Lilapila*, and *Pseudorbilia*, whereas *Mycoceros* and *Retiarius* are only known from their anamorph. Numerous species of orbiliaceous anamorphs have previously been recognized in about 20 genera (see p. 214 ff.), but for many of them a connection to a teleomorph is still unknown. Judging from their morphological and molecular data, a majority of them (~100 species) belong to *Orbilia* section *Arthrobotrys*, and particularly to series *Arthrobotrys* (~50 species). In the present monograph, within section *Arthrobotrys* the number of taxa with both teleomorphs and known or presumed anamorphs is comparatively low (~48), for about 14 only the teleomorph is known. It could be speculated that those taxa without a known teleomorph have lost the ability for sexual reproduction, but we suspect that their teleomorphs still remain to be discovered (see also p. 40). Out of the here accepted ca. 470 species of *Orbiliomycetes* with a known teleomorph, only ca. 140 are so far with a verified anamorph, but we report presumed anamorphs for further ~90 species (see also p. 108, Formation of conidial state).

Some orbiliaceous anamorphs are morphologically difficult to distinguish from those of other classes. This particularly concerns the anamorph-typified genera *Anguillospora* and *Helicoon*. These genera turned out to be highly polyphyletic in their current usage and include also members of *Leotiomycetes* and *Dothideomycetes*. Similarly, species today assigned to *Lecophagus* were previously merged with *Zoophagus* (*Zygomycota*) and *Cephaliophora* (*Pezizomycetes*). Conidia of the genus *Fusarium* (*Hypocreales*) closely resemble those of vermispora-like orbiliaceous anamorphs but differ in being formed from phialides.

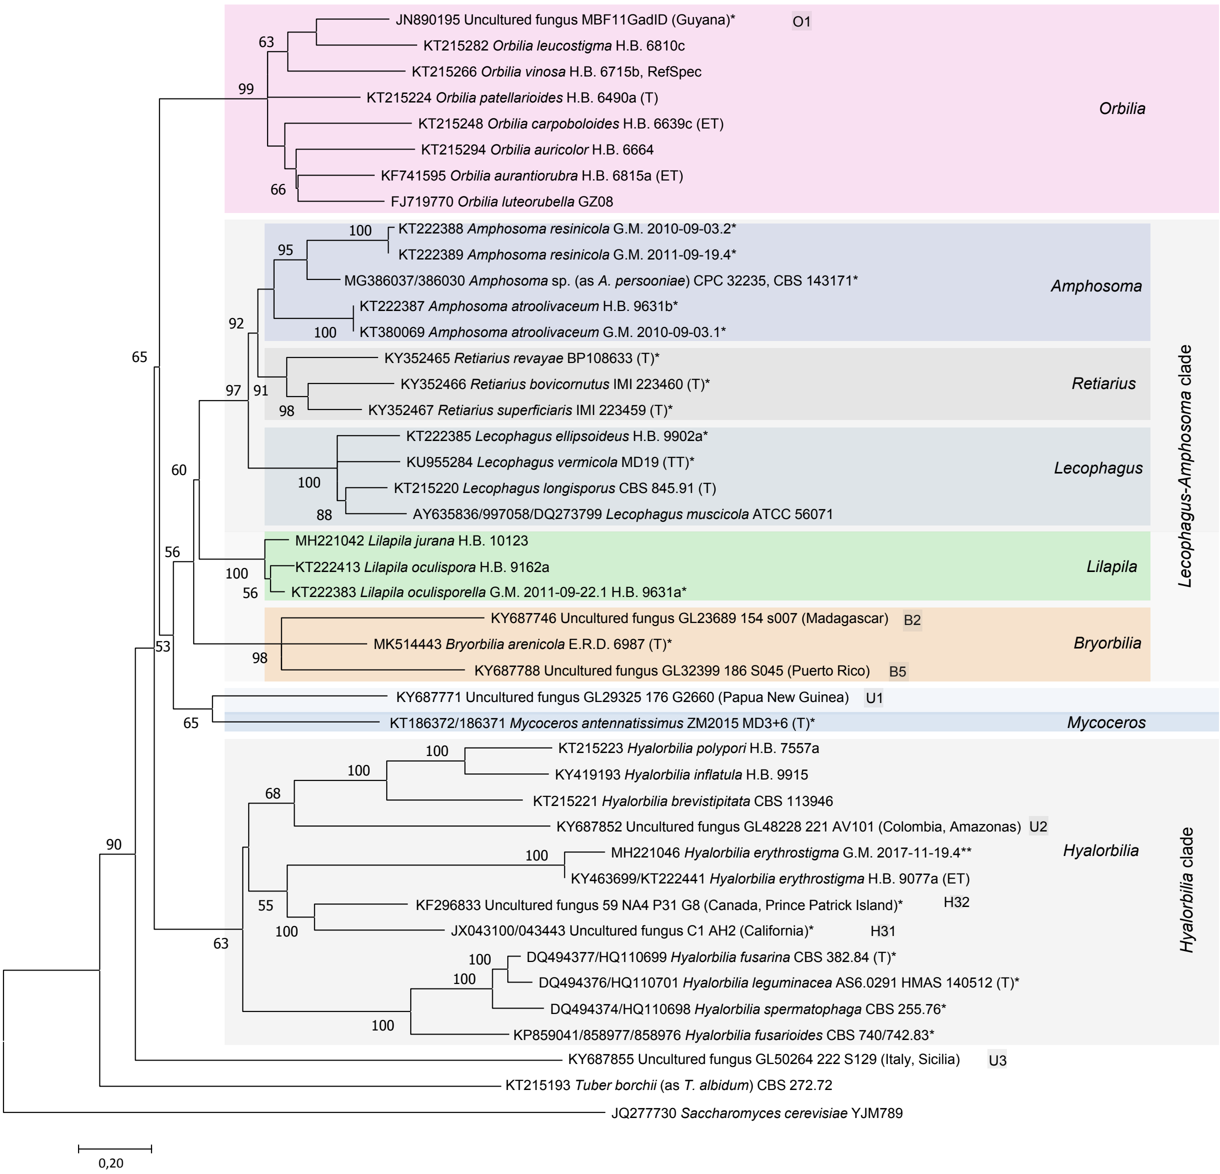
Convergent evolution is also observed in anamorphs with staurosporous conidia. For instance, dwayaangam-like conidia also occur in the *Helotiales* (*Dwayaangam colodena*). Various genera with pigmented conidia remarkably resemble orbiliaceous anamorphs in conidial shape. For instance, conidia of *Ceratosporium aequatoriale* Matsush. closely resemble *Trinacrium robustum* but have finely warted, pale brown cells. In fact, truly warted ascospores or conidia have never been observed in *Orbiliomycetes*, and also cell walls with melanin-like pigments never occurred, which suggests that the whole class is incapable to produce such pigments.

Members of *Leotiomycetes* are frequently associated with phialidic anamorphs, whereas *Orbiliomycetes* are known to produce solely holoblastic, sympodulosporous anamorphs, in which they concur with the *Pezizomycetes*. An interesting difference between the two groups lies also in the fact that polyspory of asci in *Leotiomycetes* is generally achieved by small phialoconidia formed on germinating ascospores, whereas in *Orbiliomycetes* and *Pezizomycetes* polyspory originates from multiple nuclear divisions after meiosis.





Phylogenetic analysis 1. Phylogram of *Ascomycota* inferred from combined ML analysis of 5.8S+LSU (D1–D6) rDNA dataset (97 sequences, 1686 positions, aligned with MUSCLE) using the TN+I model in MEGA7 (500 replicates), showing placement of 10 out of 12 here recognized genera of *Orbiliomycetes* within the *Ascomycota* (no sequences were available for *Pseudorbilia* and *Liladisca*). Some environmental sequences are included to indicate their affiliation in the class (B2, B5 = *Bryorbilia* spp., U1–U3 = species of unidentified genus of *Orbiliomycetes*). The tree is rooted with *Saccharomyces cerevisiae* and *Taphrina deformans*. T = type, * = without 5.8S, ** = only LSU (D1–D2); about half of the sequences without LSU (D4–D6).



Phylogenetic analysis 2. Phylogram of *Orbiliomycetes* inferred from combined ML analysis of SSU (V8–V9)+ITS1-5.8S-ITS2+LSU (D1–D2) rDNA dataset (43 sequences, 1920 positions, aligned with MUSCLE) using the GTR+G+I model in MEGA7 (500 replicates). Four main clades are recognized (*Hyalorbilia* clade, *Mycoceros*, *Lecophagus-Amphosoma* clade, *Orbilia*), whereby *Lilapila* and *Bryorbilia* are tentatively included in the *Lecophagus-Amphosoma* clade. Some selected environmental strains are included to indicate their affiliation in *Orbiliomycetes* (B2, B5 = *Bryorbilia* spp., H31, H32 = *Hyalorbilia* sp., O1 = *Orbilia* sp., U1–U3 = species of unidentified genus). The tree is rooted with *Saccharomyces cerevisiae* and *Tuber borchii*. T = type, ET = epitype, TT = topotype, * = without SSU, ** = without LSU (D2).

Phylogeny within *Orbiliomycetes*. Prior to this monograph, the subdivision of *Orbiliaceae* into genera was based on a few traits of the teleomorph, such as presence of glassy processes (*Hyalinia*) or septate hairs (*Orbiliaster*) and their absence (*Orbilia*), paraphysis apices being uninflated (*Hyalinia*), capitate (*Orbilia*), or beaked (*Habrostictis*), and apothecia being erumpent (*Habrostictis*) or superficial (remaining genera). Within *Orbilia*, infrageneric groupings followed mainly a sporological system. The present study provides evidence that all these traits have a polyphyletic origin within the class. A survey of the new system of *Orbiliomycetes* with eight included genera is given in Jaklitsch et al. (2016). At that time the genus *Retiarius* was of unclear relationship, and *Mycoceros* and *Bryorbilia* were as yet unknown.

The here presented phylogenetic trees are based on SSU, ITS, and LSU rDNA, and the S1506 intron at the 3'-end of SSU, or a combination of them. In the course of our study, rDNA sequences were taken from ca. 550 samples representing about 200 species, either from ascospore isolates or from apothecia, exceptionally from conidial isolates. A total of ca. 1400 samples with a sequence are listed in Tab. S5 as being treated in this monograph, representing ca. 320 species with a name, about 240 of them with a known teleomorph. About 225 sequences in GenBank belonging to 108 unidentified orbiliaceous species are only known from DNA isolates (abbreviated in the phylotrees as H1–37 for members of *Hyalorbilia*, O1–27 for those of *Orbilia*, etc.). On the whole, rDNA data exist for about 50% of the species treated in this monograph.

The results of our phylogenetic analyses have influenced the present classification in various ways. In many cases they confirmed conclusions gained by our morphological approach, but also provided unexpected information, particularly about the infrageneric classification of the genus *Orbilia*. The future inclusion of protein-coding genes will undoubtedly throw more light on the backbone phylogeny of the class but, irrespective of this lack of molecular data, we believe that morphological markers should be given equal attention in circumscribing taxonomic units, and even priority whenever this appears to be more logical. As a consequence, our system of classifying members of the class into genera, subgenera, sections, and series arose as a synthesis of morphological and molecular data. In the case when morphologically well-defined groups do not form monophyletic clades as, for example, series *Lentiformes* and *Phanosomates* of section *Lentiformes*, we preferred to rely more on morphology, because applying strict monophyly would inevitably result in heterogeneous assemblages, besides the impossibility to classify similar taxa for which sequences are lacking at present. We herein follow authors who accept paraphyletic taxonomic entities as a natural consequence of evolution, for instance, Brummit (2002), Davydov et al. (2010), and Gams et al. (2012b: 503).

In a recently performed Bayesian analysis of ITS-LSU rDNA by Magyar et al. (2017b), one medium and two strongly supported monophyletic main lineages could be recognized within the class: (1) the *Lecophagus* clade, which includes *Amphosoma*, *Retiarius*, *Lecophagus*, and *Lilapila*; (2) the *Hyalorbilia* clade, which includes *Hyalorbilia* s.str., *H. latispora*, the *erythrostigma-orbiliicola* clade, and the anamorph-typified genera *Vermispora* and *Microdochiella* which are considered here as congeneric with *Hyalorbilia*; (3) the large genus *Orbilia*. The two branching nodes leading to these three main lineages did not receive high support, however: the *Lecophagus* clade formed without support a sister clade to the weakly supported branch that includes *Hyalorbilia* and *Orbilia*. Magyar et al. (l.c.) described a new anamorph-typified genus and species (*Mycoceros antennatissimus*), which resembles *Retiarius* but nested very basally as a sister taxon ('*Mycoceros* clade') to all remaining *Orbiliomycetes*. That it belongs to this class is evident from the phylogenetic analysis and an evaluation of specific molecular motifs in comparison with other classes.

Sequences of *Mycoceros* and *Retiarius* were not yet available when the maximum likelihood analysis of SSU+ITS+LSU rDNA in Baral et al. (2017b) was made (erroneously as 'SSU+5.8S+LSU'). This analysis resulted in the same backbone tree topology as that of Magyar et al. (2017b), but with lacking support also at the branching node leading to *Hyalorbilia* and *Orbilia*. Magyar et al.'s Bayesian analysis included 20 species of *Orbilia*, whereas the ML analysis in Baral et al. comprised ~100 *Orbilia* species and, therefore, resolved a higher number of supported clades within the genus. Like in the entire class, the backbone phylogeny of *Orbilia* remained unresolved and the question unanswered which subgenus or section represents the ancestral one within the genus.

The present maximum likelihood analysis (Phyl. 2) additionally includes the genus *Bryorbilia*. The genus *Orbilia* formed a strongly supported clade, while the *Hyalorbilia* clade received low support. Within the *Lecophagus-Amphosoma* clade, only the genera *Amphosoma*, *Lecophagus*, and *Retiarius* clustered in a strongly supported clade. When tentatively including *Lilapila* and *Bryorbilia*, the *Lecophagus-Amphosoma* clade received only low support. Contrary to Magyar et al. (2017b), *Mycoceros* stands with low support sister to the *Lecophagus-Amphosoma*. The *Hyalorbilia* clade branches off as a sister group to all other clades, though unsupported. In Baral et al.'s (2017b) and the present ML analysis of LSU (Phyl. 4) the morphologically homogeneous genus *Amphosoma* appears paraphyletic, whereas in the Bayesian analyses of ITS+LSU by Magyar et al. (2017a, b) and our remaining ML analyses it came out as a monophyletic clade (SSU+ITS+LSU, unsupported, Phyl. 2; ITS, strongly supported (Phyl. 3).

To prove their relationship with *Orbiliomycetes* we included various environmental strains from GenBank, which were predominantly isolated from soil and clustered with *Amphosoma*, *Bryorbilia*, *Hyalorbilia*, *Lecophagus*, *Mycoceros*, *Orbilia*, *Retiarius* or unresolved in clades of their own. In cases when strains could not be assigned to a known species, we abbreviated their clades according to the first letter of the genus to which they clustered, as A1–A6, B1–B5, H1–H37, L1–L5, M1, O1–O36, R1–R4, U1–U11, and V1–V16 (U = unidentified genus of *Orbiliomycetes*, V = *Vermispora* clade of *Hyalorbilia*). For example, in our combined analysis of SSU+ITS+LSU (Phyl. 2), eight selected environmental strains which comprise more than one gene region are included. They clustered in seven different groups: three with high support (in *Orbilia* [O1] and *Bryorbilia* [B2 and B5]), four with low support (in *Mycoceros* [U1] and the *Hyalorbilia* clade [H31–H32, U2], see also Phyls 5–6), whereas the strain from Italy (U3) consistently remained unresolved. This Italy strain and that from Colombia (U2) in the *Hyalorbilia* clade show a peculiarity in the SSU V8–V9 (pos. 109 & 126) by which they concur with adhesive trap formers of *Orbilia* section *Arthrobotrys* and members of *Hyalorbilia* (see Tab. 60 and 76).

Multigene analyses are required to obtain a better supported backbone of the phylogeny of *Orbiliomycetes*. Various characteristic nucleotide positions could be detected in the available rDNA that correlate with the class or enable distinction among genera (see p. 123–129).

From a morphological point of view, the closest relatives of the large genus *Orbilia* could be sought in the small genera *Bryorbilia* and *Amphosoma*. These three genera represent all those *Orbiliomycetes* with a simple-septate, bifurcate ascus base. *Bryorbilia* and *Amphosoma* differ from *Orbilia* in ascospores with a bipolar SB arrangement and could herein resemble the common ancestor of *Orbilia*, considering also their predominant occurrence on phylogenetically old hosts (bryophytes and conifers). *Orbilia* might have descended from one of these genera by maintaining a simple-septate, bifurcate ascus base. The also small and in part conifericolous genera *Lecophagus*, *Lilapila*, and *Liladisca* share ascospores with unipolar SBs and an ascus base arising from croziers or sometimes from simple septa but never of a bifurcate shape. The genus *Liladisca* is assumed to be closely related to *Lilapila*, despite its deviating morphology regarding asci, spores, and paraphyses. The closest relative of the comparatively large genus *Hyalorbilia* should undoubtedly be sought in the small genus *Pseudorbilia*. Both have asci with croziers but differ in a hemispherical vs. truncate ascus apex. Members of the *Hyalorbilia* clade combine homopolar ascospores with mainly bipolar SBs. With this combination of characters, the *Hyalorbilia* clade possesses three plesiomorphic traits and would, therefore, most closely resemble the common ancestor of the *Orbiliomycetes*.

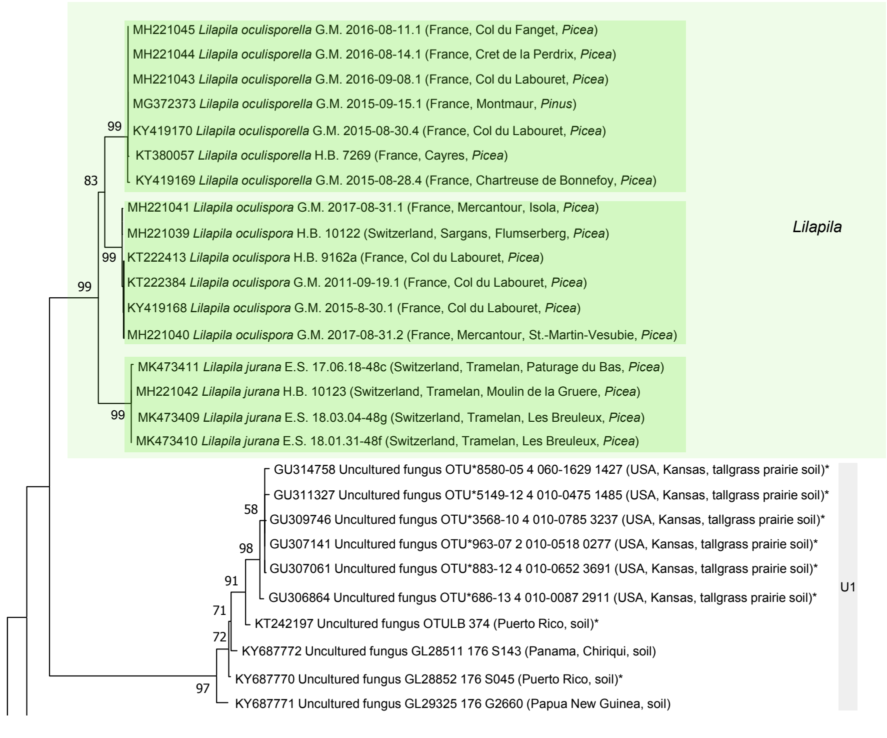
Plesiomorphic characters in *Orbiliomycetes*. We have developed hypotheses on the evolution of various morphological traits of both ana- and teleomorph within the class *Orbiliomycetes* (see the two chapters on teleomorph and anamorph morphology). Based on the combination of these traits and comparison with the situation in other classes, we present arguments about which of them might be the primary, plesiomorphic and which the secondary, apomorphic character states. Examples of characters of the teleomorph which we believe to be plesiomorphic are: desiccation tolerance of apothecia, dark pigments, equally septate, apically uninflated paraphyses, presence of croziers, hemispherical and/or thick-walled ascus apices, octospory, homopolar, globose to ellipsoid ascospores, and globose spore bodies attached by a short filum, and a bipolar arrangement of SBs.

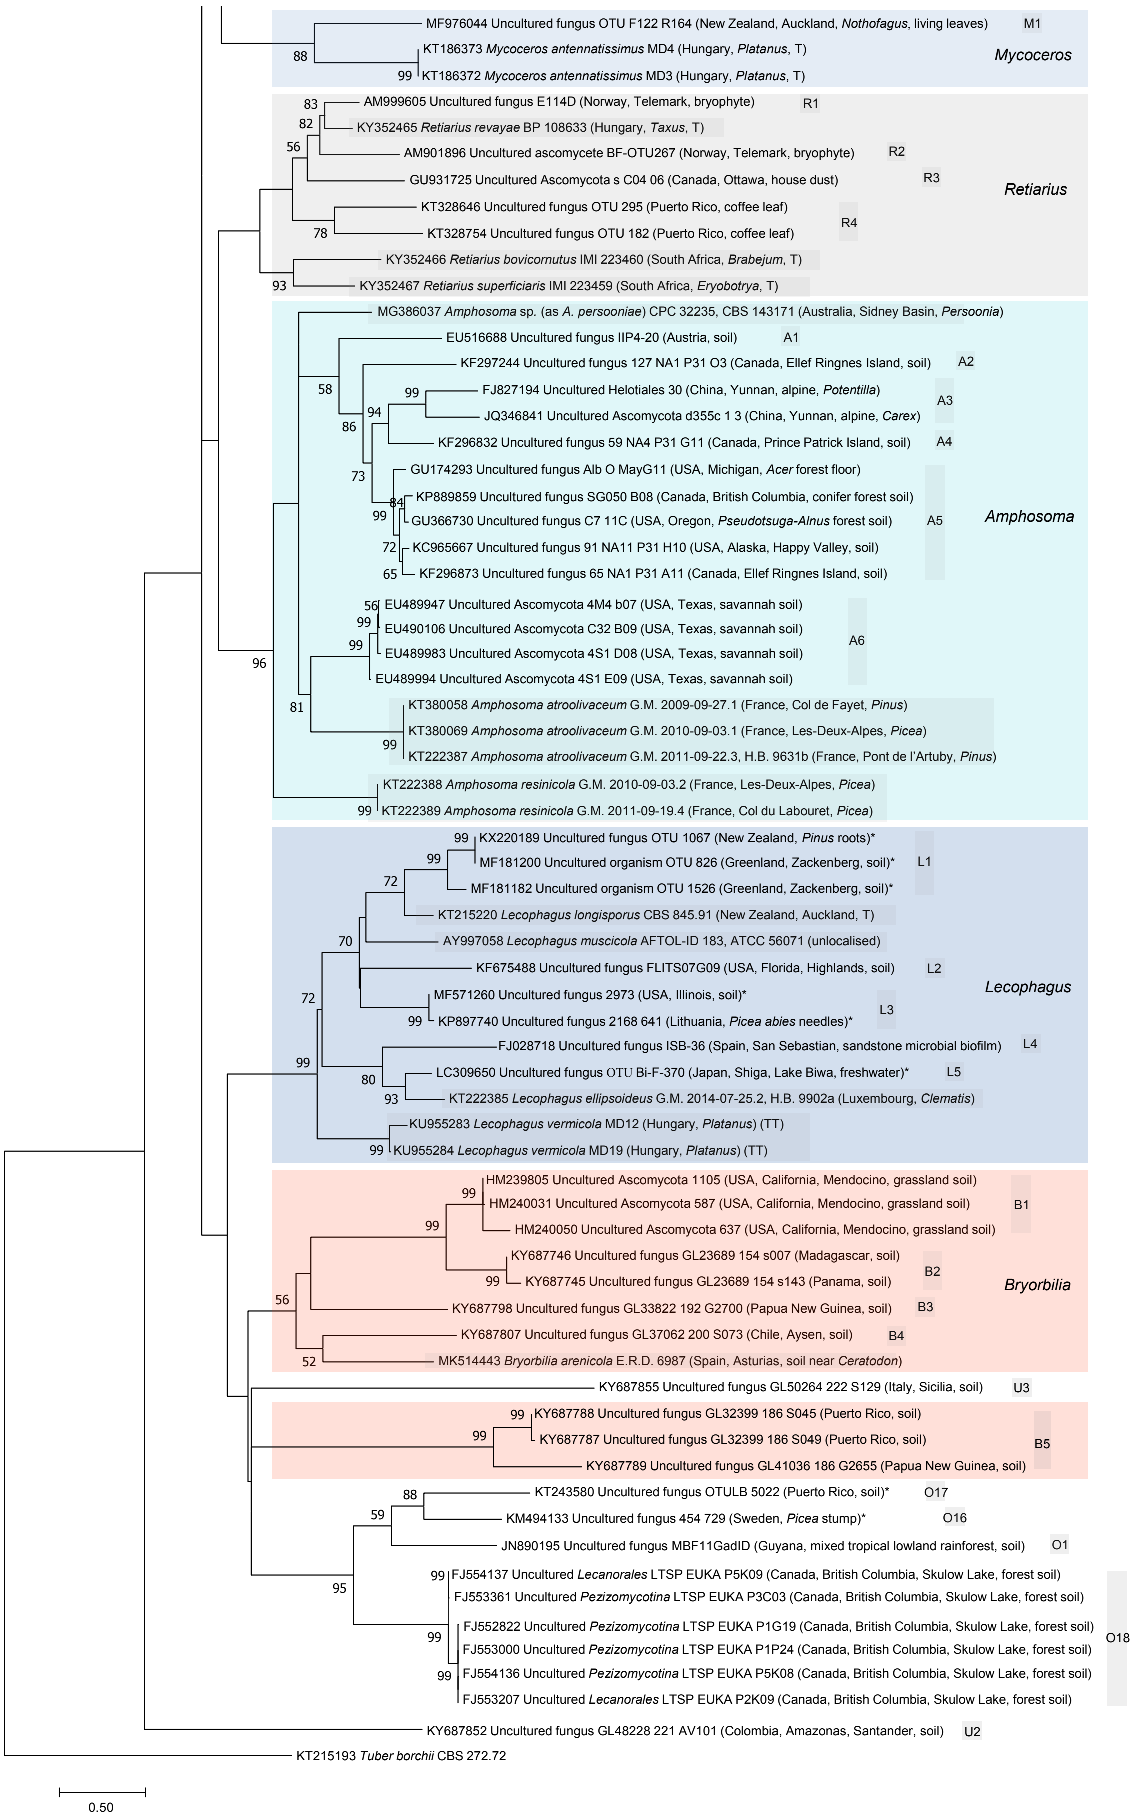
Whether crystalloid SCBs and glassy processes or hairs are plesio- or apomorphic remained unclear, but a secondary loss of these features undoubtedly occurred. Crystalloid SCBs are largely absent in *Hyalorbilia* and *Orbilia* section *Lentiformes*, which supports the hypothesis of apomorphy, but they occur as an exception in *Hyalorbilia ulicicola* and in *Orbilia cercidicola* of section *Lentiformes*, which suggests an ancient origin of these organelles. An ectal excipulum of horizontal textura prismatica, typical of *Hyalorbilia*, might have developed from a vertical t. angularis, typical of *Lilapila* and most members of *Orbilia*, but also the reverse case is imaginable, or a scenario in which both types of excipulum emerged from an intermediate case with oblique or ambiguous orientation which is found in *Amphosoma*, *Bryorbilia*, and *Lecophagus*. Plesiomorphic characters of the anamorph may include: short conidiophores, unbranched, straight conidia, and adhesive pegs as trapping device. A survey of selected characters is shown in Tab. 56.

Our hypotheses on plesiomorphic characters within *Orbiliomycetes* is supported to some extent by our molecular analyses, which confirm that *Amphosoma*, *Bryorbilia*, *Hyalorbilia*, *Lecophagus*, and *Lilapila* represent the ancestral group of the class (no DNA data exist for *Liladisca* and *Pseudorbilia*). Within *Orbilia* it is subgenus *Hemiorbilia* which complies best with this set of morphological criteria, and within that subgenus it is series *Vibrioides* of section *Hemiorbilia* and a majority of section *Lentiformes* which appear to form the phylogenetically older part, whereas a majority of section *Hemiorbilia* and a small minority of section *Lentiformes* (series *Ovales* and *Cercidicola*) might represent younger parts of the group. Also section *Ovoideae* of subgenus *Orbilia* complies with the above criteria to a certain degree, except that the ascus apices are predominantly thin-walled and truncate, the paraphyses often apically inflated, and glassy processes and crystalloid SCBs present in some species. Croziers occur in *Bryorbilia*, *Hyalorbilia*, *Lecophagus*, *Liladisca*, *Lilapila*, and *Pseudorbilia*, but in combination with a thick-walled ascus apex they occur only in *Lecophagus*.

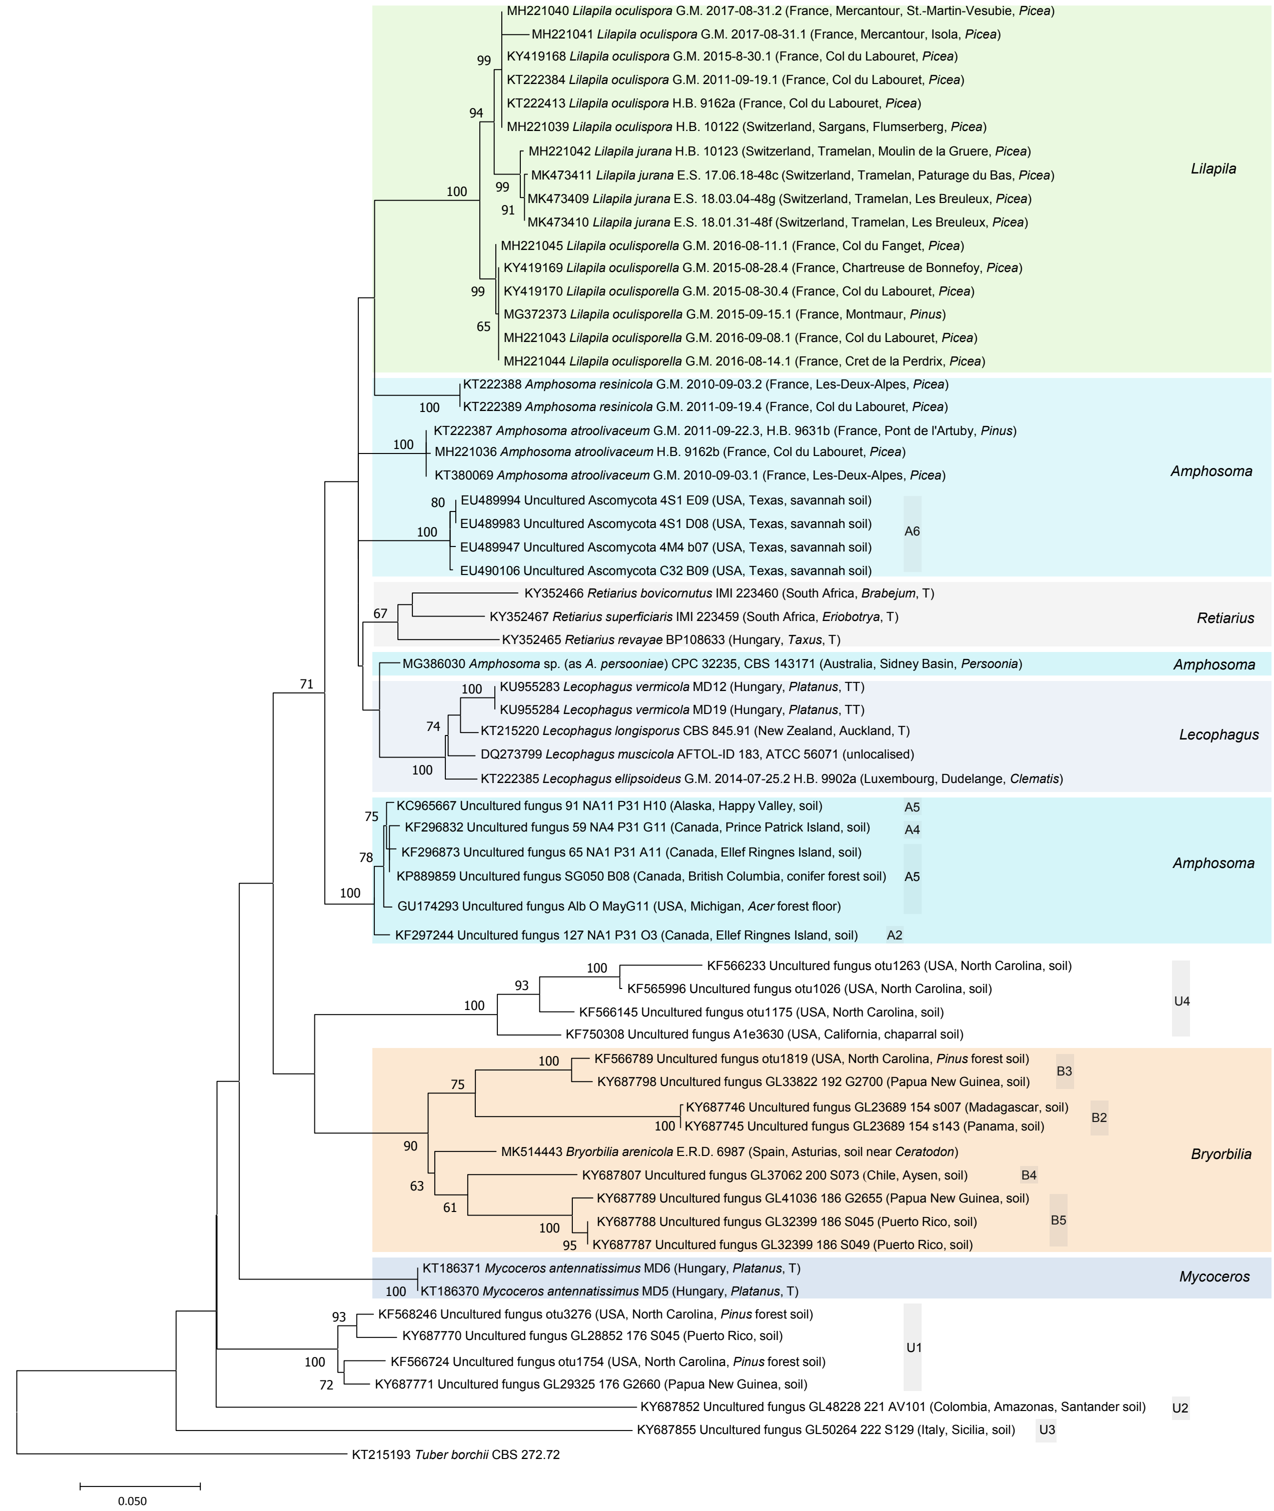
Whether the lens- or the lantern-shaped type of SBs represents the more plesiomorphic spore body type is difficult to determine. Besides series *Lentiformes*, lens-shaped SBs are characteristic of *Lilapila*, *Pseudorbilia*, and *Amphosoma*. They also occur in *O. microlentiformis* (series *Microsomates* of subgenus *Orbilia*) and inconsistently in *O. multicreosoteris* and *O. yuccae* (section *Ovoideae*). A tendency to lens-shaped SBs is observed in *Hyalorbilia multiguttulata*, in which globose SBs may get flattened at the attachment to the wall. More or less lantern-shaped SBs with a rather long filum are typical of series *Phanosomates*. The lantern-shaped type much more resembles the here postulated ancient type of SB which is globose and attached by a short, visible or invisible filum. This hypothesis would be in concordance with the general ontogeny of vacuoles as globose vesicles with a short and narrow attachment to the plasmalemma. Globose SBs attached by a short filum occur in *Lecophagus* but also in various groups of *Orbilia*. Also in *Hyalorbilia* roundish SBs with a filiform attachment appear to be typical but this attachment is usually below the resolution of the light microscope.

The bipolar arrangement of SBs is characteristic of *Amphosoma*, *Pseudorbilia*, and *Hyalorbilia* p.p.maj., and was observed in the large genus *Orbilia* only in abnormal spores as an exceptional case of regression. The reduction from bipolar to unipolar and also the migration of the SB attachment from apical to lateral appears to have occurred polyphyletically in different lineages. Within *Hyalorbilia* *H. erythrostigma* and *H. orbiliicola* (with unipolar SBs) clustered in a clade distant from the majority of taxa, all of





Phylogenetic analysis 3. Phylogram of *Lecophagus-Amphosoma* clade (see Phyl. 2) and *Mycoceros* inferred from ML analysis of ITS1-5.8S-ITS2 rDNA dataset (94 sequences, 1187 positions, aligned with MUSCLE) using the GTR+G+I model in MEGA7 (500 replicates). The genera *Amphosoma*, *Bryorbilia*, *Lecophagus*, *Lilapila*, *Mycoceros*, and *Retiarius* are well resolved, but their relationship among each other remained unsupported. Environmental strains from GenBank clustered in supported clades with species of known genera (A1–A6 = *Amphosoma* spp., B1–B5 = *Bryorbilia* spp., L1–L5 = *Lecophagus* spp., M1 = *Mycoceros* sp., R1–R4 = *Retiarius* spp.) or formed clades with unresolved relationship (U = unidentified genus). The tree is rooted with *Tuber borchii*. T = type, TT = topotype, * = without ITS1 and partial 5.8S.



Phylogenetic analysis 4. Phylogram of *Lecophagus-Amphosoma* clade (see Phyl. 2) and *Mycoceros* inferred from ML analysis of LSU (D1–D3) rDNA dataset (63 sequences, 945 positions, aligned with MUSCLE) using the GTR+G+I model in MEGA7 (500 replicates). Except for *Amphosoma*, the recognized genera are well resolved, but their relationship among each other remained unresolved. Environmental sequences assigned in Phyl. 3 to *Amphosoma* (A1–A6) likewise clustered in clades with unresolved relationship. U = unknown genus of *Orbiliomycetes*. The tree is rooted with *Tuber borchii*. T = type, TT = topotype; without LSU (D3) in some sequences.

which being characterized by bipolar SB arrangement (Phyls 2, 7); whether the common ancestor possessed bipolar SBs is unclear since teleomorphs in several basal anamorph genera are unknown and our sequence of *H. latispora* (with bipolar SBs and isolated position) needs confirmation.

Ecology. Species of *Orbiliomycetes* form their apothecia as saprobionts on usually strongly decayed bark and wood, also herbaceous stems, sometimes basidiomycetes or pyrenomycetes, exceptionally dung or other residues of animals, and soil. Some species are adapted to rather undecayed bark and wood, or occur on more or less decayed resin of conifers. *Orbiliomycetes* inhabit a wide range of climatic regions, extending from humid to arid vegetation types. A more or less pronounced desiccation tolerance of the apothecia (xerobiotic species) applies to ~80% of *Orbiliomycetes* (455 out of a total of ca. 575 species treated in our study, unnamed

Key to genera of *Orbiliomycetes* based on characters of the teleomorph

(including easily confusable discomycetous genera with hyaline ascospores belonging to *Leotiomycetes*, *Lecanoromycetes*, *Pezizomycetes*, or apothecioid *Dothideomycetes*)

1. Asci amyloid[1] (apical ring and/or entire outer ascus wall); living mature ascospores eguttulate or containing globose refractive inclusions ('guttules') in a generally symmetrical arrangement, guttules KOH-resistant (LBs[2]), rarely KOH-sensitive (VBs[3]).......[certain genera of ***Helotiales*** (e. g., ***Laetinaevia***), ***Pezizales*** (e. g., ***Iodophanus***), ***Ostropales*** (e. g., ***Coenogonium***), ***Lecanorales*** (e. g., ***Scutula***), ***Agyriales*** (e. g., ***Agyrium***) etc.]

1. Asci inamyloid, when KOH-pretreated without any trace of a blue iodine reaction 2

2. Asci 8-spored, frequently producing small phialoconidia directly from the spores (often as ascoconidia formed already inside living asci); living ascospores never containing SBs[4] (or VBs[2]); apex of dead asci never truncate, apical or rarely lateral wall slightly to strongly thickened; hymenial parasite in apothecia of *Orbilia* spp. (if apothecia dark-coloured compare members of *Tympanidaceae*)...... .... ***Helicogonium*** (?***Phacidiales***)[5]

2. Asci 8- or multispored (by multiple mitoses), spores not producing small phialoconidia; living ascospores usually containing SBs (one or more per spore); apex of dead asci hemispherical to conical or truncate, with or without apical thickening 3

3. Apothecia macroscopically black, under transmitted light appearing bright purplish or olivaceous 4

3. Apothecia macroscopically white, yellow, ochre, rose, orange, red, rarely greyish-brownish-vinaceous, under transmitted light appearing hyaline or pale yellow, rose-orange, or ochraceous 9

4. Tissue deep purple-lilac under transmitted light; asci arising from croziers 5

4. Tissue dark olivaceous, blue-green, or grey-brown under transmitted light 6

5. Apothecia 0.3–0.4 mm diam., with a crenulate, hairless margin; spores narrowly fusoid-clavate, †7–11.5 × 1.5–1.8 µm, with a single tear-shaped SB at upper end (faintly visible in dead state); apices of paraphyses capitate, covered by deep purple caps of exudate; medullary excipulum hardly different from ectal excipulum; fallen needles of *Pinus*, temperate .... ***Liladisca***, p. 259

5. Apothecia 0.4–2(–4) mm diam., covered with dark purple-lilac, thick-walled, septate, finely warted hairs 50–200 × 6–9 µm; spores (sub) globose, *3–4.8 × 2.5–4.7 µm, with a single, broadly attached, lens-shaped SB; paraphyses not apically inflated, purple exudate between them but not on top; medullary excipulum sharply differentiated from ectal excipulum; resinous wounds of xeric branches or trunks of conifers, orotemperate to suprasubmediterranean .... ***Lilapila***, p. 262

6. Asci usually bitunicate: in dead state both apical and lateral wall often strongly thickened, 8- or multispored, usually arising from croziers; living spores without SBs, lipid content high or low .... ***Patellaria*** (*Dothideomycetes*), ***Symbiotaphrina*** (*Xylonomycetes*), ***Deltopyxis*** (*Lecanoromycetes*)

6. Asci unitunicate: in dead state laterally thin-walled, 8- or 16-spored, arising from simple septa (ascus bases ± bifurcate); living spores containing ± distinct SBs, lipid content ± low 7

7. Exudate light to dark grey-brown; spores *4.2–7.5 × 1–1.4 µm, SBs very small, ± eccentric; margin with glassy processes; hygric angiosperm wood, temperate .... ***Orbilia polybrocha*** (**series *Drechslerella***), p. 1631

7. Exudate dark olivaceous to blue-green; spores *5–17 × 2.3–4.2 µm; apothecia with ± smooth margin without glassy processes; xeric wood and bark, boreal or mesomediterranean 8

8. Living spores with 2 SBs (one at each end); living paraphyses and marginal excipulum containing globose, strongly refractive VBs .... ***Amphosoma***, p. 271

8. Living spores with a single apical SB; living paraphyses and marginal excipular cells without VBs .... **series *Lentiformes*** (**subgenus *Hemiorbilia***), p. 459, and ***Orbilia olivacea*** (**section *Ovoideae***), p. 1290

9. Anchoring hyphae *(5–)6–13(–17) µm wide, each cell usually containing one or a few cubical refractive bodies (SCBs[6]) 0.4–2 µm diam. in their centre; dead asci with a hemispherical to indistinctly mammiform apex with a small lens-shaped apical thickening; apothecia white, 0.08–0.25 mm diam.; spores subglobose to ellipsoid, *3.8–8 × 3–4.6 µm, with a single globose SB shortly connected to the spore apex; xeric wood & bark, parasitic on rotifers etc., subarctic to submediterranean .... ***Lecophagus***, p. 287

9. Anchoring hyphae *1.5–6 µm wide (only exceptionally wider), without central cubical bodies; dead asci with a hemispherical or truncate (partly saddle-shaped) apex, apical thickening absent or present (then almost as broad as ascus) 10

10. Living spores without SBs, with low to high lipid content, ellipsoid to oblong; ascus base never distinctly furcate .... ***Calloria***, ***Calloriopsis***, ***Gelatinopsis***, ***Laetinaevia*** etc. (***Helotiales***), ***Thelebolus*** (***Thelebolales***)[7]

10. Living spores mostly with one or several SBs, lipid content mostly low 11

11. Spores with a single SB in each spore [if SBs absent then ascus apex (†) distinctly truncate in front view], variously shaped; asci 8–128-spored; hymenial elements not firmly conglutinated in gel; plurivorous, from subarctic to temperate and tropical. ***Orbilia***, p. 444
If asci with croziers compare also *Hyalorbilia erythrostigma* (p. 417) and *H. orbiliicola* (p. 424).

11. Spores consistently with two or more SBs, situated near both ends or in both halves of the spore [if no SBs present then ascus apex (†) ± hemispherical]; asci 8(–16)-spored 12

12. Asci arising from simple septa, ascus base ± furcate or T- to L-shaped (exceptionally a few perforated croziers may occur among the simple-septate ascus bases); apex (†) with or without internal wall thickening; paraphyses multiguttulate or without VBs 13

12. Asci consistently arising from croziers (sometimes perforated, looking bifurcate); apex (†) without internal wall thickening; paraphyses and marginal excipulum usually with globose to often elongate, low- to medium refractive, hyaline to pale chlorinaceous VBs 14

13. Asci (†) often with internal wall thickening at apex, laterally always thin-walled; terminal cell of paraphyses containing a few large or many small, always globose and strongly refractive, hyaline VBs, without SCBs; spores with one SB at each end; xeric bark, wood & resin, temperate to subtropical .... ***Amphosoma***, p. 271

13. Asci (†) apically always thin-walled but laterally thick-walled when immature; terminal cell of paraphyses containing one globose refractive SCB, without VBs; spores with various small and large SBs; soil among moss, suprasubmediterranean ...... ***Bryorbilia***, p. 302

14. Hymenial elements non-gelatinized, easily separable; ectal excipulum at flanks of textura angularis; ascus apex (†) hemispherical (to conical) or strongly truncate depending on viewing direction; spores with one lens-shaped SB at each end; anchoring hyphae 1.2–2.5 µm wide, not radiating; apothecia white, 0.09–0.35 mm diam.; wood or bryophytes, subboreal to subtropical .... ***Pseudorbilia***, p. 305

14. Hymenial elements usually strongly gelatinized and conglutinate; ectal excipulum at flanks of horizontal t. prismatica (sometimes short-celled); ascus apex (†) hemispherical to conical or subtruncate irrespective of viewing direction; spores with 1–6 SBs towards each end; anchoring hyphae (1.3–)2–5(–10) µm wide, often radiating to form a hairy apothecial base; apothecia whitish to chlorinaceous or yellow, rarely reddish, 0.05–5 mm diam.; plurivorous, boreal to tropical .... ***Hyalorbilia***, p. 307

[1]) amyloid = parts of the ascus wall stain faintly to strongly blue (euamyloid) or red (hemiamyloid) when applying IKI directly, or consistently blue in IKI or MLZ when KOH-pretreated.

[2]) LBs = lipid bodies (oil drops). LBs represent a storage organelle for energy reserves. They are consistently globose inside living cells, but tend to fuse to irregular aggregations in damaged cells.

[3]) VBs = refractive vacuolar bodies. VBs are usually only visible in the living state; they disappear in KOH and selectively stain turquoise in CRB when applied to living cells. Usually they occur in the cells of paraphyses and marginal excipulum, but in some species in ascospores or conidia. They are either small and globose (multiguttulate) or large and globose to ellipsoid or very elongate.

[4]) SBs = spore bodies. SBs are a special type of refractive vacuolar bodies (VBs) inside the ascospores that are only known to occur in the *Orbiliomycetes*. Like vacuoles they are formed by invagination of the plasmalemma and stain with basic dyes; yet, they remain attached to the plasmalemma, either broadly or by a narrow point or filum (when very narrow the filum is invisible under the light microscope).

[5]) Members of *Helicogonium* do not produce ascomata but grow as intrahymenial parasites in ascomata of discomycetes (*Orbiliomycetes*, *Helotiales* and other orders) by forming asci among the paraphyses of the host, and often completely suppressing the asci of the host. Three species are known to occur in apothecia of *Orbilia*: *H. fusisporum* with fusoid ascospores with large LBs (conidia unknown), *H. orbiliarum* and *H. hyphodisci* with ellipsoid to subglobose, almost eguttulate ascospores, the former budding off ellipsoid ascoconidia, the latter cashew-shaped ascoconidia.

[6]) SCBs = KOH-sensitive ('soluble') cytoplasmic bodies. SCBs are ± refractive, variously shaped organelles which are only visible in the living state. They disappear in KOH and, contrary to VBs, do not stain in CRB.

[7]) Compare also couplet 13 (a few species of *Orbilia* and *Hyalorbilia* are without SBs; *Hyalorbilia* is then difficult to separate from *Gelatinopsis*, even on the basis of living material).

taxa included), whereas ± desiccation-sensitive apothecia (hygrobiotic species) were observed in ~20 % (ca. 120 species; see also Tab. 5).

Predatory capabilities, mainly of the anamorph, are so far observed with certainty in *Hyalorbilia* (testaceous rhizopods, nematode eggs), *Lecophagus* (rotifers and nematodes), and *Orbilia* (nematodes, copepodes, arthropods). Utilization of pollen as additional nutrient source is observed in many taxa but is especially typical of *Mycoceros* and *Retiarius*, and utilization of oospores occurs in *Hyalorbilia*.

Table 56. Synoptic table of genera of *Orbiliomycetes* with known teleomorph (presumed plesiomorphic features are highlighted in bold; for a more detailed treatise see Tab. S3). Explanation: **Apothecial pigment**: hyal = ± hyaline/white, red = yellow/orange/rose/lilaceous, oliv = black-olivaceous/blue-green. **Ascus apex**: con = conical, hem = hemispherical, trc = truncate, thin = thin-walled, lent = lens-shaped thickening, thick = broad thickening (often with apical chamber); **ascus base**: + = croziers, – = predominantly simple septate. **Ascospore shape**: g = (sub)globose, e = ellipsoid, c = cylindrical, f = fusoid/fusiform, t = with a tail; **ascospore curvature**: – = not curved, + = slightly to strongly curved; **number of spore bodies**: 1 = one SB per spore (usually apically), 2+ = two or more SBs per spore; **spore body shape**: g = ± globose, l = lens- (to plug-)shaped, t = tear-shaped, v = vermiform/filiform. **Paraphysis apex**: 0 = not inflated, 4 = very strongly inflated; **exudate over paraphyses**: -/+ = absent/present. **Ectal excipulum** at lower flanks: │ = vertical textura angularis or t. prismatica (70–90°), ⁄ = obliquely oriented t. prismatica (20–70°), — = horizontal t. (angularis-)prismatica(-porrecta) (0–20°). **Hairs**: – = without hairs, s = septate hairs, g = glassy processes. **Cell inclusions in paraphyses and excipular cells (or sometimes in conidia)**: **VBs**: g = with strongly refractive, globose guttules, e = with low- to medium refractive, soon elongate vacuoles; **SCBs**: a = small angular (cubical) central bodies, g = globose, hyaline, low-refractive bodies, c = crystalloid, partly pigmented, refractive bodies. **Anchoring hyphae**: n = narrow (< 5 µm), w = wide (> 5 µm). **Desiccation tolerance of apothecia**: t = desiccation-tolerant, s = desiccation-sensitive. **Anamorph**: bra = brachyphoris-like, cur = curucispora-like, dwa = dwayaangam-like, lec = lecophagus-like, tri = trinacrium-like, ver. = vermispora-like, var. = anguillospora-, arthrobotrys-, curucispora-, dactylella-, dactylellina-, descalsia-, dicranidion-, drechslerella-, dwayaangam-, helicoon-, tridentaria-, trinacrium-, and vermispora-like.

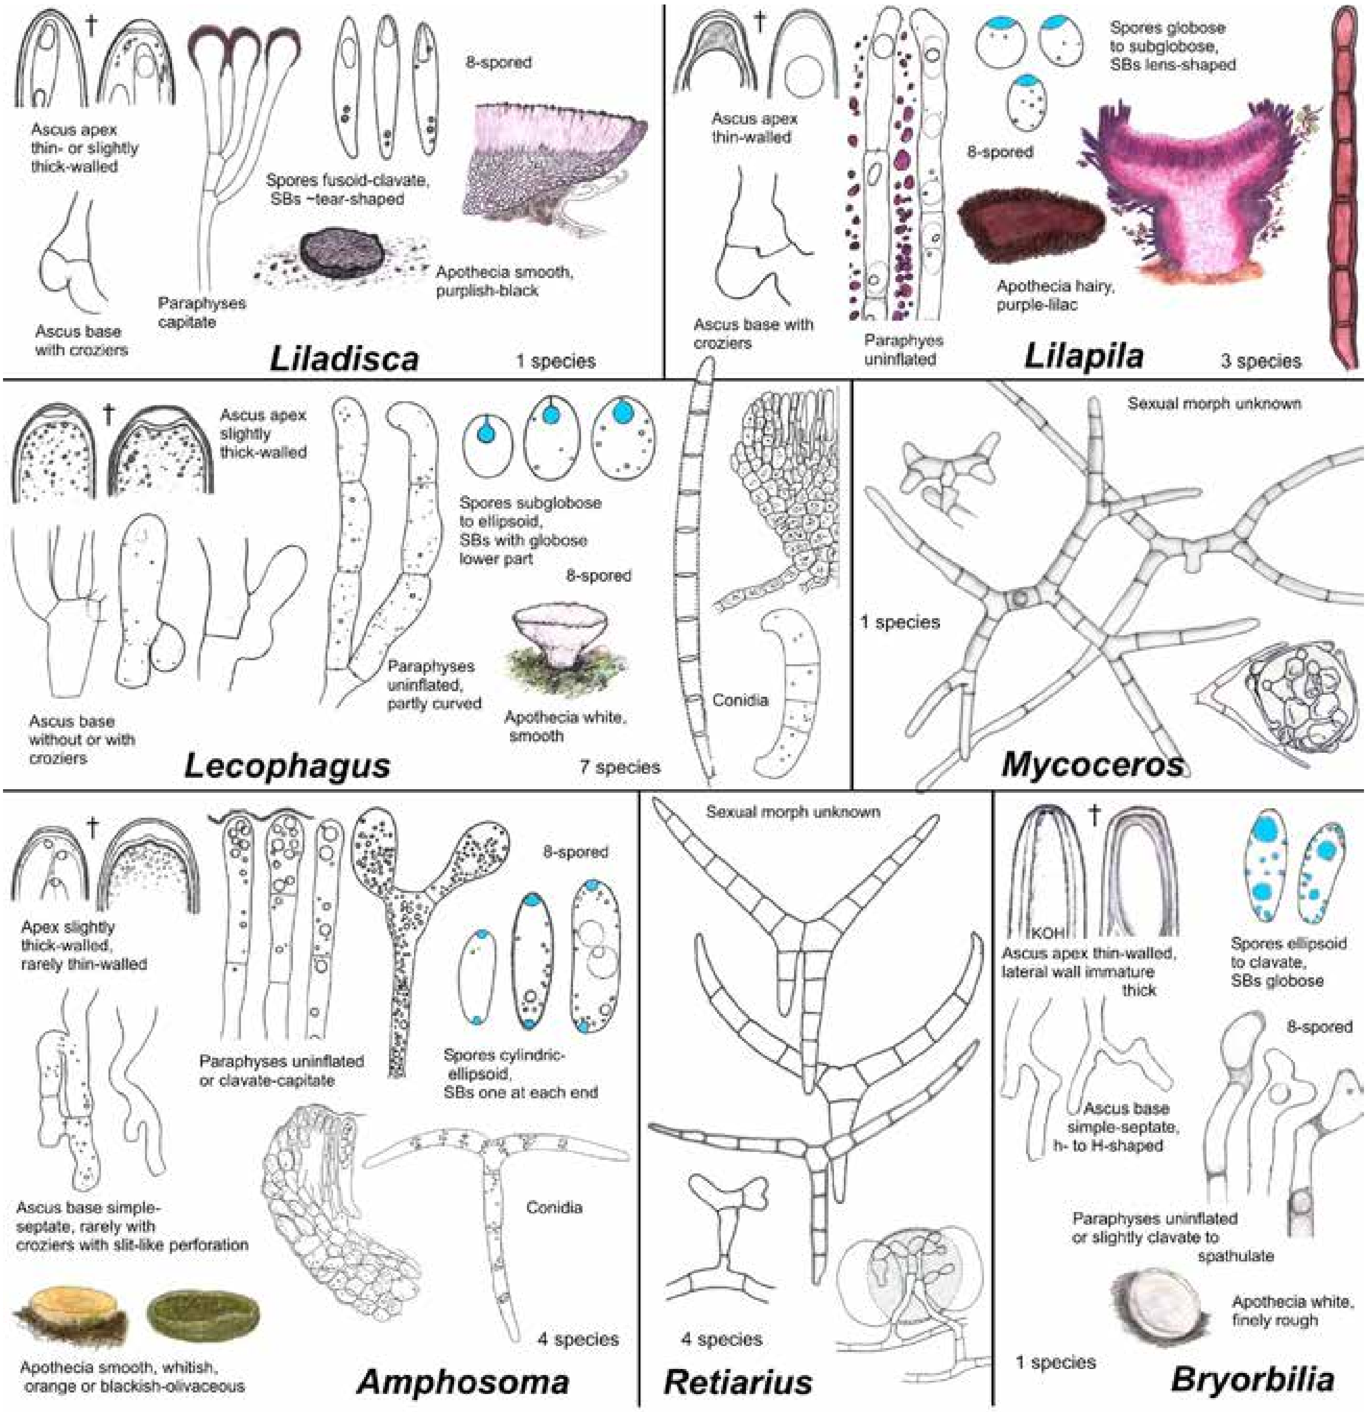

Plate 25. Overview of the genera of *Orbiliomycetes* I.

Liladisca Baral, **gen. nov.**, MB 812647

Type species: *Tympanis acicola* Fuckel

Etymology: referring to the deep purple-lilac colour of the apothecia when seen under transmitted light.

Latin diagnosis: *Apothecia in statu rehydratato 0.2–0.4 mm diam., orbicularia, sessilia, erumpentia, tota obscure purpureo-lilacea vel atra, hymenio plano vel convexo, margine irregulariter minute crenulato. Asci clavati, apice obtuso vel conico, tunica in statu emortuo tenui vel minute incrassata, non amyloidei (IKI), octospori, stipitati, ex uncis nati. Ascosporae distichae in asco emortuo, oblonge fusiformes-clavatae, aseptatae, hyalinae, in statu emortuo prope apicem corpusculum non refringens, ellipsoideum vel lacrimiformem continentes. Paraphyses ad apicem capitatae, exsudato crasso et fortiter purpureo-lilaceo tectae, non cohaerentes, ramosae. Excipulum ectale e textura prismatica(-angulari) crassitunicata, exsudato intercellulari fortiter purpureo-lilaceo, excipulum medullare e textura prismatica similiter compositum. Habitat ad acus putridos dejectos* Pini sylvestris.

Recognized species: *L. acicola*.

Liladisca acicola (Fuckel) Baral, **comb. nov.**, MB 812648 — Pls 27–28

Basionym: *Tympanis acicola* Fuckel, Fungi Rhen. Exs., suppl. fasc. V, no. 1965 (1867)

≡ *Pezicula aterrima* Fuckel, Jahrb. Nassau. Ver. Naturkd. 23–24: 278 (1870), nom. illegit., ICN Art. 30.8, 52.1

≡ *Phacidium aterrimum* (Fuckel) Sacc., Syll. Fung. 8: 713 (1889)

≡ *Patinella aterrima* (Fuckel) Rehm, Rabenh. Krypt.-Fl., 1.3: 312 (1889)

Etymology: *acicola*: referring to the habitat (needles of *Pinus*); *aterrima*: according to the black apothecial colour in external view.

Typification: Germany, Rheinland-Pfalz, Ingelheim, needles of *Pinus sylvestris*, undated (autumn), L. Fuckel (Fungi Rhen. Exs. 1965, M-0206556, lectotype, designated here, MBT382100).

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.3–0.4 mm diam., 0.11–0.12 mm high (receptacle 0.07–0.09 mm), purplish-black, non-translucent, round, slightly gelatinous, scattered or gregarious in

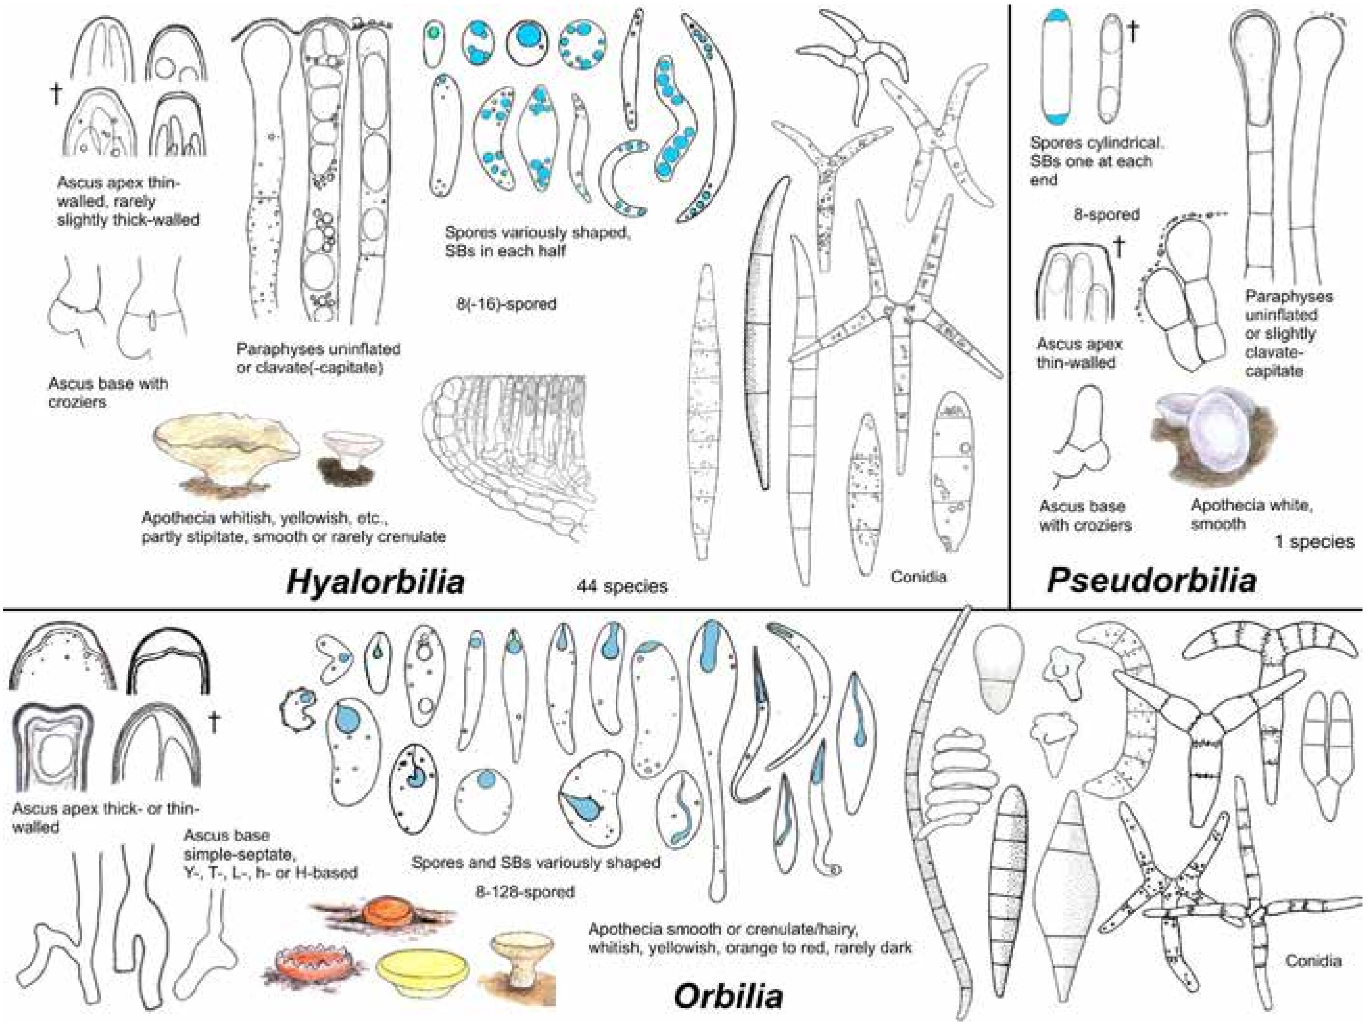

Plate 26. Overview of the genera of *Orbiliomycetes* II.

small groups; disc flat to slightly concave, margin distinct, irregularly crenulate by small protruding warts; broadly sessile, erumpent from beneath epidermis; dry black. **Asci** †40–62 × 4–6 µm, 8-spored, spores biseriate, lower spores inverted, pars sporifera †20–30 µm long; **apex** (†) obtuse to conical irrespective of the viewing direction, with or without minute dome ~0.7 µm thick, without apical chamber; **base** with short to medium long and thick, often flexuous stalk, arising from croziers (without perforation). **Ascospores** †7–10.5(–11.5) × 1.5–1.8 µm, non-septate, smooth, narrowly fusoid-clavate, apex obtuse (to subacute), base slightly to strongly attenuated, straight to very slightly curved; **SBs** †1.7–2.2 × 0.8–1.2 µm, tear-shaped to ellipsoid, seen as a transparent area in KOH, attachment to wall unclear, perhaps by a small point. **Paraphyses** apically medium to strongly capitate, terminal cells †12–23 × 2.5–4.3 µm, lower cells †4.5–15 × 1.2–1.8 µm; frequently branched in upper half, not immersed in gel, therefore separable by pressure, hymenium in H_2O pale to bright (apically dark) purple-lilac. **Medullary excipulum** in H_2O deep purple-lilac to wine-red, ~35 µm thick, of strongly gelatinized textura prismatica-angularis (common walls ~0.5–2.5 µm thick), upwards oriented in centre, horizontally at flanks, indistinctly delimited from ectal excipulum. **Ectal excipulum** in H_2O deep purple-lilac, of strongly gelatinized t. prismatica(-angularis) (common walls ~0.5–3 µm thick), 15–20 µm thick from base to margin, oriented at a 10–50° angle to the surface, cells at flanks †4–10 × 2.8–5 µm, marginal cortical cells not clearly seen; **glassy processes** and **hairs** absent. **Anchoring hyphae** medium abundant, hyaline, †2–2.8 µm wide, walls 0.3 µm thick, smooth. **SCBs** no data available. **Exudate** in ectal and medullary excipulum intercellular, homogeneously pigmented, in H_2O dark purple-lilac or wine-red; over paraphyses forming 1–3 µm thick, individual, firmly attached caps, over margin and flanks 1–3 µm thick. **Chemical reactions**: purple-lilac pigment in alkali (KOH) turning darker and more greyish-lilac-violet, purplish-violet-brown, or blackish-brown, in acids (PVA) deep (fox-) orange- to red-brown. **— ANAMORPH**: unknown.

Habitat: on rather strongly decayed needles of *Pinus sylvestris* fallen to ground, on both sides of the needles, green algae not seen. **Associated**: *Lophodermium pinastri*. **Desiccation tolerance**: probably desiccation-tolerant, according to the associated *Lophodermium*. **Altitude**: 85 m a.s.l. **Geology**: Devonian Taunus quartzite. **Phenology**: autumn.

Taxonomic remarks. *Liladisca acicola* is easily recognized by its deep purple-lilac pigment of the intercellular gel-like exudate in the entire excipulum when viewing under transmitted light in a water mount. The species differs from *Lilapila* in the absence of hairs, narrower anchoring hyphae with a thin, smooth wall, an ectal excipulum of textura prismatica oriented at a low to oblique angle at the flanks, a medullary excipulum being hardly differentiated from the ectal excipulum, narrowly fusoid-clavate ascospores with ± tear-shaped SBs, a conical ascus apex which is often provided with a small apical thickening, and capitate paraphyses covered by thick, deep purplish caps of exudate. These differences support distinction at the generic level, although admittedly similar amounts of differences occur within the large genus *Orbilia* as circumscribed at present.

The purple-lilac or wine-red pigment appears to be very similar to that found in *Lilapila*. However, when mounted in KOH or PVA the pigment exhibits colours different from

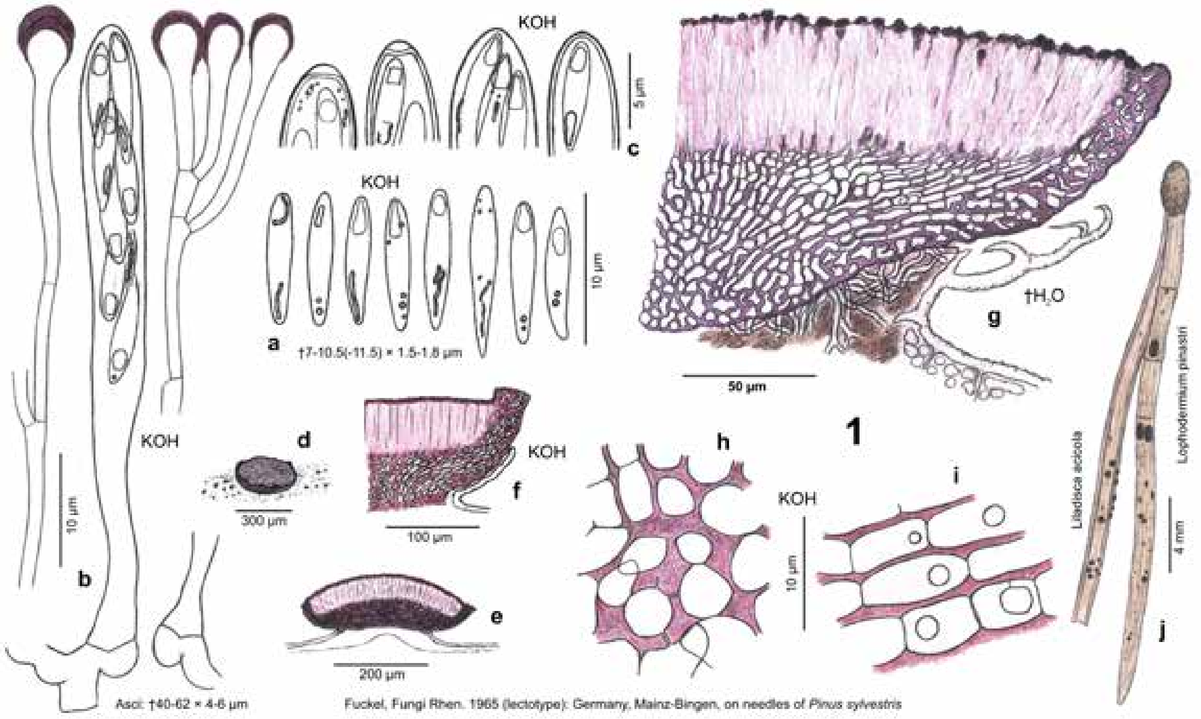

Plate 27. **1**: *Liladisca acicola*. – **a**. ascospores; **b**. ascus and paraphyses; **c**. ascus apices; **d**. apothecium (rehydrated); **e–g**. apothecia in median section; **h**. id., central part of medullary excipulum; **i**. id., lateral part of medullary excipulum at mid flanks, near ectal excipulum; **j**. needles of *Pinus sylvestris*.

Lilapila. In KOH it keeps the purplish-violet shade whereas that in *Lilapila* changes to an olivaceous colour. In PVA *Liladisca* turns orange-brown whereas *Lilapila* keeps the purple-lilac pigment. In both media the exudate is not dissolved in either of the two genera.

Rehm (1889) described the pigment over the paraphyses and in the excipular tissue as 'brown-red'. Fuckel (1867, 1870) reported the apices of paraphyses as uniguttulate, fuscous, 5 µm wide, but he did not mention the pigmentation of the excipular tissue under transmitted light. The spores were described by Fuckel and Rehm as cylindrical although they are actually more fusoid-clavate.

The single species here recognized in *Liladisca* is only known from the old type collection made by L. Fuckel in or before 1867. It undoubtedly belongs to the *Orbiliomycetes* on account of the presence of a spore body in the ascospore apex, and because of the inverse orientation of the lower spores within the asci, characters which were overlooked by Fuckel and also by Rehm who examined a syntype specimen. The SBs are now rather inconspicuous (Pl. 27: 1a), but have probably been refractive and perhaps more slender in the living state. There are also irregular, strongly refractive, filiform artifactual structures to be found in the dead sporoplasm which probably originate from fusion of small LBs.

Because of inamyloid asci and a pigmented medullary excipulum, Rehm (1889) doubted a relation to *Pezicula* and *Phacidium*, but believed that the species belonged to the *Patellariaceae*. Without personal studies, DiCosmo et al. (1984: 172) excluded it from *Phacidium*, and Verkley (1999: 141) suggested affinities with the tribe *Mollisieae* s. Korf (*Helotiales*).

Nomenclature and type studies. Fuckel introduced two different names for the same collection. On the printed herbarium label of the excsiccatum distributed in 1867 (Fungi Rhen. Exs. 1965) he named the species *Tympanis acicola* and provided a Latin diagnosis. An almost exactly concurring diagnosis was later published in his 'Symbolae Mycologicae'. Here Fuckel (1870) changed the name to *Pezicula aterrima* by referring to the older name *Tympanis acicola*. According to Art. 30.8 (Turland et al. 2018), printed matter accompanying exsiccatae must be considered as effectively published. Hence '*acicola*' becomes the correct epithet (see also Pfister 1985: 49) and '*aterrima*' is nomenclaturally superfluous (Art. 52.1, Turland et al. 2018).

The specimen in M consists of about 40 well-preserved apothecia and fully concurs with the protologue. Rehm (1889) appears to be the only author who ever published a reexamination of the fungus. Saccardo (1889) copied Fuckel's description, and Migula (1913: 890) copied that of Rehm. Syntype specimens exist

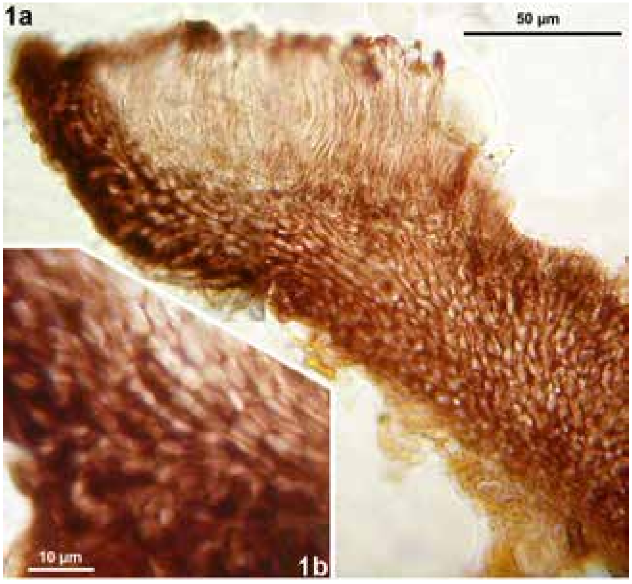

Plate 28. **1**: *Liladisca acicola*. – **1a**. apothecium in median section; **1b**. id., closeup of ectal and medullary excipulum at mid flanks. – Dead state (permanent slide, in PVA). — **1a–b**. Fungi Rhen. Exs. 1965 (H.B. 5045): Germany, Ingelheim, on *Pinus*.

also in other herbaria (e.g., S-F90272), but were not requested in the present study. In order to fix the new genus on a specimen, we here designate M-0206556 as **lectotype** of *Tympanis acicola*.

Ecology. *Liladisca acicola* grew on fallen, rather rotten needles of *Pinus sylvestris* probably in a pine forest, near the Rhine river, in cold-temperate humid, subcontinental central Europe. This remarkable fungus was considered to be 'very rare' by Fuckel, and indeed no further collections came to our notice.

Specimens included. **GERMANY**: **Rheinland-Pfalz**, Rheingau between Mainz and Bingen, NW of Ingelheim, near Frei-Weinheim, 85 m, on needles of *Pinus sylvestris*, undated (autumn), L. Fuckel, Fungi Rhen. Exs. 1965 (M-0206556, **lectotype**, H.B. 5045 ø).

Lilapila Baral & G. Marson, **gen. nov.**, MB 813441

Type species: *Lilapila oculispora* Baral & G. Marson

Etymology: named according to the deep purple-lilac colour of the apothecial tissue and hairs when seen under transmitted light.

Latin diagnosis: *Apothecia in statu rehydratato subsessilia, superficialia, hymenio obscure purpureo-lilaceo vel atro, pilis longis lilaceo-nigris dense confertis. Asci cylindrici, apice in statu emortuo rotundati, tunica tenui, non amyloidei (IKI), octospori, ad basim uncinati. Ascosporae monostichae in ascis vivis, globosae vel subglobosae, intus corpusculo refringente lentiforme ad tunicam appresso. Paraphyses deorsum ramosae, ad apicem non inflatae, non cohaerentes. Pili cylindrici, plerumque 50–150 µm longi, crassitunicati, 3–7 septati, in toto intense lilaceo-purpurei, tunica dense minute granulosa, apice rotundato. Excipulum ectale e textura prismatica-angulari, cellulis hyalinis, extus crassitunicatis, exsudato brunneo-lilaceo tectis, excipulum medullare in parte inferiore textura oblita leniter vel valde gelatinosa. Inter cellulis hymenii, subhymenii et excipuli medullaris exsudatum abundans e multis granulis lilaceo-rubris compositum. Habitat in ramis vulneratis siccis* Piceae *et* Pini, *vivis vel leniter putridis, in corona arborum, ad corticem vel plerumque resinam nigram, in Alpibus meridio-occidentalibus.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated dark purple-lilac-blackish, round, somewhat elliptical or irregular if large, slightly to medium gelatinous, scattered to gregarious in small groups; disc medium concave to flat, margin and exterior densely covered by fascicles of blackish-purple hairs; sessile or mostly with a ± abrupt stipe, stipe sometimes also with scattered purple-brown hairs and completely immersed in blackish layer of associated hyphomycetes; dry black, contracted, sometimes ± hysterioid, disc completely covered by the converging hairs. **Asci** *(43–)50–80(–84) × (4.5–)5–10.3(–11.5) µm, †(44–)49–65(–70) × (4–)4.3–5.8(–6.7) µm, 8-spored (rarely 1–2 spores aborted), spores (*) uniseriate, sometimes subbiseriate, orientation irregular but SBs preferably pointing sideways; **apex** (†) hemispherical to very slightly truncate or conical (irrespective of the viewing direction), apical wall only slightly thickened [†0.3–0.4(–0.5) µm {3}], without internal wall thickening, wall CR–; **base** with a medium long, thick, slightly flexuous stalk, arising from croziers of variable shape, mostly with a 1–3 µm long, ± slit-like perforation (up to 6 µm in ascogenous hyphae). **Ascospores** *(3–)3.3–4.5(–5.5) × (2.5–)2.8–4.5(–5.5) µm, †2.8–4.2 × 2.3–4 µm, smooth, globose to subglobose, slightly flattened (e.g., 4 × 3.7 × 2.8 µm, distinctly subglobose only in profile view); **SBs** (0.3–)0.4–0.8(–1) × 1.4–3.3 µm, strongly refractive, lens- to calotte-shaped, circular in front view, very broadly attached to wall where flattened spore is broadest (simulating terminal attachment, Pls 31: 1a, 2a, 3a; 32: 4b); with 1–7 minute LBs; germination by germ tubes once seen in an old apothecium. **Paraphyses** apically uninflated or only slightly inflated or attenuated, *(1.7–)2–3(–3.7) µm wide, ± equalling the living asci (protruding 0–5 µm over dead asci), ± equidistantly septate, branched only near base, here sometimes with anastomoses, paraphyses and asci ± easily separable, hymenium bright purple-lilac by numerous exudate granules. **Medullary excipulum** 50–200 µm thick, hyaline but young with dense, later scattered patches of purple-lilac granules, especially in the perihymenial region and towards the ectal excipulum, granules embedded in an invisible gel matrix; 2-layered: **upper part** non- or medium gelatinized, ~40–150 µm thick, of medium dense to dense, horizontally or ± upwards oriented textura intricata, hyphae *1.8–2.5 µm wide, intermingled with many inflated, globose to ellipsoid, catenate cells *5–15(–20) × 5–10(–15) µm; **lower part** of slightly to strongly gelatinized t. intricata-porrecta-oblita, 10–100 µm thick, irregularly oriented or at 0–50° towards the very sharply delimited ectal excipulum, individual cells *17–30 × 1.7–3(–5) µm, †1.2–3 µm wide, if strongly gelatinized then with slightly refractive gelatinous sheath ~1 µm thick. **Ectal excipulum** hyaline to pale yellowish-ochraceous, near base with bright to dark ochre-brown to purple-lilac intercellular exudate, of vertically oriented t. angularis-prismatica from base to mid flanks, cells *(7–)9–19(–22) × (5–)7–10(–14) µm, (†) strongly gelatinized (wall swelling in dead state to 1.5–3 µm), outer wall of cortical cells *1.5–2 µm thick, lateral wall *0.5–1.5 µm, glassy; marginal cortical cells more elongated, oriented at a 20–30° angle to the surface. **Hairs** covering the whole exterior but sometimes lacking at base and flanks, inserted on cortical cells, free or in converging, agglutinated fascicles, at margin and flanks (30–)80–150(–200) × 5–9(–11) µm, cylindrical, straight to slightly flexuous, with (1–)3–8(–11) refractive septa (0.3–1.3 µm thick), apex rounded, whole surface densely covered by low but distinct warts, wall surface and warts dark purple-lilac in H_2O, sometimes ochre-brown when dead, marginal hairs ± paler towards apex (upper 5–20 µm or more), sometimes almost smooth; lateral wall */†1–2.5 µm thick {3}, 2-layered, warts 0.1–0.3 µm high, 0.2–0.8 µm wide, sometimes almost confluent, **glassy processes** absent. **Anchoring hyphae** sparse to very abundant, restricted to base, subhyaline to pale yellowish-cream, (3.5–)4–5.5(–6.5) µm wide, walls *(0.2–)0.5–1.3 µm thick [†(0.2–)1–1.5(–2) µm], surface finely or mostly roughly and densely warted, rarely some hyphae smooth. **SCBs** in terminal cells of paraphyses absent or globose to ellipsoid, sparse, very slightly or medium refractive; in cells of medullary excipulum regularly present, 1.5–4 µm diam., strongly refractive, ± globose or often ring-shaped, unstained in CRB_A; **VBs** sometimes present inside vacuoles of asci, paraphyses and medullary excipulum: one or a few strongly refractive, globose, hyaline, trembling bodies 0.3–1 µm diam., staining tardily blue in CRB_A, disappearing in KOH; **LBs** never containing carotenoids. **Exudate**: bright to deep purple-lilac granules or clods 0.3–1.5 µm diam., abundant in hymenium and medullary excipulum, between paraphyses from base to apex or subapex, not covering the tips, in ectal excipulum abundant between the cells, also covering the entire hair wall as a thin film; exterior covered by a ± continuous reddish-brown layer, in stipe pale yellowish-ochraceous; anchoring hyphae warted by a hyaline exudate. **Chemical reactions**: purple-lilac exudate in 5% **KOH** turning light to dark dirty grey- to olive-brown, warts on hairs not dissolved; adding strong acids to the KOH-mount fully recovers the purple-lilac colour. **CRB** stains the warted exudate on the anchoring hyphae (turquoise-)blue and a thin gel layer beneath lilac and the medullary excipular gel faintly lilac. — **ANAMORPH**: **Colonies** whitish to pale yellowish, slow-growing (see below). **Conidiophores** and **conidia** unknown (but see under *L. oculispora*).

Habitat: on resinous, usually blackened wounds of corticated, living or recently dead, still-attached branches or standing trunks of conifers, never directly on wood, wounds either with small to large, resinous decorticated areas or completely overgrown by bark, apothecia often only on bark that borders the decorticated wound, preferably growing in the niche between bark and wood; often also on the decorticated resinous area but then on a ± thick layer of resin covered by a black layer of dark brown hyphomycetes, green algae sparse or lacking. Growing in association with various resinicolous ascomycetes.

Recognized species: *L. jurana*, *L. oculispora*, *L. oculisporella*, *L. gallica* nom. prov.

Taxonomic remarks. The genus *Lilapila* is quite extraordinary by it purplish-black apothecia covered with large, deep purple, septate, thick-walled, finely warted hairs and by (sub)globose ascospores with a single, broad and thin, lens-shaped spore body. Further characteristics are: asci arising from croziers, with rounded, thin-walled apex, paraphyses simple, non-inflated at apex, with purple-lilac exudate between, ectal excipulum of thick-walled, angular to prismatic, vertically oriented cells, medullary excipulum sharply delimited, of gelatinized textura intricata.

Some variation was noted in the rate of gelatinization of the outer medullary excipulum, but this seems to depend on the development stage: in younger apothecia the gel was more refractive and therefore more obvious. The purple-lilac pigment of *Lilapila* belongs to the most spectacular characteristics of the genus. It is best seen under transmitted light in a water mount, but also in acidic solutions. Unlike *Liladisca*, the pigment turns greyish-olivaceous in alcali, moreover, it is granular in the inner regions of the apothecium, and only on the surface of the hairs it forms a continuous layer. In aged but still-living apothecia the lilac pigment on the hairs may change to red-brown in water without application of alkali. Thus, the hairs at the flanks may appear brownish while the younger marginal hairs are still bright lilac.

Species delimitation. Although the four taxa within *Lilapila* are morphologically very similar, we have separated them based on strong molecular evidence. However, a correlation of molecular data with differences in ascus and ascospore measurements was noted between some of them. This variation was observed when sequences were not yet available, and was considered as quite unusual within the species level.

Cultural characteristics and anamorph. Ascospores of *L. oculispora* and *L. oculisporella* tardily germinated when shot on agar (CMA:5), and the whitish to very pale yellowish mycelium was very slow-growing. No conidiophores and conidia could be obtained in culture under different CMA concentrations.

Phylogeny. Sequences from 28 samples of *Lilapila* spp. were obtained, comprising ITS and LSU (D1–D2, often also D3–D4 and D5–D6; 2 sequences only ITS), 10 also SSU (V7–V9). Two sequences (*L. oculispora* H.B. 10122, *L. jurana* H.B. 10123) include SSU V1–V9, LSU D1–D12, *L. oculispora* also IGS. Sequence similarity and phylogenetic analysis support affiliation of the genus in *Orbiliomycetes*. BLAST search for SSU (V7–V9) yields *Lecophagus* spp. as closest hit (distance 2%). When analysing 5.8S+LSU or SSU+ITS+LSU, *Lilapila* clustered in a clade with *Amphosoma*, *Bryorbilia*, *Lecophagus*, and *Retiarius* with medium or low support, respectively (Phyls 1, 2). However, a high distance to these and other genera is observed, ranging in the LSU (D1–D2) at 6.2–7.5% (*Amphosoma*), 8.3–10% (*Bryorbilia*), 8.7–10.5% (*Lecophagus*), 9–10.7% (*Retiarius*), 10–12% (*Mycoceros*), and 13–19% (*Hyalorbilia*).

Nucleotide positions specific for the genus. A few motifs occur in the more frequently sequenced rDNA regions that characterize *Lilapila*. In the SSU V9 at pos. 287 *Lilapila* has AGT**A**AGT (*L. oculispora*, *L. oculisporella*) or AGT**G**AGT (*L. jurana*, *L. gallica*), whereas other *Orbiliomycetes* have **T** (mostly AGT**T**GGT). In the LSU D1 domain pos. 226 is unique (GTT**G**ACGGC or in *L. oculisporella* GTC**G**TCGGC; in all other *Orbiliomycetes* mainly **C**, sometimes **T** or **A** but never **G**), and also pos. 300 and 311 are unique (**A**GGTAAATTTC**T**), except for *O. pilifera* which has likewise A + T. In a few more variable regions of the LSU D2 domain the following motifs are almost unique for *Lilapila*: TCGGTGCAATG (pos. 561–571) also occurs in *Retiarius bovicornutus*, and CGCGATCGAG (pos. 580–589) in section *Lentiformes* p.p. (*O. foliicola*, *O. cucumispora*, *O.pluristomachia*). In the D3 domain the motifs AGGTGGGAGCCGC (pos. 717–729) and adjacent AAGGTGCACCATCG (pos. 730–743) each were otherwise only observed in *O. crenatofalcata*.

In the region of the three '*Orbiliales*-specific' primers (Smith & Jaffee 2009, see Tabs 18–19), *Lilapila* concurs with different other genera of *Orbiliomycetes*. For primer Orb5.8s1F this is *Amphosoma*, *Bryorbilia*, *Lecophagus*, *Retiarius*, and the *Vermispora* clade of *Hyalorbilia*, whereas for Orb5.8s3F it is *Mycoceros* and *Orbilia* p.p.maj. *Lilapila* is variable in the primer region Orb28s2R: *L. oculispora* concurs here mainly with *Mycoceros*, *L. oculisporella* with *Retiarius*, *Amphosoma*, and *Lecophagus*, and *L. jurana*/*L. gallica* show a further variant which is so far unique within *Orbiliomycetes*. However, especially in Orb28s2R various non-orbiliaceous ascomycetes concur with *Lilapila*. Congruence of *Lilapila* with *Mycoceros* and *Hyalorbilia* p.p. is observed in stem-loop B8 near the 3'-end of 5.8S (Tab. S4).

Nucleotide positions specific for the recognized species. Despite their close morphological similarity, a high distance is observed between the three validly described species, although the infraspecific variability is negligibly low (Tab. 57, Phyl. 3). In the ITS region more than 50 nt and 9 gaps consistently differ between *L. oculispora* and *L. oculisporella*, which easily permits recognition of the species from the alignment, and an even higher distance is noted between those and *L. jurana*. In the LSU D1–D2 domain, 14 nt differ between *L. oculispora* and *L. oculisporella* (mainly in D2). The number of deviating D1–D2 nucleotides in *L. jurana* is lower in comparison with *L. oculispora* (10) than with *L. oculisporella* (18–19).

The S1506 intron is absent in all sequences of the four recognized species. The S943 intron is present in *L. oculispora* (380 nt) but absent in *L. oculisporella* and *L. jurana*. This enables recognition of *L. oculispora* already from the PCR product on gel without sequencing, using the primer SR5 which binds upstream of the S943 intron. Also L2449 and L2563 introns are present in *L. oculispora* but not in *L. jurana* (this region so far is not covered in *L. oculisporella*). Deviations in the SSU region occur at 2 positions in the V9 region: at pos. 238 and 241 *L. oculispora* has CT**C**TC**G**G, *L. jurana* and *L. gallica* CT**T**TC**G**G, and *L. oculisporella* CT**C**TC**A**G (other *Orbiliomycetes* have **T**+**G**); in addition, *L. jurana* and *L. gallica* deviate from the other two at pos. 287 by **A** vs. **G** (see above). All this supports the existence of three four different species.

Ecology. Members of *Lilapila* were so far only detected in montane to subalpine, orotemperate to orosub- or rarely suprasubmediterranean, humid to slightly semihumid, often pure conifer forests of Southern French Alps (Rhône-Alpes and Provence-Alpes-Côte d'Azur) and Massif central (Auvergne) in southern Europe, from orotemperate humid Northern and Central Alps and High Tatras, and from (alti)montane, orotemperate humid French and Swiss Jura. The forests are often on steep north-, east-, or south-exposed slopes, but also on the top of high plateaus. The geology was almost always calcareous, but in the samples from Central Alps and High Tatras it was acidic bedrock. Apothecia were exclusively found on black resinous wounds of still-attached, xeric branches or trunks of *Picea* and *Pinus*, which were often still viable by carrying green needles at their ends. The wounds have been injured some years ago, perhaps as a result of avalanches and snowslides or other influences of snow and frost during winter, or by rockfall, also by passing forestry machines.

Apothecia of all species usually grow in a black mould of dark brown hyphae of some dematiaceous hyphomycetes that

Table 57. Distances in the rDNA among the three described species of *Lilapila*.

rDNA	*oculispora-oculisporella*	*oculispora-jurana*	*oculisporella-jurana*
ITS (505–513 nt)	10–10.8%	13–13.5%	13.5%
ITS1 (199–205)	16.5–18%	21.7–22.6%	25.5–26%
ITS2 (149–153 nt)	12.1–12.8%	14.7–15.3%	10.8–11.5%
LSU D1–D2 (643 nt)	2.2%	1.7%	2.8–3%
SSU V8–V9 (360 nt)	0.3%	0.6%	0.8%

abundantly cover the resin. The dry contracted apothecia appear blackish and can hardly be detected when growing in black mould, but even after rehydration the lilac pigment appears blackish in external view (similar as in *Liladisca*). Although the apothecia are comparatively large and occur in numbers of dozens on a given branch, the genus appears to have escaped notice on account of its camouflage, xeric habitat, and ecological restriction.

The currently known phenology of the genus *Lilapila* (mainly summer and autumn) is certainly only accidental. It results from the difficulty during winter and spring to travel and collect in mountainous areas rich in snow. The detection by E. Stöckli (pers. comm.) of mature apothecia of *L. jurana* in late January and early March proved our assumption. A striking correlation is observed in the distribution area of samples on *Picea* and *Pinus* in the Southern French Alps. Those on *Picea* are more in the north (*L. oculispora*, *L. oculisporella*) and those on *Pinus* more in the south (*L. oculisporella*). Together with an altitude of sometimes below 1000 m in the *Pinus* samples, it appears that *L. oculisporella* is adapted to a warmer, strictly orosub- or rarely suprasubmediterranean climate. Because *L. oculisporella* occurred at about equal frequency on *Picea* and *Pinus* and was recorded even at the type locality of *L. oculispora* (Col du Labouret) on *Picea*, a sharp geographical or host specificity limit cannot be recognized. Therefore, a number of older collections remained undetermined due to the lack of ascus or spore measurements, voucher specimens, or DNA data.

Lilapila oculispora Baral & G. Marson, **sp. nov**.,
MB 813442 — Pls 29–30, Map 1

Etymology: referring to the living ascospores with their spore body resembling the transection of an eye.

Typification: France, Alpes-de-Haute-Provence, Col du Labouret, resinous branch of *Picea abies*, 24.X.1992, G. Marson, (ex H.B. 4822, M-0276610, holotype).

Latin diagnosis: *Apothecia in statu rehydratato 0.4–2.5 mm diam., subsessilia. Asci *43–84 × 5.8–11.5 µm. Ascosporae *3.8–5.3 × 3.7–5.3 µm, corpusculo refringente 2.4–3.3 µm lato. Pili cylindrici, plerumque 6–9 µm lati, 5–8-septati. Habitat in ramis vulneratis siccis* Piceae, *vivis vel leniter putridis, ad corticem vel plerumque resinam nigram, in zona orotemperata et orosubmediterranea praealpium et alpium Europae.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.4–1.5(–2.5) mm diam. (including hairs), 0.27–0.35 mm high (receptacle 0.12–0.23 mm), subsessile with indistinct, broad stipe or with ± abrupt stipe 0.08–0.17 × 0.25–0.3 mm. **Asci** *(43–)60–77(–84) {3} × 5.8–7.2 {2} or (7–)7.5–9(–11.5) µm {3}, †(49–)53–65(–70) × 5–7 µm {5}, pars sporifera *(22–)26–33 µm long, †(30–)40–53 µm; **base** arising from croziers {4}. **Ascospores** *(3.8–)4–4.7(–5.3) × (3.5–)3.7–4.5(–5.3) µm {9}, †3–4.2 × (2.5–)3–4 µm {4}, globose to subglobose (slightly flattened in side view); **SBs** 0.4–1 × 2.2–3.3 µm {6}. **Paraphyses** terminal cells *14–27 × 2.5–3.5 µm {1}, lower cells *7–21 × 2–3(–3.5) µm {2}. **Ectal excipulum** 30–50 µm thick near base, cells *11–21 × 5–9.5 µm {1}; 25–35 µm thick at lower flanks. **Hairs** */†100–150(–200) × (5–)6–9(–10) µm {3}, at flanks 40–70 µm long, (1–)5–8(–11)-septate, terminal cells 8–25 µm long {1}. **Anchoring hyphae** †(3.5–)4–5.5(–6.5) µm wide, walls †0.2–0.4 up to 1–1.5 µm thick {2}. — **ANAMORPH**: unknown (but see below).

Habitat: collected 1–2.5(–5) m above the ground, on small or mostly large, strongly resinous, (8–)15–43 mm thick wounds of corticated, completely undecayed (often living), still-attached branches of *Picea abies* {13}, on not or slightly decayed bark {2} or on blackened layer of resin {13}. **Associated**: *Amphosoma atroolivaceum* {3}, *A. resinicola* {2}, *Capronia* sp. {1}, *Chrysodisca peziculoides* {1}, *Ciliolarina* sp. {1}, *Claussenomyces olivaceus* {1}, *Lachnellula resinaria* {1}, *Lilapila oculisporella* {1}, *Melaspileella proximella* {1}, *Orbilia flagellispora* {1}, *Parmelia* sp. {1}, *Resinomyces griseus* {1}, *R. kirschsteinianus* {1}, *Sarea difformis* {3}, *Tryblidiopsis pinastri* {1}, crustose and foliose lichens. **Desiccation tolerance**: fully tolerant for at least 2 months, after 6 months many spores, paraphyses, and excipular cells still viable. **Altitude**: 1002–1820 m a.s.l. **Geology**: France: Middle & Upper Jurassic lime- & marlstone, rarely alluvial gravel (migmatite); Switzerland: peat over Permian mud- & sandstone, alluvial gravel (amphibolite, migmatite). **Phenology**: VI–X (but probably throughout the year).

Taxonomic remarks. *Lilapila oculispora* is distinguished from *L. oculisporella* merely by larger, especially wider asci, larger ascospores, and wider SBs. Because all remaining traits are virtually the same, the observed differences were previously thought to originate from variation. Yet, available rDNA-data show a high distance between small- and large-spored populations and a very low genetic variation within each group, therefore, a split into two different species seemed necessary.

Variation. Ascus size varied from *60–80 × 7–8.3(–8.8) µm (H.B. 4822, 9162a, Col du Labouret) to *61–84 × 8.5–10.3(–11.5) µm (6.X.1993, Col St.-Jean), and ascospore size from *3.7–4.5 × 3.5–4 µm to 4.2–5.2 × 4–4.8 µm. The largest spores (up to *5.3–5.5 × 5.2–5.3 µm) were measured in samples from Col du Labouret. SBs varied between 2.2–2.6 µm and 3–3.3 µm in diam. and between 0.5 µm and 1 µm in height. That this range of variation is not due to confusion is confirmed by the high molecular similarity among the six samples with available sequences and morphological data.

Key to species of *Lilapila*

(unequivocal species identification only possible by molecular methods)

1. Orotemperate humid Swiss and French Jura, Carpathians, on *Picea*; SBs 1.8–2.9 µm wide 2
1. Orotemperate to orosub- or suprasubmediterranean humid Massif central, Jura, Alps, on *Picea* and *Pinus* 3

2. Asci mainly *50–70 × 6–8 µm; spores *3.7–4.3 × 3.3–4 µm; 1003–1408 m .... ***L. jurana***, p. 269
2. Asci *69–74 × 7–8.2 µm; spores *4.1–4.7 × 3.5–4.5 µm; 888–912 m .... ***L. gallica*** nom. prov., p. 271

2. Asci mainly *60–77 × 7.5–9 µm; spores *4–4.7 × 3.7–4.5 µm, SBs 2.2–3.3 µm wide; on *Picea*, 1002–1820 m .... ***L. oculispora***, p. 264
2. Asci mainly *50–65 × 5–6.5 µm; spores *3.3–4 × 2.5–3.5 µm, SBs 1.4–2.3 µm wide; on *Picea* & *Pinus*, 800–1445 m........ ***L. oculisporella***, p. 267

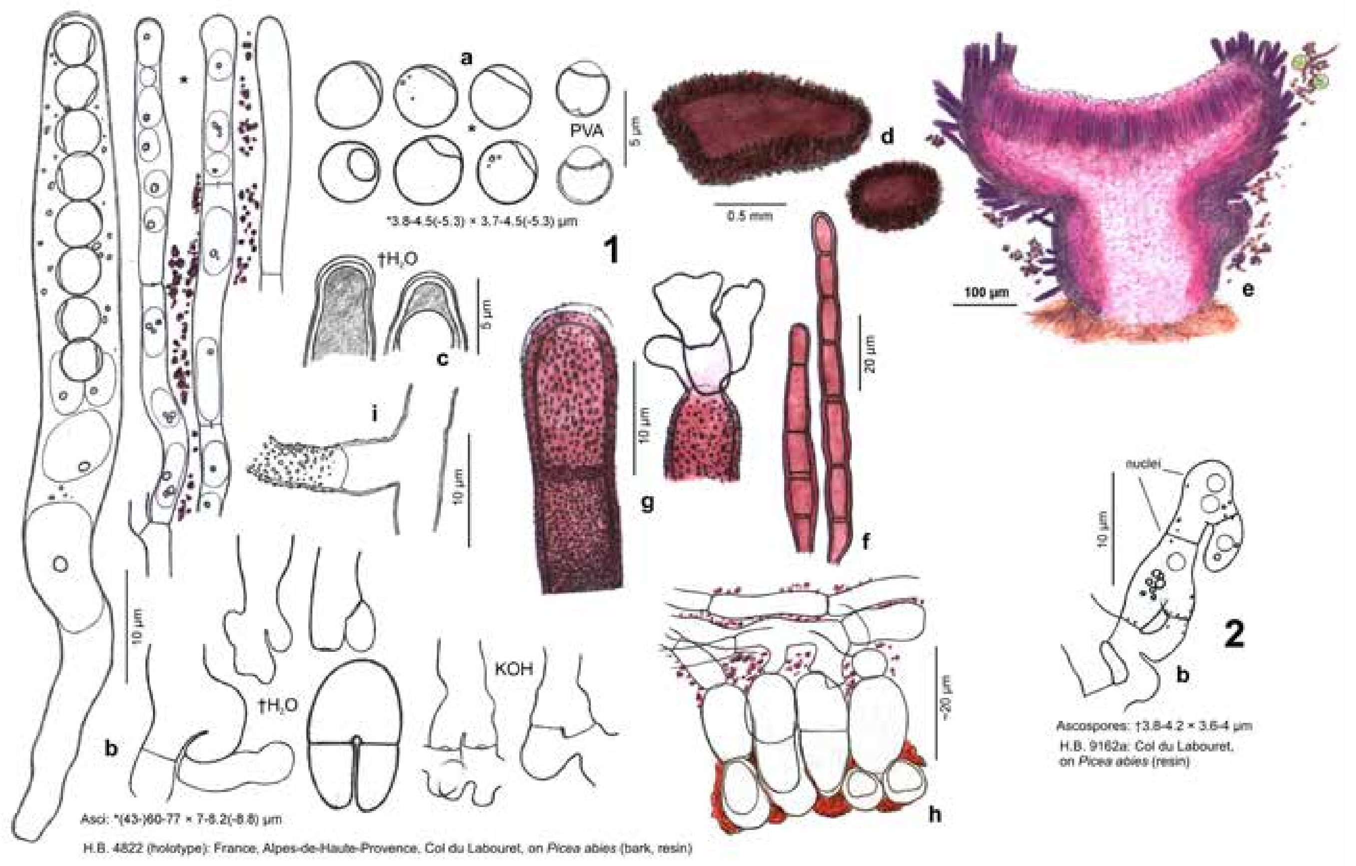

Plate 29. **1–2**: *Lilapila oculispora*. – **a**. ascospores; **b**. asci and paraphyses (vacuoles of paraphyses often containing small VB-guttules, sometimes with SCBs near the apex), ascus bases (**2b** with dikaryon); **c**. ascus apices; **d**. rehydrated apothecia; **e**. apothecium in median section; **f**. hairs; **g**. details of hairs (hairs rarely with hyaline apical outgrowths); **h**. ectal and medullary excipulum (lower flanks, median section); **i**. anchoring hypha.

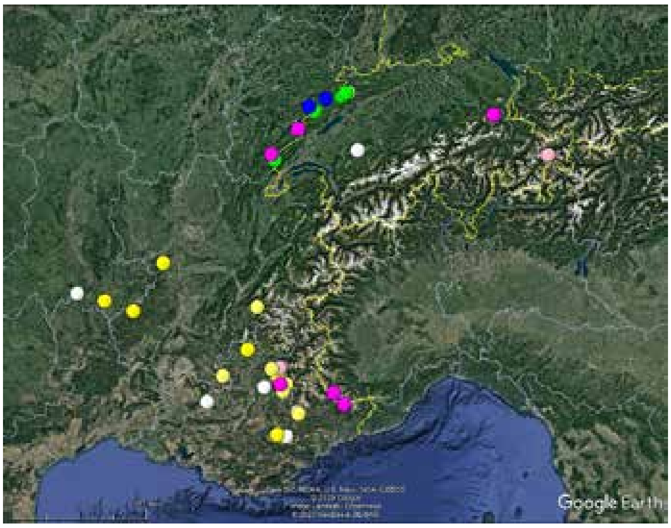
Cultural characteristics and anamorph. A pure culture was obtained from ascospores of G.M. 2015-08-30.1. The mycelium grew very slowly (~2.5–3 mm radius per week on CMA:5), and conidia were not observed. Curved, vermispora-like conidia were seen on the natural substrate in two collections: Col du Labouret: *(26–)32–37(–41) × 4–4.6(–4.9) µm (in situ, ~35–42 µm actual length), (1–)2–3–5(–6)-septate (Pl. 30: 1u); Flumserberg: *17–22 × 2.4–2.8 µm (in situ, ~25–29 µm actual length), 6–7-septate (IVV: H.B. 10122). Similar conidia were also twice observed near apothecia of *Amphosoma atroolivaceum* on *Pinus sylvestris* (IVV: 6.VIII.1999 and H.B. 7248, without apothecia of *Lilapila*), with a size close to the former sample and a septal number more as in the latter.

Phylogeny. Sequences of *L. oculispora* were taken from eight collections, seven from apothecia and one from pure culture, comprising ITS+LSU (D1–D3), in some also SSU (V7–V9) or complete SSU and LSU. In the ITS region they vary by 0–1.4%, even within a collection (G.M. 2015-08-30.1/.3, 0.8%). In the LSU (D1–D2) all eight collections are identical. For the interspecific distances see Tab. 57.

DNA data were not available for the type collection, but sequences were taken from three later collections at the type locality. Since ascus and spore size differences were shown to be correlated with DNA data, we conclude that the holotype should also fall in the clade.

Ecology. *Lilapila oculispora* is so far only known with certainty from eight collection sites in altimontane humid conifer forests. Four are in orosubmediterranean or once orotemperate (Isola, 1820 m) Southern French Alps, two in orotemperate French Jura, and two in orotemperate Northern and Central Swiss Alps (Map 1). The geology is mainly calcareous, whereas the sample on acidic soil from Zernez in the Central Alps needs molecular confirmation. The apothecia occurred on old resinous wounds of attached, corticated, often living branches of *Picea abies*. The species was repeatedly recorded from the type locality, but there also *L. oculisporella* was three times found (on *Picea*). At present, the available collections suggest a restriction of *L. oculispora* to *Picea*.



Map 1. Known distribution of *Lilapila* spp. in southeastern France and Switzerland: magenta = *L. oculispora*, yellow = *L. oculisporella*, green = *L. jurana*, blue = *L. gallica*. Pale colours indicate unsequenced samples; white = *Lilapila* sp. (without both measurements and DNA data).

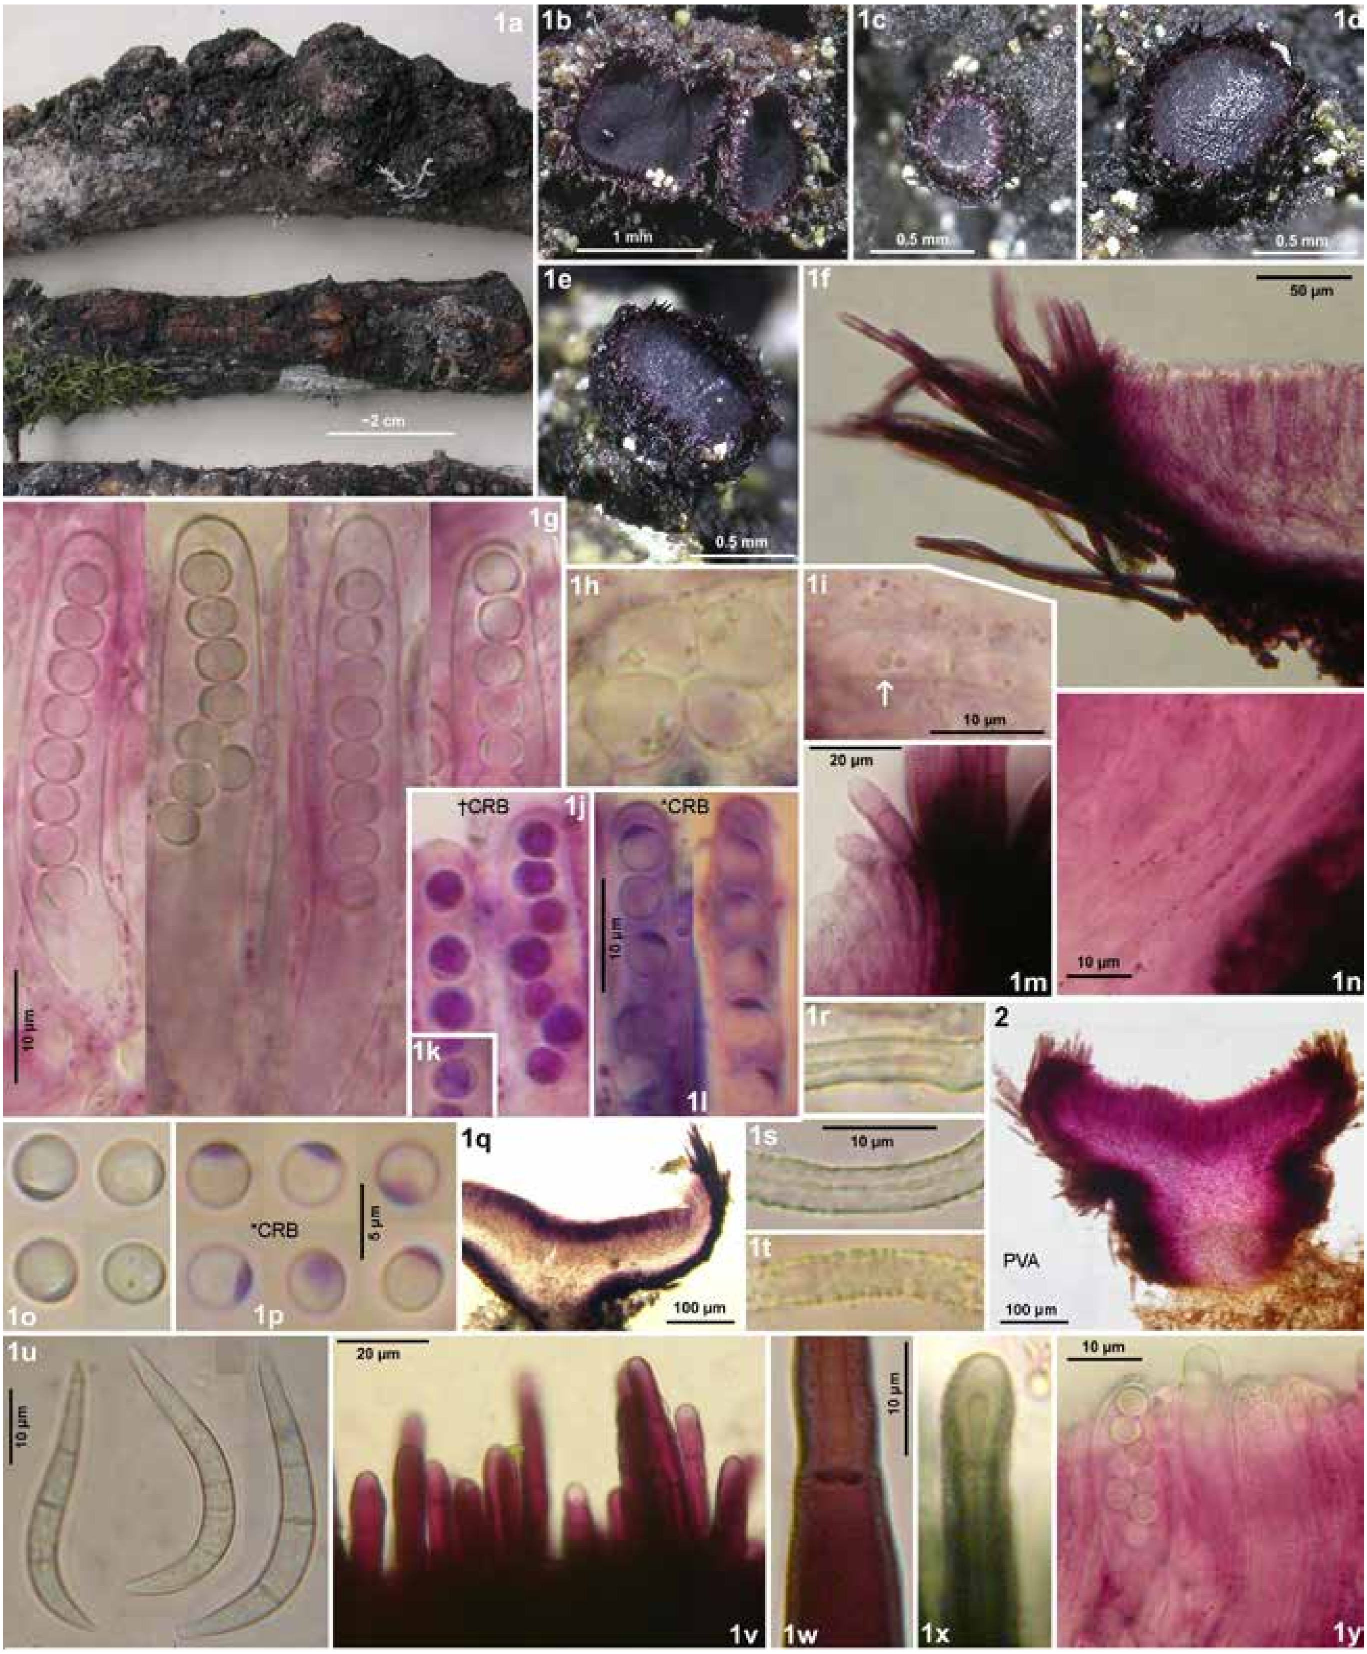


Plate 30. **1–2**: *Lilapila oculispora*. – **1a**. branches of *Picea abies* with blackened resinous wounds; **1b–e**. rehydrated apothecia; **1q**, **2**. apothecia in median section; **1f**, m. id., marginal region; **1v–x**. hairs; **1n**. gelatinized medullary excipulum at flanks (median section); **1h–i**. SCBs in inflated cells of medullary excipulum; **1r–t**. anchoring hyphae; **1g**. mature asci; **1y**. asci (mature and immature) and paraphyses; **1j–l**. ascospores in asci; **1o–p**. free ascospores; **1u**. conidia from substrate. – Living state (**1l** & **p**: SBs selectively stained violet in CRB), except for **1r–s** (in H_2O); **1x** (in KOH); **1j–k** (KOH+CRB, the sporoplasm is stained excluding the SBs); asci in **1l**. — **1a–y**. Lilapila oculisporella G. Marson, Baral & E. Weber, **sp. nov.**, MB 825639 — Pls 31–32, Map 1

Etymology: named after the similar but larger-spored *L. oculispora*.

Typification: France, Alpes-de-Haute-Provence, Seyne-les-Alpes, branches of *Pinus sylvestris*, 24.VIII.1996, G. Marson (M-0281047, holotype).

Latin diagnosis: Lilapilae oculisporae *similis, sed asci angustiores (*45–70 × 4.5–7.5 µm), ascosporae minores (*3–4.8 × 2.5–4 µm), corpusculo refringente minore (1.4–2.2 µm lato), pili leniter minores (plerumque 5–7.5 µm lati, 3–7-septati), sequentia nucleotidium valde distincta. Habitat in ramis vel truncis vulneratis siccis* Piceae *et* Pini, *vivis vel leniter putridis, ad corticem vel plerumque resinam nigram, in zona orotemperata ad orosub-, raro suprasubmediterranea praealpium Europae.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated (0.5–)0.7–1.5(–2.2) mm diam. (including hairs), 0.2–0.3(–0.4) mm high (receptacle 0.12–0.28 mm), subsessile with indistinct or mostly ± abrupt broad stipe 0.06–0.25 × 0.1–0.25 mm. **Asci** *(45–)50–65(–70) × (4.5–)5–6.5(–7.5) µm {8}, †(44–)48–60(–70) × (4–)4.3–5.5 µm {4}, pars sporifera *23–28 → 19–22 µm long, †(25–)28–32 µm; **base** arising from croziers {4}. **Ascospores** *(3–)3.3–4(–4.8) × (2.5–)2.8–3.5(–4) {12}, †2.8–3.5 × 2.3–3.3(–3.5) µm {3}, globose to subglobose (slightly flattened in side view); **SBs** (0.3–)0.5–0.8(–1) × 1.4–2.3 µm {6}. **Paraphyses** terminal cells *8–19(–28) × (1.7–)2–2.8(–3.7) µm {4}, lower cells *8–15 × 1.7–2.5(–2.8) µm {2}. **Ectal excipulum** 30–40 µm thick near base, cells *(7–)10–19(–22) × (6.5–)8–10(–14) µm {2}, 20–35 µm thick at lower flanks, cells †10–15 × 6–9 µm, 15 µm at mid flanks and margin. **Hairs** */†80–150(–200) × 5–7.5(–9) µm {4}, at flanks ~30–80 µm long, (1–)3–7(–9)-septate, terminal cells 7–27 µm long {2}. **Anchoring hyphae** †(3.5–)4–5(–6.5) µm wide, walls †1–2 µm thick {4}. **— ANAMORPH**: unknown.

Habitat: collected 1–5 m above the ground, on small or mostly large, strongly resinous, 10–60 mm thick wounds of corticated, completely undecayed, often living, still-attached branches, also on resinous knotholes of thick trunks, of *Picea abies* {8}, *Pinus sylvestris* {7}, on on usually blackened layer of resin {15} or on not or slightly to medium decayed bark {7}. **Associated**: *Amphosoma atroolivaceum* {5}, *Capronia* sp. {1}, *Ciliolarina* sp. {1}, *C. pinicola* {1}, *Cistella* sp. {1}, *Claussenomyces olivaceus* {1}, *Crumenulopsis pinicola* {1}, *Hysterium angustatum* {1}, *Lachnellula resinaria* {3},

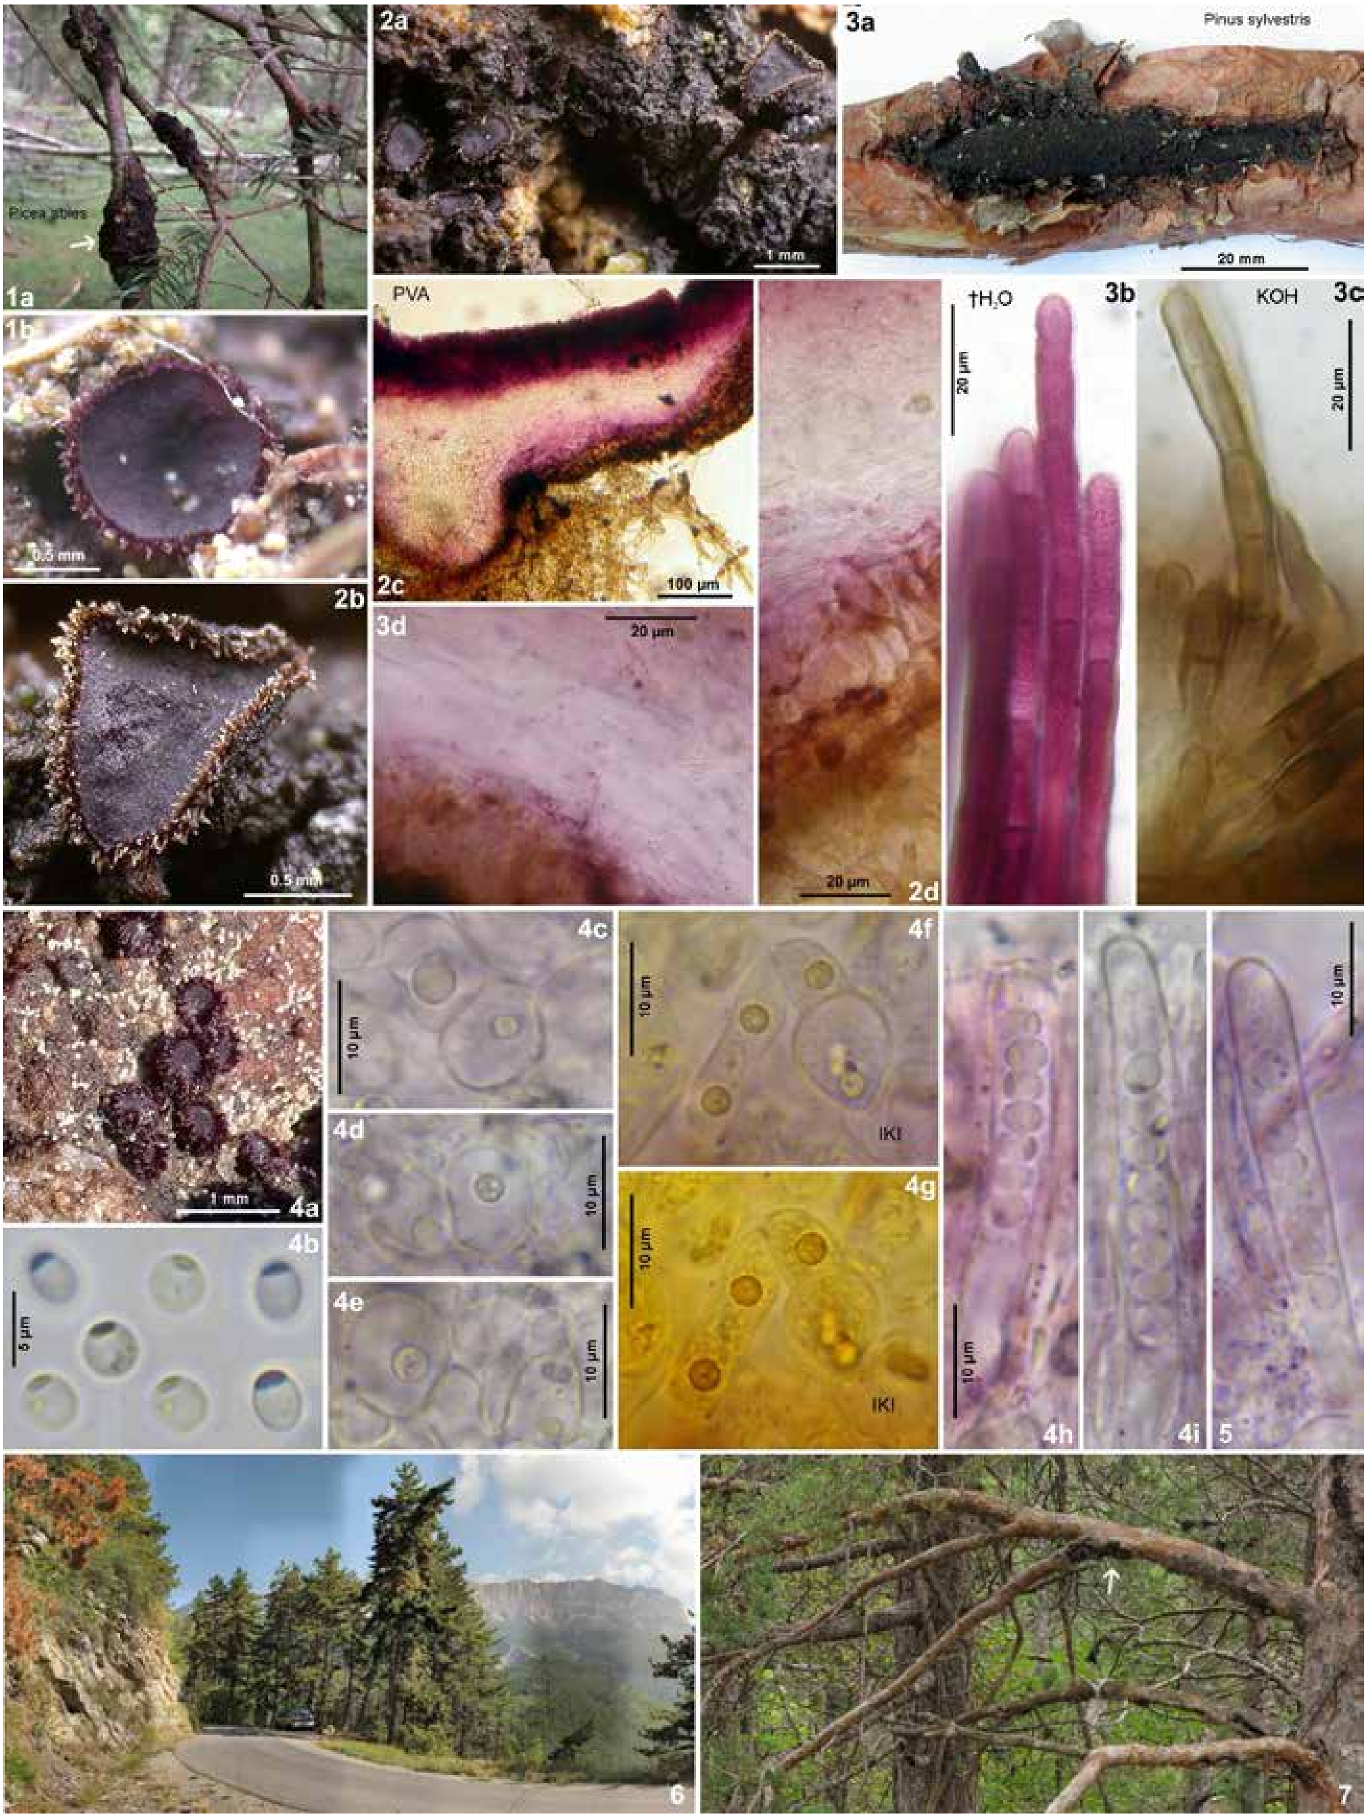

Plate 32. **2–5**: *Lilapila oculisporella*; **1**, **6**, **7**: *L.* cf. *oculisporella*. – **6**. south-exposed orosubmediterranean pine forest in Préalpes de Digne; **7**. living *Pinus sylvestris* trunk and branches with blackened resin; **1a**. living *Picea abies* branches with swollen blackened resinous wounds; **3a**. cut piece of *Pinus sylvestris* branch with blackened resinous wound; **1b**, **2a–b**, **4a**. rehydrated apothecia (**4a**: in situ, **1b**: after 10 days, **2a–b**: after 4.5 years); **2c**. apothecium in median section; **3b–c**. marginal hairs in different media; **2d**. ectal and medullary excipulum at lower flanks, with anchoring hyphae (median section); **3d**. (ectal and) gelatinized medullary excipulum at flanks (median section); **4b**. ascospres; **4h–i**, **5**. asci; **4c–g**. SCBs in inflated catenate cells of medullary excipulum. – Living

Lecophagus pini {1}, *Lilapila oculispora* {1}, *Orbilia eucalypti* {1}, *O. flagellispora* {1/1}, *O. ?graminis* {2}, *O. sphaerospora* {2}, *Pragmopora amphibola* {1}, *Propolis betulae* {1}, *Resinomyces griseus* {5}, *R. kirschsteinianus* {6}, *Sarea difformis* {7}, *S. resinae* {2}. **Desiccation tolerance**: fully tolerant for at least 3.5 months. **Altitude**: 800–1445 m. **Geology**: French Alps: Middle & Upper Jurassic and Cretaceous lime- & marlstone and clay; Massif central: basalt, gneiss. **Phenology**: VI–X (but probably throughout the year).

Taxonomic remarks. *Lilapila oculisporella* is distinguished from *L. oculispora* by narrower asci and smaller ascospores, but measurements overlap in the two species. Another clear distinguishing character appears to be the diameter of the spore bodies. Separation into two species is mainly based on strongly deviating DNA data.

Variation. Ascus size varied between *50–65 × (4.5–)5–5.5 and *55–70 × 5.5–6.5(–7.5) µm, spore size between *3–3.5 × 2.5–3 and 3.5–4(–4.8) × 3–3.5(–4) µm, and SBs between 1.4–2 and 1.8–2.2 µm in diam. and between 0.3 and 1 µm in thickness. This variation was observed on both host tree genera and is confirmed by molecular data.

Not included collections. In five older samples on *Pinus* from Southern French Alps {4} and *Picea* from Auvergne {1} neither measurements were taken nor a voucher specimen retained nor DNA data gained. Since we have so far never collected *L. oculispora* with certainty on *Pinus*, we assume that the *Pinus* samples belong to *L. oculisporella*, and also that on *Picea* might belong here because only *L. oculisporella* was so far recorded from Auvergne.

Cultural characteristics. A pure culture was obtained from ascospores of G.M. 2015-08-30.4. The mycelium grew very slowly (~2.5–3 mm radius per week on CMA:5). Conidia were not observed, neither in culture nor on the natural substrate.

Phylogeny. Sequences from eight samples were taken, six on *Picea* and two on *Pinus*, seven from apothecia and one from pure culture, comprising ITS+LSU (in H.B. 7269 only ITS), four of them also SSU (V7–V9). In the ITS region, strain G.M. 2015-08-28.4 differs by 1 nt (A vs. G) in the ITS1 and 3 nt (A vs. G, T vs. C, C vs. T) in the ITS2, and strain H.B. 7269 by 2 nt (T vs. C) in the ITS1 from the other six samples which show full identity. In the LSU (D1–D2) the seven strains are identical, except for one (G.M. 2016-08-11.1) which deviates at pos. 445 from the typical character of *L. oculisporella* (C) by concurring with *L. oculispora* (T). For the interspecific distances Tab. 57.

DNA data were not available for the type collection. However, in all eight sequenced samples of *L. oculisporella*, which derive from seven remote sites, small asci and spores similar to the holotype were documented.

Ecology. Collections of *Lilapila oculisporella* on *Picea* derive from orotemperate to orosubmediterranean humid Southern French Alps and Massif central, whereas those on *Pinus* are from orosub- or rarely suprasubmediterranean, humid or slightly semihumid Southern French Alps. The geology comprises calcareous bedrock from different epochs.

Specimens included. **FRANCE** (all on resin): **Auvergne**, **Haute-Loire**, Massif central, 15.5 km ESE of St.-Étienne, 4 km ENE of Le Bessat, Mont Pilat, Crêt de la Perdrix, 1370 m, branch of *Picea abies*, 14.VIII.2016, G. Marson (ø). – **Var**, E of Gorges du Verdon, 1.6 km NNW of Comps-sur-Artuby, 2.3 km S of Jabron, 910 m, branch of *P. sylvestris*, 27.IX.2009, G. Marson (ø). – **Auvergne**, **Haute-Loire**, Massif central, 21 km ESE of St.-Flour, 6 km E of Clavières, Forêt d'Auvers (W of Mt. Mouchet), 1346 m, branch of *Picea abies*, on bark & resin, 26.VIII.2004, G. Marson (ø).

Lilapila jurana Stöckli, G. Marson, Baral, U. Graf, Gilgen, Wergen & E. Weber, **sp. nov.**, MB 825647 — Pl. 33, Map 1

Etymology: referring to the occurrence in the Swiss Jura.

Typification: Switzerland, Jura, Tramelan, Moulin de la Gruère, resinous branch of *Picea abies*, 4.VI.2017, J. Gilgen & U. Graf (ex U.G. 0406-17UG1 & ex H.B. 10123, M-0291754, **holotype**; sq.: MH221042)

Latin diagnosis: Lilapilae oculisporae *morphologia persimilis, sed sequentia nucleotidium valde distincta. Habitat ad resinam nigram in ramis siccis, vulneratis, vivis vel leniter putridis* Piceae abietis *in zona orotemperata jurassicae et carpathicae Europae.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.8–2(–3) mm diam. (including hairs), receptacle 0.15–0.25 mm thick, sessile or with a stalk 0.2 × 0.28 mm. **Asci** *(44–)50–70(–80) × (5.5–)6–8(–10) µm {7} [type: *57–70 × 6.2–7.2 µm], spores uniseriate or sometimes 4 spores biseriate, SBs mainly laterally oriented, pars sporifera *25–30 µm long; **base** arising from croziers {4}. **Ascospores** *(3.3–)3.7–4.3(–4.7) × (3–)3.3–4(–4.5) µm {9} [type: *3.7–4.2(–4.5) × (3–)3.3–3.7(–4.2) µm], globose to subglobose (very slightly flattened in side view); **SBs** (0.3–)0.6–0.9(–1.1) × 1.8–2.8 µm {8}. **Paraphyses** terminal cells *13–20 × 2.8–3.5(–4) µm {1}, lower cells *12–18 × 2–3 µm {1}. **Ectal excipulum** 40 µm thick near base and lower flanks, cells *8–19 × 6–11 µm {1}. **Hairs** at margin */†(40–)80–160 × (5–)6–7(–7.5) µm {3}, (3–)6–7(–9)-septate, upper cell 10–20(–35) µm long. **— ANAMORPH**: unknown.

Habitat: collected 1–6 m above the ground, on small to often large, strongly resinous, often swollen wounds of corticated, completely undecayed, still-attached, mostly living, 1.5–10 cm thick branches

---

or rarely 35–40 cm thick trunks of *Picea abies* {17}, always on blackened layer of resin. **Associated**: *Amphosoma atroolivaceum* {1}, *Claussenomyces olivaceus* {1}, *Colpoma crispum* {~3}, *Eustilbum aureum* {1}, *Lachnellula resinaria* {3}, *Lepraria* sp. {1}, *Sarea difformis* {~10}, *S. resinae* {1}. **Desiccation tolerance**: after 6.5–7 months many cells of medullary excipulum and spores still viable. **Altitude**: 1003–1408 m a.s.l. **Geology**: French & Swiss Jura: Upper Jurassic limestone, micrite & marl, decalcified clay, peat; Slovakia: granite, granodiorite. **Phenology**: I, III–IX (throughout the year).

Taxonomic remarks. Morphologically, *Lilapila jurana* appears to be intermediate between *L. oculispora* and *L. oculisporella*. We here recognize it as a separate species because of its strongly deviating DNA data, which was obtained in eight of the 17 included samples. All those without DNA data were tentatively included in the description because they derive from the same substrate, vegetation type, and geographical region in the Swiss Jura on calcareous soil. Four of them are unpreserved and without documentation. Remarkable is the disjunct record from the Slovakian Carpathians on acidic soil. Co-occurrence of different species within a mountain range could be demonstrated by molecular methods; for instance, *L. jurana*, *L. gallica*, and *L. oculispora* are shown to occur in the French Jura (Map. 1).

Variation. Ascus size varied among the collections between *53–75 × 5.3–6.5 and *34–70 × 7–10 µm. This variation was correlated with an infrequent partial biseriate spore arrangement rather than differences in spore size. But also ascospore size varied from *3.3–4 × 3–3.6 to 4–4.7 × 3.6–4.5 µm, though sometimes due to a small amount of oversized spores in 6–7-spored asci. Two collections from the acidic Carpathian Mountains concur well in their asci (*70–75 × (5.5–)6–6.5 µm) and spores (*3.7–4.3 × 3.4–4.2 µm).

Not included collections. The sample from Fribourg is not included because it was not from the Jura region and no documentation or voucher exists. Some recent collections from French Jura sufficiently differ in their rDNA to be treated here as a separate species, ***Lilapila gallica*** G. Marson, Baral & E. Weber nom. prov., which morphologically does not noticeably differ from the other species of the genus: the apothecia measured 0.6–1.25 mm diam., the spores *4.1–4.7 × 3.5–4.5 µm, and the SBs 1.9–2.9 × 0.3–0.7 µm (see IVV).

Phylogeny. Sequences were taken from apothecia of the holotype and three paratypes from Switzerland (ITS, LSU D1–D2, in the holotype also SSU V7–V9), two French samples (SSU V9, ITS, LSU D1–D4), and one from Slovakia (ITS). Six of them coincide in the ITS region, including the holotype and the French and Slovakian samples (the latter three not shown in Phyl. 3), except for an inserted nucleotide at the 5'-end of ITS1 in two of them. One sample (from Pâturage du Bas) deviates by 3 nt in the ITS. In the LSU three positions are variable: pos. 243 and 297 are either C or T, and pos. 136 deviates in the sample from Pâturage du Bas (T) from all other *Lilapila* sequences which have C. All these deviations are unequivocal in the chromatograms. For the interspecific distances see Tab. 57.

L. gallica has the lowest distances to *L. jurana* (ITS/LSU D1–D2: 7–8/1.1–2 %) and clusters with it in a strongly supported clade in NJ or ML analyses of ITS (not shown). In comparison, *L. oculispora* differs from *L. gallica* by 11–13/2.2–2.6 % and *L. oculisporella* by 14–15.3/2.7–3.1 %. The five *L. gallica* samples belong to two genotypes (A/B) which deviate by 1.2–1.4/0.6 %.

Ecology. *Lilapila jurana* is so far mainly known from the orotemperate (altimontane) Swiss and French Jura, where it was collected on blackened resinous wounds of the lowermost living or sometimes recently dead branches of *Picea abies*. It always occurred at sites with a long-lasting snow cover and frequent wafts of mist over the ground. The area of the Swiss Jura is a high plateau with many bogs of which only some remainders exist, because the region is used as a wood pasture for horses and cows, being also manured with slurry. *Picea abies* is the main tree, but also *Abies alba* and different deciduous trees occur. Many collection sites are located close to ± boggy places. The inhabited branches belong to large and old trees that stand free under high sun-exposure and, therefore, have projecting living branches extending down to the ground (Pl. 33: 1). The soil was mainly calcareous (Upper Jurassic) but in Slovakia acidic. Low temperatures all over the year are typical (in winter down to –35 °C), and also high precipitation throughout the year and frequent winds characterize the area. Since *L. jurana* also occurs during winter, the apothecia resist the cold, which could be shown in January 2018 when they survived -22 °C (E. Stöckli pers. comm.). The collection sites in the Slovakian Carpathians are characterized by a similar climate but, in contrast, a strongly acidic bedrock. *L. gallica* from French Jura (on Upper Jurassic limestone, in one case covered by a peat bog) also grew on wounds of *Picea* branches and, like *L. jurana* from French Jura, often in association with *Eustilbum aureum*, but at lower altitudes.

Specimens included (all on resin of *Picea abies*). **SWITZERLAND**: **Jura**, Swiss Jura, 18 km NW of Biel, 2.3 km N of Tramelan, 3 km SW of Les Genevez, La Tourbière du Pâturage du Bas, 1035 m, branch of *P. abies*, 5.VI.2017, J. Amphosoma Baral, **gen. nov.**, MB 813478

Type species: *Amphosoma resinicola* Baral & G. Marson

Etymology: referring to the presence of a spore body at both ends of ascospores.

Latin diagnosis: *Apothecia rehydratata 0.1–0.5 mm diam., alba, roseo-aurantiaca vel atro-olivacea, sessilia vel breviter stipitata, superficialia vel immersa. Asci apice rotundati, tunica in statu emortuo plerumque incrassata, non amyloidei (IKI), octospori, in basi non uncinati, bifurcati. Ascosporae di- vel tristichae in ascis vivis, cylindrico-ellipsoideae vel fusoideo-clavatae, rectae, intus ad polis in statu vivo cum corpusculo lentiformi ad globoso, refringenti. Paraphyses ad apicem non vel valde inflatae, exsudato continuo vel granuloso tectae, cohaerentes vel non cohaerentes. Cellulae excipuli marginalis et paraphysium in statu vivo vacuolas globosas refringentes continentes. Habitat ad corticem, lignum et resinam, in ramis arborum plerumque coniferarum, in aere prominentibus.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.1–0.5 mm diam., whitish to rose-orange or dark blackish-olivaceous, translucent when light-coloured, sessile to short-stalked, superficial to immersed. **Asci** *26–120 × 5.5–11 µm, protruding 1–3 µm beyond exudate when turgescent, 8-spored, spores 2–3-seriate inside living asci; **apex** hemispherical to conical or slightly truncate, with distinct apical thickening (rarely without); **base** simple septate, T-, L-, Y-, h- (or H-) shaped, exceptionally with true croziers with long slit-like perforation. **Ascospores** *(3.3–)5–15(–17.5) × (1.7–)2–4(–5) µm, cylindric-ellipsoid, also fusoid, usually homopolar in shape but some distinctly clavate (then some spores inversely oriented), straight, overmature sometimes becoming 1(–3)-septate, **SBs** *(0.2–)0.3–1(–1.2) × 0.5–1.3 µm, strongly refractive, lens- to plug-shaped or (sub)globose, ± broadly attached to wall at both spore ends. **Paraphyses** apically not or only slightly inflated, rarely strongly clavate-capitate or sublanceolate, *1.8–6 µm wide, terminal cells about as long as lower cells. **Medullary excipulum** of dense textura angularis(-intricata), indistinctly to medium sharply delimited. **Ectal excipulum** hyaline or with yellowish or olivaceous exudate, near base of t. angularis, at flanks and margin of t. angularis to t. prismatica oriented at a high or low angle, (†) slightly to medium gelatinized (common walls 1–1.5 µm thick), cells near base *5–12(–16) × 4–8(–11) µm; **glassy processes** and **hairs** absent. **Anchoring hyphae** *1.8–6 µm wide, wall 0.2–0.5 µm thick, sometimes covered by a thick gel sheath. **SCBs** not observed; **VBs** present in both paraphysis and ectal excipular cells (living state), scattered to abundant, consistently globose and strongly refractive, hyaline, 0.2–2 µm diam., staining bright turquoise in CRB, dead plasma showing a light copper-amber pigmentation due to oxidation of VBs; **LBs** with carotenoids sometimes present. **Exudate** 0.2–0.5 µm thick, continuous, externally smooth or warted to granular, hymenial elements conglutinated or ± easily separable by pressure, **gel** staining distinctly lilac in CRB. — **ANAMORPH**: trinacrium-like. **Colonies** whitish to pale salmon-coloured, slow growing (CMA:2, MEA 2%; *A. resinicola*). **Conidiophores** not observed. **Conidia** 2-armed (T-shaped), total size */†16–41.5 × 11–44 µm, stipe 1–6-septate, arms bent downwards, 0–5-septate.

Habitat: on dead, ± undecayed bark and wood of coniferous branches (usually associated with blackened resin), rarely on angiosperm bark. **Desiccation tolerance**: mature asci tolerating ~0.5–2 years. **Distribution**: Europe, North America, South Africa, (oro)temperate to (sub)tropical, humid to semi- or subhumid.

Recognized species: *A. atroolivaceum*, *A. macrosporum*, *A. natalense*, *A. resinicola*, *A.* aff. *resinicola.*

Taxonomy and relationship. The genus *Amphosoma* forms a small, undoubtedly natural group of species with desiccation-tolerant apothecia, which are predominantly conifer-inhabiting and associated with slightly decayed, blackened resinous wounds. Two characteristics are only visible in the living state, but serve as consistent key characteristics of the genus: (1) small, lens- to plug-shaped SBs occur at both ends of the ascospores; (2) refractive, globose VBs are regularly found inside the terminal cells of paraphyses and marginal ectal excipulum. When only dead specimens are studied, the genus *Amphosoma* may easily be misclassified in the *Helotiales*.

The bipolar arrangement of SBs and the preference for gymnosperms appear to argue for a phylogenetically old group within the *Orbiliomycetes* (see Phylogeny). *Amphosoma* seems to represent a connecting link between *Hyalorbilia* and *Orbilia* by sharing characteristics of both genera. *Amphosoma* resembles *Hyalorbilia* mainly in sporological features: the ascospores are more or less homopolar in shape, and the SBs bipolar-symmetrically arranged. For instance, *Hyalorbilia subfusispora* closely resembles *Amphosoma* in spore shape and bipolar SBs. Also the thin continuous exudate over the paraphyses of *A. resinicola* is reminiscent of a *Hyalorbilia*. However, *Hyalorbilia* differs in a number of traits, especially concerning ascus apex and base, orientation of the ectal excipulum at flanks, length of terminal cells of paraphyses in relation to lower cells, and type of VBs (see also Tab. 56).

The ascospores in the large genus *Orbilia* possess, in contrast to *Amphosoma*, only 1 SB per spore (usually at the upper end, rarely ± laterally), and the spores are often ± heteropolar in shape. As a rare exception, a few aberrant spores of *Orbilia* may contain two SBs, one at each end, reminiscent of *Amphosoma*. What underlines proximity of *Amphosoma* to *Orbilia* is that their asci have a bifurcate, generally simple-septate base and a more or less pronounced apical dome, sometimes with an apical chamber, reminiscent of subgenus *Hemiorbilia*. *Amphosoma* appears to represent the common ancestor of the large genus *Orbilia*, when assuming that in this genus the bifurcate ascus base lacking croziers evolved for the first time within the *Orbiliomycetes*.

The hymenial elements of *Amphosoma* are usually easily separable because the gel on the walls forms an only thin layer, which can be visualized by a deep lilac stain in CRB. The living paraphyses and marginal excipular cells contain strongly refractive, hyaline, globose VBs. This striking guttular pattern provides a characteristic being never observed in *Hyalorbilia* or *Orbilia.* The VBs are consistently globose and usually show no or only slight Brownian motion, apparently because the vacuoles in which they occur are rather small. However, in *A. macrosporum* strong Brownian motion was noted. In *Hyalorbilia* a similar guttular pattern inside the paraphyses and cortical cells may be seen in submature apothecia, but the VBs are larger and only slightly to medium refractive, sometimes pale chlorinaceous, and at progressed maturity they tend to fuse by forming large elongate bodies of a width corresponding to that of the cell lumen. No such fusion of VBs has been seen in *Amphosoma*.

The molecular closeness of *Amphosoma* and *Retiarius* (see below) raises the question whether it is justified to distinguish these two genera. The morphology of the teleomorph of *Retiarius* is unknown, and an adaptation to pollen as nutrient source was so far not determined in *Amphosoma*.

Species delimitation and confusion. The four recognized species are quite easily distinguished. Only in the rare case of albinism in *A. atroolivaceum*, delimitation against the shorter-spored *A. resinicola* was difficult.

Amphosoma persooniae Crous was proposed by Crous (2017) for a pycnidial fungus on stem canker of *Persoonia* sp. from southeastern Australia. It was placed in *Amphosoma* solely based on molecular data which clearly point to that genus (see below). We have doubts, however, that the described fungus is orbiliaceous. The species formed minute, globose, dark brown pycnidia which contain hyaline phialidic conidiogenous cells with prominent periclinal thickening that form 4.5–7 × 2–3 µm large, hyaline, smooth, subcylindrical conidia. For the time being we consider *Amphosoma persooniae* as non-orbiliaceous and the associated molecular data as belonging to an unknown species of *Amphosoma*. Besides, the taxon is invalid because the generic name was only proposed as a nomen provisorium in Baral et al. (2017b) (ICN Art. 35.1).

Anamorph. In three of the *Amphosoma* species a trinacrium-like anamorph was recorded in which the arms of the slender, Y- or T-shaped conidia are consistently bent downwards. This anamorph strongly resembles that found in *Hyalorbilia erythrostigma* and *H. orbiliicola*. Similar but more robust conidia with downwards curved arms resemble *Trinacrium incurvum* and occur in *Orbilia* in series *Lentiformes*, *Piliferae*, and *Hesperideae* (*O. corculispora*).

Phylogeny. Molecular data were available for three species, *A. atroolivaceum*, *A. resinicola*, *A.* aff. *resinicola* (G.M. 2015-09-15.2), and the dubious *A. persooniae*, comprising ITS and LSU. A deviating sequence of *A. atroolivaceum* (G.M. 2017-11-05.1) includes also SSU V6–V9. The S1506 intron is absent in all of them. Our phylogenetic analyses of 5.8S+LSU or SSU+ITS+LSU (Phyls 1–2) support the position of *Amphosoma* near *Lecophagus*, *Retiarius*, and *Lilapila* by showing a higher distance to the morphologically similar genus *Hyalorbilia.* However, the distance to all these genera is very high, and even between *A. atroolivaceum* and *A. resinicola* it is 21% in the ITS. In the combined analysis of SSU+ITS+LSU in Baral et al. (2017b), the genus appeared paraphyletic by forming together with *Lecophagus* and *Lilapila* a strongly supported clade, distant from the *Hyalorbilia* clade and *Orbilia*. In the present combined analysis of all orbiliaceous genera with DNA data (Phyl. 2), *Amphosoma* appeared as an unsupported monophyletic clade which formed a strongly supported clade only under inclusion of *Retiarius* (and *Lecophagus*). This result is astonishing, considering the high morphological similarity between *Amphosoma* and *Hyalorbilia*, particularly regarding the bipolar SB arrangement in the ascospores.

When analysing ITS (Phyl. 3), *Amphosoma* formed a strongly supported monophyletic clade, whereas when analysing LSU (Phyl. 4) its species clustered unresolved among the other genera. Based on these analyses we feel affirmed in recognizing *Amphosoma* and *Retiarius* as two different genera, which is supported by a number of distinctive nucleotides in the ITS and LSU (Tab. 58). In Magyar et al.'s (2017a, b) Bayesian analyses of ITS+LSU the two genera formed strongly supported monophyletic clades in an unsupported sister position. The two genera include also various environmental sequences of different taxa from GenBank (A1–A6, R1–R4 in Phyl. 3; A5–A6, R1–R4 in Magyar et al. l.c.). It seems interesting that in the SSU V8–V9 *Amphosoma* and *Lecophagus* concur at some informative positions (Pl. 56) at which other genera differ (no SSU was available for the genus *Retiarius*).

A. persooniae shows a 10.5% ITS distance to *A.* aff. *resinicola*, 14.5% to *A. resinicola*, and 19% to *A. atroolivaceum*. In our analysis of SSU+ITS+LSU (Phyl. 2), it clustered strongly supported with *A. resinicola* in a clade, but when including *A.* aff. *resinicola* (not shown) it clustered strongly supported with this species (NJ) or unresolved with *A. resinicola* s.l. (ML). The morphological similarity between *A.* aff. *resinicola* and *A. natalense*, including a very similar spore size, might indicate that the *A. persooniae* sequence belongs to a teleomorph that closely resembles *A. natalense*. Both originate from angiosperm hosts and the present phylogeny suggests that angiosperm inhabiting species of *Amphosoma* developed from the so far predominant conifericolous taxa. The phylogeny of the angiosperm inhabiting sister genus *Retiarius* appears to have taken place in a separate lineage.

Specific nucleotide positions. In the entire 5.8S region *Amphosoma atroolivaceum*, *A.* aff. *resinicola*, and '*A. persooniae*' concur with *Retiarius revayae* and *R. superficiaris*, whereas *A. resinicola* differs by 1 nt and *R. bovicornutus* by 2 nt (3 nt between the latter two). Because of this similarity, *Amphosoma* concurs with *Retiarius* in the region of the '*Orbiliales*-specific' primers Orb5.8s1F and Orb5.8s3F (Smith & Jaffee 2009), except that *A. resinicola* deviates in Orb5.8s3F by concurring with *Lecophagus* (Tab. 18). In the primer Orb28s2R, *A. atroolivaceum* and '*A. persooniae*' concur with *R. bovicornutus* and *R. superficiaris*, but also with *Lecophagus*, *Lilapila* p.p., and some *Orbilia* spp., whereas *A. resinicola* and *R. revayae* deviate by the same nucleotide, and *A.* aff. *resinicola* shows another variant (Tab. 19). In the LSU D3 domain, 2 positions are unique for *Amphosoma* (including the strains from Texas): at pos. 748 and 770 the genus has GACCG**G**TCCTG and GGAT**C**TGAG, respectively, in contrast to all other *Orbiliomycetes* (including *Retiarius*) which have GACCG**A**TCCTG (very rarely other variants) and GGAT**T**TGAG. Another motif (pos. 726–730) is characteristic for *Amphosoma* (including the strains from Texas) and *Retiarius revayae* (AGGTGGGAG**CCCGC**AAG), in contrast to various other variants of this motif in the remaining *Orbiliomycetes*. However, *A.* aff. *resinicola* has here AGGTGGGAGCCCG**T**AAG similar as *Bryorbilia* sp. (B2, AGGTGGGAGCCCG**T**AG). Members of the *Vermispora* clade of *Hyalorbilia* have a similar motif here, deviating only at pos. 722: AGGTG**A**GAG**CCCGC**AAG.

Ecology. The two European members of *Amphosoma* occur in the same habitats as those of *Lilapila*, i.e., resinous, xeric, undecayed coniferous bark or sometimes wood in montane to subalpine, orotemperate to orosubmediterranean, humid (mixed) conifer forests. *A. atroolivaceum* also occurs in temperate colline regions of central Europe. The single record of the North American *A. macrosporum* was on xeric, rotten, non-resinous bark of *Pinus* in the cold-temperate subhumid southwest, and that from South African *A. natalense* on xeric, medium decayed bark of a legume tree in a subtropical humid (winter-dry) coastal forest.

Key to species of *Amphosoma*

1. Asci *80–120 × 10.5–11 µm; spores *11–15(–17.5) × 3.5–4.5(–5) µm, SBs 1.1–1.3 µm wide; paraphyses apically *3–6 µm wide; anchoring hyphae *4–6 µm wide; apothecia whitish to pale rose; bark of *Pinus edulis*, cold-temperate subhumid western North America .... ***A. macrosporum***, p. 281

1. Asci *26–70 × 5.5–11 µm; spores *4–10.5 × 1.7–3 µm, SBs 0.5–1 µm wide; paraphyses apically *1.8–4.3 µm wide; anchoring hyphae *1.8–3.5 µm wide 2

2. Apothecia dark blue-green-olivaceous to almost black, exceptionally some apothecia light blue-green or whitish; spores *(5.5–)6.5–9.5(–10.5) × (2.2–)2.5–3 µm, ellipsoid to clavate; blackened resinous cankers of various gymnosperms, (oro)temperate to (oro) submediterranean humid Europe .... ***A. atroolivaceum***, p. 278

2. Apothecia whitish to light cream-reddish; spores *(3.3–)4–6.5(–8) µm long 3

3. Spores *(3.3–)4–6.5(–8) × (1.8–)2–2.7(–3) µm, ellipsoid, rarely subclavate; asci *32–63 µm long; resinous cankers of various gymnosperms, orotemperate to orosub- or suprasubmediterranean humid southern Europe, boreal western North America .... ***A. resinicola***, p. 274

3. Spores *(4.8–)5.5–6.5(–7) × 1.7–2.1 µm 4

4. Asci *36–40 µm long; spores ellipsoid-fusoid to subclavate; resinous canker of *Pinus*, orosubmediterranean humid southern Europe .... ***A.* aff. *resinicola***, p. 275

4. Asci *~ 24–33 µm long; spores fusoid to clavate; bark of angiosperm (?*Pterocarpus*), subtropical humid southeastern Africa .... ***A. natalense***, p. 277

Amphosoma resinicola Baral & G. Marson, **sp. nov.**, MB 813479 — Pls 34–35, Map 2

Etymology: referring to the growth on resinous wounds of gymnosperms.

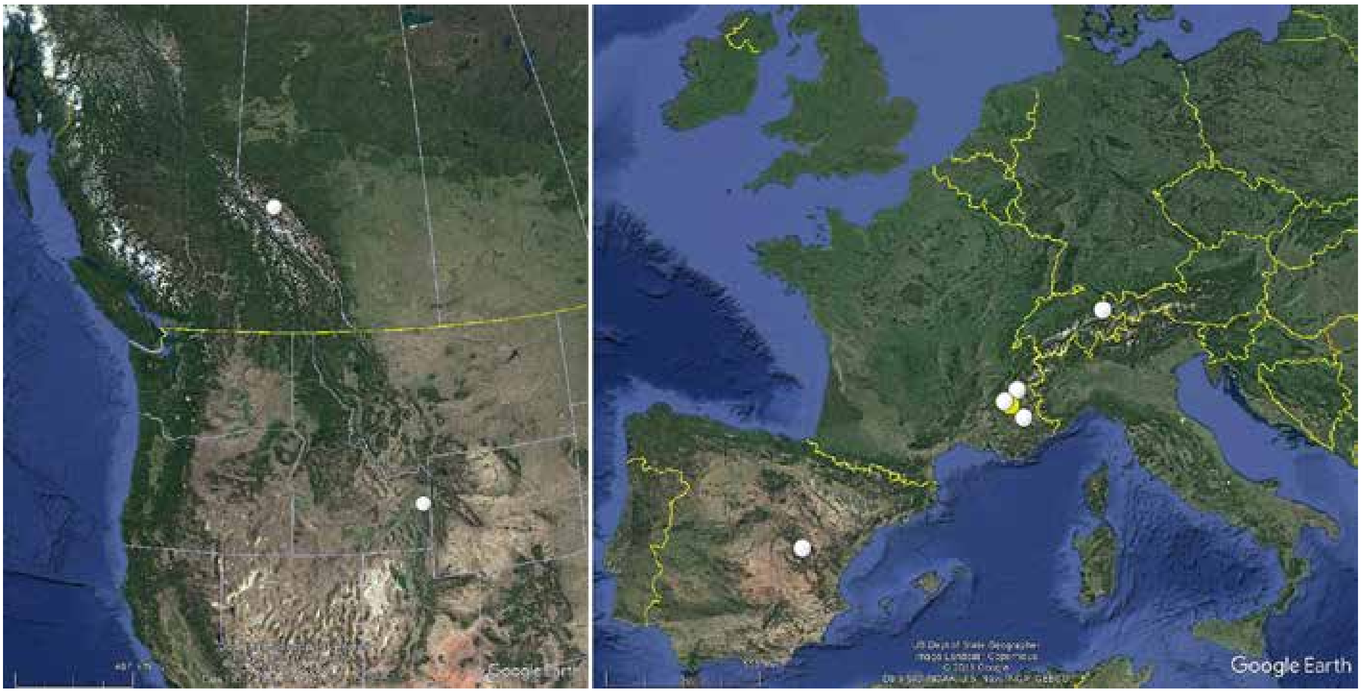
Typification: Spain, Teruel, Frías de Albarracín, branch of *Pinus sylvestris*, 26.IX.1999, G. Marson (ex H.B. 6491, M-0276404, holotype).

Latin diagnosis: *Apothecia in statu rehydratato tota alba, luteo-ochracea vel roseo-aurantiaca, lentiformia, margine glabro. Ascosporae *4–6.5 × 2–2.8 µm, (clavato-)ellipsoideae. Habitat in ramis vulneratis siccis coniferarum, leniter putridis, in aere prominentibus, plerumque ad resinam nigram, in zona orotemperata et orosubmediterranea Europae meridionalis et zona boreale Americae septentrionalis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.1–0.35(–0.5) mm diam., 0.1–0.14(–0.21) mm thick (receptacle 0.07–0.08 mm), whitish-greyish or usually pale to light (or bright) (cream-)rose, yellowish-ochraceous, or amber-orange, translucent, round, scattered to subgregarious in small groups; disc flat to slightly convex, margin thin, 0–5 µm rising above disc, exterior glabrous; sessile on an obconical base, also with an obconical stipe 0.05–0.14 × 0.15–0.25 mm sometimes immersed in biofilm; dry deeper orange-reddish. **Asci** *(32–)36–52(–63) × (4.5–)5.5–7 {8} → 7–8 µm, †33–48(–61) × (4.3–)5–5.8(–7) µm {3}, 8-spored (rarely 1–4 spores aborted), spores 2–3-seriate, sometimes 1–3 spores inverted if distinctly heteropolar, pars sporifera *15–24 → 15 µm long; **apex** (†) hemispherical to slightly truncate, dome *0.6–0.8 µm thick {2}, immature †0.7–1.2(–1.8) µm, mature †0.6–1.2 µm thick {5}, rarely with a distinct annular protrusion and apical chamber, sometimes only */†0.3–0.8 µm thick {2} thick; **base** with medium long, thick, slightly flexuous stalk, L-, Y- or h-shaped, croziers only exceptionally present (with slit-like perforation). **Ascospores** *(3.3–)4–6.5(–8) × (1.8–)2–2.7(–3) µm {8}, †4–5.5 × 1.8–2.4 µm {1}, (subcylindric–)ellipsoid, sometimes slightly to distinctly clavate, ends rounded (rarely obtuse), straight to somewhat inequilateral; **SBs** *(0.2–)0.4–0.8 × 0.5–1 µm {8}, lens- to plug-shaped, broadly attached to wall at both spore ends; **LBs** very sparse, small; rarely some overmature 1-septate spores observed. **Paraphyses** apically uninflated to medium clavate-capitate, terminal cells *5–16 × (1.8–)2.2–3.7(–4.3) µm {4}, lower cells *6–13.5 × 1.5–2.7(–3.5) µm {4}, frequently branched near base, rarely at upper septum. **Medullary excipulum** 20–60 µm thick, of dense textura angularis-intricata, indistinctly to medium sharply delimited. **Ectal excipulum** hyaline, of (†) slightly to medium gelatinized (common walls 1–1.5 µm thick), indistinctly oriented t. angularis(-prismatica) from base to mid flanks, 20–30(–130) µm thick near base, cells *7–12(–16) × 6–10(–11) µm {3}, cells at flanks *5–8 µm wide; near margin of 10–15 µm thick t. prismatica-globulosa oriented at a 0–45° angle to the surface, marginal cortical cells *(4.5–)6–11 × 3–4(–4.5) µm {3}. **Anchoring hyphae** sparse, */†1.8–2.5 µm wide, walls 0.2–0.4 µm thick {2}. **VBs** present in paraphyses [upper 1–2(–3) cells] and uppermost margin {5}, globose, 0.2–0.6(–1.3) µm diam., strongly refractive, hyaline, medium abundant (multiguttulate); **LBs** in paraphyses scattered, small, also in ectal excipulum, excipular cells at base and flanks each with 1–2 LBs 1.5–2 µm diam. {1}. **Exudate** over paraphyses and entire excipulum 0.2–0.5 µm thick {6}, hyaline, strongly refractive, continuous, smooth or finely warted. **— ANAMORPH**: trinacrium-like (from ascospore isolate {1} and natural substrate {2}). **Conidiophores** not observed. **Conidia** 2-armed (T-shaped), total size *25–41.5 × 24–44 µm {2}, stipe *22–34.5 × 2.5–3 µm, (1–)2–6-septate, arms not or slightly tapering, bent downwards, *11.5–22 × 2.5–3.5 µm in situ (actual length ~ 12–23 µm), (0–)1-5-septate.

Habitat: on still-attached (0.8–2.5 m above the ground), living or recently dead, corticated, 6–35 mm thick branches, also 10–15 cm thick trunks, of *Abies alba* {1}, *Picea* sp. {1}, *P. abies* {5}, *Pinus sylvestris* {1}, *Pseudotsuga menziesii* {1}, always in or close to ± swollen wounds, mainly on medium to strongly blackened resin {9}, or on bulging bark along decorticated wound, on slightly to sometimes medium decayed bark {5} and wood {1}, green algae sparse to abundant. **Associated**: *Amphosoma atroolivaceum* {3}, *Capronia ?mansonii* {1}, *Ciliolarina* sp. {1}, *C. ?laricina* {1}, *C. pinicola* {1}, *Claussenomyces olivaceus* {1}, *Eustilbum aureum* {1}, *Durandiella gallica* {1}, *Evernia prunastri* {1}, *Hypogymnia physodes* {1}, *H. vittata* {1}, *Lachnellula abietis* {1}, *L. resinaria* {2}, *Lilapila oculisporella* {2}, *Orbilia alpigena* {1}, *O. aristata* {2}, *O. flagellispora* {3}, *O. vinosa* {1}, *?Pragmopora* sp. {1}, *Pseudohelotium sordidulum* {1}, *Resinomyces griseus* {2}, *Sarea difformis* {4/1}, *Stictis* sp. {1}, *Usnea* sp. {1}. **Desiccation tolerance**: fully tolerant for at least 5.5 months, some mature asci, ascospores and conidia still viable after 2 years. **Altitude**: 1165–1780 m a.s.l. **Geology**: USA: Cambrian-Ordovician & Devonian-Carboniferous sedimentary rock, basalt; Europe: Lower to Upper Jurassic marl- & limestone, dolomite. **Phenology**: VI–IX (possibly throughout the year?).

Taxonomic remarks. *Amphosoma resinicola* is characterized by rather small, ± ellipsoid ascospores containing two small polar SBs, and light-coloured apothecia. *A. macrosporum* differs in much



Map 2. Known distribution of *A. resinicola* in North America and Europe (yellow = genetically deviating collection).

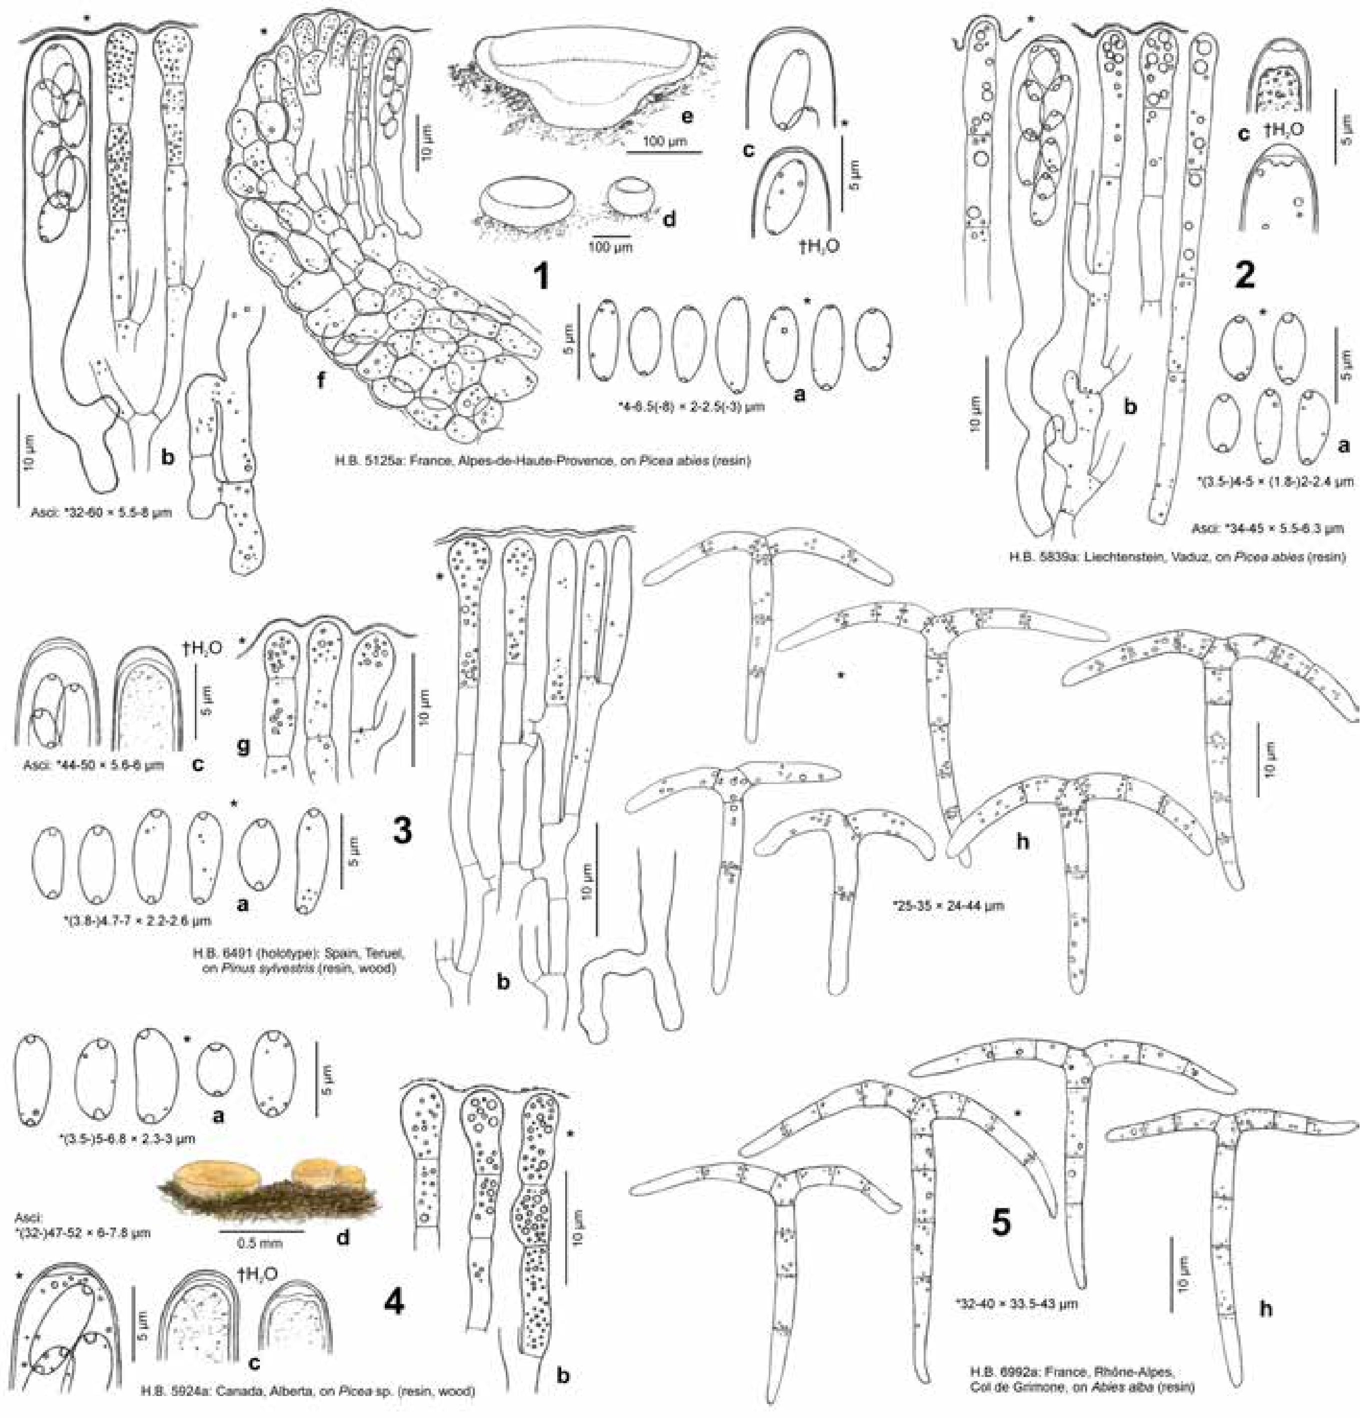


Plate 34. **1–5**: *Amphosoma resinicola*. – **a**. ascospores; **b**. asci and paraphyses (containing VBs); **c**. ascus apices; **d**. rehydrated apothecia; **e**. apothecium in median section; **f**. id., ectal excipulum at margin and flanks; **g**. external view on marginal cells; **h**. conidia (from substrate).

larger asci and spores. For confusion with the similar but usually dark-coloured *A. atroolivaceum* see under that species (p. 278).

Variation. A certain degree of variation was noted in ascus and spore size. In the North American collections the width of asci, ascospores and paraphyses was at the upper end of the range of the species, but in their morphology they fit well European populations. The asci are usually provided with a distinct apical thickening, but in two collections from Col du Labouret (H.B. 5125a, 9136d/9162e) the apices were almost thin-walled, without an internal wall thickening in the dead state. Remarkable is the occasional formation of croziers at the ascus base.

Not included collection. A sample with slightly longer and especially narrower spores (*5.7–6.7 × 1.7–2 µm) is genetically quite distant and represents a species of its own, though occurring like *A. resinicola* on coniferous resin in orosubmediterranean Europe (IVV: 15.IX.2015). In spore size it approaches the African *A. natalense* on angiosperm bark, but its spores are less fusoid-clavate and its asci longer (*36–40 × 5.2–5.8 µm).

Anamorph. In our agar cultures of the holotype of *A. resinicola* (CMA:2, MEA, WA) no conidia were produced. However, when an agar block was flooded with water, a few trinacrium-like conidia were seen after about a week which fully coincided with those observed on the natural substrate.

Phylogeny. Sequences were taken from apothecia of three samples (G.M. 2010-09-03.2, Isère, *Picea*; G.M. 2011-09-19.4, Alpes-de-Haute-Provence, *Picea*; G.M. 2015-09-15.5, Hautes

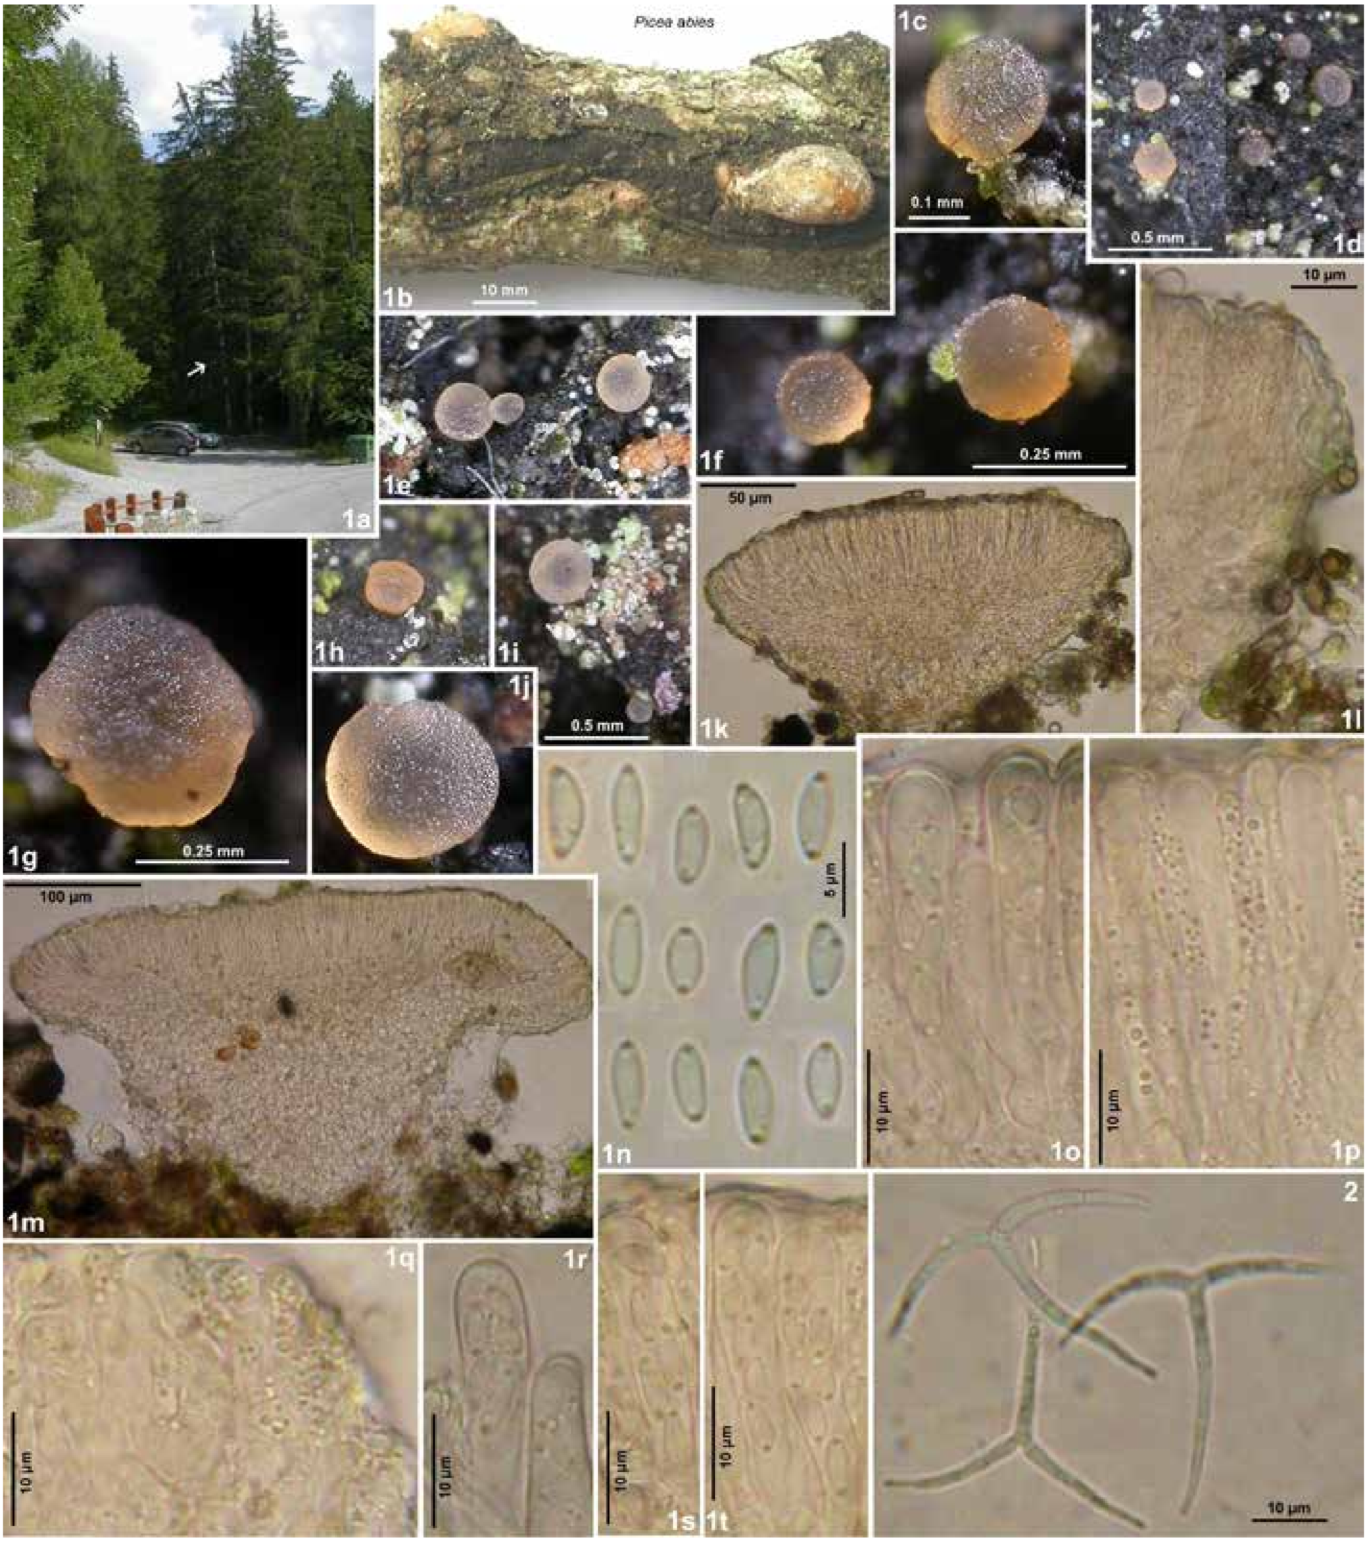

Plate 35. **1–2**: *Amphosoma resinicola*. – **1a**. orosubmediterranean *Picea* forest (Massif des Trois-Évêchés); **1b**. living *Picea* branch with blackened resinous wound; **1c–j**. rehydrated apothecia; **1k**, m. apothecia in median section; **1l**. id., ectal excipulum at flanks and margin; **1q**. id., marginal excipular cells containing VBs; **1o**, **r–t**. mature asci; **1p**. paraphyses (containing VBs); **1n**. ascospores; **2**. conidia from substrate. – Living state, except for **2** (in H_2O), **1o** (right ascus) — **1a–t**. H.B. 9162e: France, Col du Labouret, on *Picea*; **2**. H.B. 6992a: France, Col de Grimone, on *Abies*.

Alpes, *Pinus*), comprising ITS and LSU. In all the S1506 intron is absent. In the ITS region the two on *Picea* are 100 % identical. The distance to *A. atroolivaceum* lies at ~21 % in the ITS and at 5.5 % in the LSU (D1–D3).

The *Pinus* sample surprisingly differs in the ITS from both *A. resinicola* and *A. atroolivaceum* by 19 % and from *A. persooniae*, with which it clustered in a supported clade in our analysis (not shown), by 10.5 %. Because of its whitish apothecia and resinicolous habitat it is named *A.* aff. *resinicola* here.

Ecology. *Amphosoma resinicola* appears to be restricted to resinous wounds of still-living or recently dead xeric branches and trunks of gymnosperms. The apothecia grew mainly on resin covered by black hyphomycetes. The species is apparently not rare in subcontinental, altimontane to subalpine, orotemperate to orosubmediterranean, sometimes almost suprasubmediterranean, humid (to slightly semihumid), mixed or pure conifer forests of the Northern Calcareous and Southern French Alps and the Sistema Ibérico in Spain on Jurassic soil (the not included sample on Oligocene marl & molasse). *A. resinicola* in western North America was found in the boreal humid Douglas fir mixed forest of the Canadian and Northern Rocky Mountains on Paleozoic soil.

Specimens included. **LIECHTENSTEIN**: 5 km SE of Vaduz, S of Steg, Saminatal, Im Grund, 1310 m, branch of *Picea abies*, on resin, 7.VII.1997, H.O. Baral (H.B. 5839a). — **FRANCE**: **Rhône-Alpes**, **Drôme**, 55 km S of Grenoble, 5 km NW of Lus-la-Croix-Haute, Col de Grimone, 1330 m, branch of *Abies alba*, on resinous bark, 3.VIII.1999, G. Marson (H.B. 6992a, anam. substr.). – **Isère**, 38 km SE of Grenoble, 1.5 km SSE of Les-Deux-Alpes, 1780 m, trunk of *Picea abies*, on resinous bark, 3.IX.2010, G. Marson (G.M. 2010-09-03.2; sq.: KT222388). – **Provence-Alpes-Côte d'Azur**, **Alpes-de-Haute-Provence**, 22 km NE of Digne-les-Bains, 1.6 km NE of Le Labouret, Col du Labouret, 1250 m, branches of *P. abies*, on resin, 17.VII.1994, G. Marson (H.B. 5125a, G.M. 5205). – ibid., branches of *P. abies*, on resin & bark, 14.VIII.2009, G. Marson, H.O. Baral & B. Liu (H.B. 9136d, 9162e). – ibid., branch of *P. abies*, 19.IX.2011, G. Marson (G.M. 2011-09-19.4; sq.: KT222389). — **SPAIN**: **Aragón**, **Teruel**, Sierra de Albarracín, 49 km W of Teruel, 5.8 km WSW of Frías de Albarracín, 1615 m, branch of *Pinus sylvestris*, on bark & resin, 26.IX.1999, G. Marson (ex H.B. 6491, M-0276404, **holotype**; anam. substr., anam. cult.). — **CANADA**: **Alberta**, 7 km NE of Jasper, Maligne Canyon, 1165 m, branch of *Picea* sp., on wood & resin, 17.VIII.1997, G. Marson (H.B. 5924a). — **USA**: **Idaho**, Columbia Plateau, base of Rocky Mountains, 60 km E of Idaho Falls, 47 km W of Jackson, Swan Valley, 1750 m, branch of *Pseudotsuga menziesii*, on bark & resin, 5.VI.1996, G. Marson (H.B. 5603).

Not included. **FRANCE**: **Provence-Alpes-Côte d'Azur**, **Hautes-Alpes**, 16 km W of Gap, NNE of Montmaur, 1020 m, branch of *Pinus sylvestris*, on resin, 15.IX.2015, G. Marson (G.M. 2015-09-15.2, sq.: MN151404).

Amphosoma natalense Baral, **sp. nov.**, MB 813480 — Pls 36–37

Etymology: named after the geographical origin, KwaZulu-Natal (South Africa).
Typification: South Africa, KwaZulu-Natal, Santa Lucia, branch of indet. angiosperm (?*Pterocarpus*), 25.II.2006, V. Kummer (ex H.B. 8086a, M-0276403, holotype).

Latin diagnosis: Amphosomati resinicolae *similis, sed asci breviores, ascosporae angustiores, magis fusoideae. Habitat ad corticem putridum rami sicci arboris ?*Pterocarpi *in zona subtropica humida Africae australis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.2 mm diam., whitish-cream, round, scattered; disc flat, margin smooth; with a short and broad stipe, superficial. **Asci** *26 × 5.6 µm, †22–30 × 4.7–5.1 µm, 8-spored, spores *3-seriate, ~4 lower spores inverted, pars sporifera *14.5 µm long; **apex** (†) hemispherical to slightly truncate-conical, dome †0.7 → 0.2–0.5 µm thick, without apical chamber; **base** with short to medium long, flexuous stalk, Y- to h-shaped. **Ascospores** *(4.8–)5.5–6.5(–7) × (1.7–)1.8–2(–2.1) µm, fusoid-ellipsoid to fusoid-clavate or clavate, ends obtuse to subacute, sometimes rounded, straight to slightly inequilateral; **SBs** *0.5–0.9 × 0.5–0.8 µm, globose to somewhat plug-shaped, ± broadly attached to wall at both spore ends; often with some small and medium-sized LBs. **Paraphyses** apically uninflated to slightly clavate-capitate, terminal cells *1.8–2 wide. **Medullary excipulum** not studied. **Ectal excipulum** of slightly gelatinized textura angularis(-prismatica) from base to margin, cells at flanks *5–7 × 4–5 µm, oriented at a high angle to the surface, marginal cortical cells *5–9 × 3–4.7 µm; **glassy processes** absent. **Anchoring hyphae** not seen. **VBs** in paraphyses not seen, in marginal ectal excipulum globose, strongly refractive, hyaline, 1.3–2 µm diam. **Exudate** over paraphyses and margin 0.2–0.3 µm thick, hyaline, continuous, ± smooth. — **ANAMORPH**: trinacrium-like (presumed, from natural substrate {1}). **Conidiophores** not observed. **Conidia** 2-armed (Y/T-shaped), total size */†20–23 × 24–27 µm {1}, stipe */†16–18 × 3–4 µm, 2–4-septate, arms gradually tapering, mostly distinctly bent downwards, */†11.5–14.5 × 2.7–3.2 µm, (1–)2-septate.

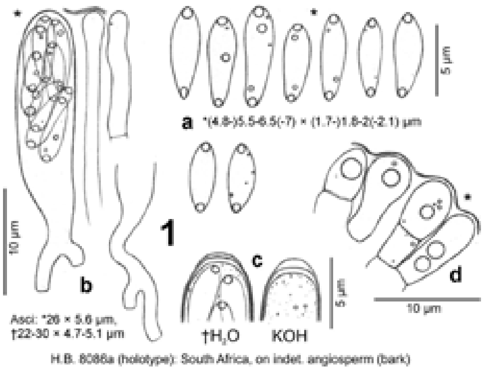

Plate 36. **1**: *Amphosoma natalense*. – **a**. ascospores; **b**. ascus and paraphyses; **c**. ascus apices; **d**. marginal excipular cells (containing VBs).

Habitat: collected ~4 m above the ground, medium sun-exposed, corticated, 20 mm thick branch of indet. angiosperm (?*Pterocarpus*), recently dead, on medium decayed bast in transversal cleft of bark. **Associated**: *Helicoma muelleri*, *Tremella* sp., various lichens (fruticose, foliose, crustose). **Desiccation tolerance**: fully tolerant for at least 3 weeks. **Altitude**: 10 m a.s.l. **Phenology**: II (southern hemisphere).

Taxonomic remarks. *Amphosoma natalense* differs from *A. resinicola* in shorter asci and narrower, more fusoid ascospores, and especially in growing on bark of an angiosperm.

Anamorph. A few conidia similar to *Trinacrium angamosense* (?= *Hyalorbilia erythrostigma*) were found on the natural substrate (Pl. 37: 1d). Among them was also one with 3 arms that formed the shape of a K (curucispora-like), and one reminiscent of *Retiarius revayae*.

Phylogeny. No sequence was available, but based on habitat, angiosperm bark, *A. natalense* might be related to '*A. persooniae*' (see p. 272).

Ecology. *Amphosoma natalense* was collected on a xeric branch of a free-standing broad-leaved tree of an unidentified member of *Fabaceae*. Only a single apothecium could be discovered on medium decayed bast in a transversal cleft of bark. The area belongs to a subtropical humid (winter-dry savannah) oceanic coastal dune and swamp forest in southeastern Africa.

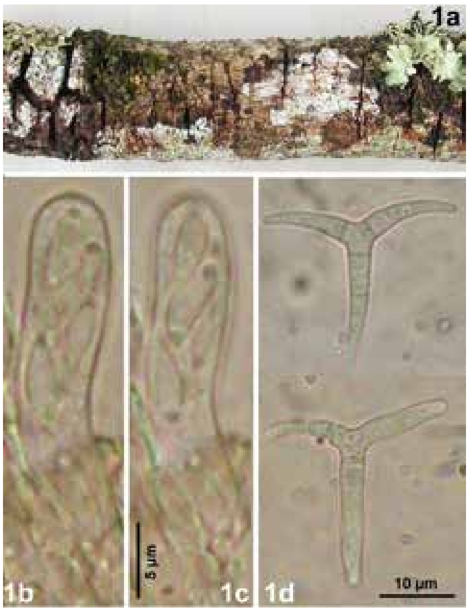

Plate 37. **1**: *Amphosoma natalense*. – **1a**. dead corticated branch with transversal clefts and foliose and fruticose lichens; **1b–c**. ascus with ascospores; **1d**. conidia (from substrate). – Living state (except for left arm of lower conidium). — **1a–d**. H.B. 8086a (holotype): South Africa, on indet. angiosperm (?*Pterocarpus*).

Specimens included. **SOUTH AFRICA**: **KwaZulu-Natal**, 210 km NE of Durban, 55 km NE of Richards Bay, 1 km SE of Santa Lucia, St. Lucia Estuary, Sugarloaf Rest Camp, 10 m, branch of indet. *Fabaceae* (?*Pterocarpus*), on bark, 25.II.2006, V. Kummer (ex H.B. 8086a, M-0276403, **holotype**, anam. substr.).

Amphosoma atroolivaceum Baral & G. Marson, **sp. nov.**, MB 813481 — Pls 38–39, Map 3

Etymology: named after the dark-coloured, blackish-olivaceous apothecia.

Typification: France, Vaucluse, Mont Ventoux, branch of *P. sylvestris*, 14.VIII.2009, H.O. Baral & G. Marson (ex H.B. 9143b, M-0276401, holotype).

Latin diagnosis: *Ab* Amphosomate resinicola *apotheciis atroolivaceis, ascosporis longioribus differt. Habitat in ramis vel truncis vulneratis siccis coniferarum, leniter putridis, in aere prominentibus, plerumque ad resinam nigram, in zona (oro)temperata ad (oro)submediterranea Europae centralis et meridionalis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated (0.1–)0.15–0.35(–0.5) mm diam., 0.11–0.18 mm thick (receptacle 0.07–0.1 mm), dark blue-green-olivaceous to black (exceptionally light blue-green or whitish-cream), shining, round, rarely irregular by mutual pressure, scattered to gregarious; disc slightly concave to slightly convex, margin distinct, only young slightly rising above disc, even, externally glabrous; sessile on a narrowed base, often with a pale stalk ~0.05–0.09 × 0.06–0.15 mm completely immersed in layer of dark hyphomycetes; dry black, invisible. **Asci** *(32–)40–61(–68) × (6.3–)7–8.5(–11) µm {7}, †28–40 {1} or 40–67 {2} × 5.5–7.3 {3} µm, 8-spored (rarely only 6 spores developed), spores *2–3-seriate, 1–4 lower (exceptionally upper) spores inversely oriented (if heteropolar) {5}, pars sporifera *18–33 µm long; **apex** (†) hemispherical to slightly truncate, dome *1 µm thick, †0.8–1.5(–1.8) µm {5}, sometimes with apical chamber, surface often covered by a thin olivaceous cap; **base** with or without short to medium long, thick, ± flexuous stalk, H-, h-, U-, T- or L-shaped, simple-septate, exceptionally forming a crozier with slit-like, 12 µm long perforation. **Ascospores** *(5.5–)6.5–9.5(–10.5)((–12.5)) × (2.2–)2.5–3((3.5)) µm {20}, †5.5–9.2 × 2.3–2.8 µm {2}, (subcylindric-)ellipsoid, sometimes distinctly (fusoid-)clavate, ends rounded or obtuse, straight, rarely medium curved near base; rarely some free spores 1-septate {2}; **SBs** *0.3–0.8 × 0.7–1.1 µm {7}, lens- or plug-shaped, broadly attached to wall at both spore ends {23}; usually with 1–2 large **LBs** 0.4–1(–1.3) µm diam. and a few or many small ones. **Paraphyses** apically uninflated to slightly (rarely medium) clavate-capitate, sometimes sublanceolate, terminal cells *7–14(–19) × 1.8–3(–3.6) µm {5}, lower cells *7–15 × 1.7–2.3 µm {5}; rarely branched near apex. **Medullary excipulum** hyaline to pale olivaceous-brownish, 30–50 µm thick, of dense irregular textura angularis, cells *4–11(–13) × 4–8 µm, distinctly delimited from ectal excipulum by a thin, olivaceous t. porrecta. **Ectal excipulum** with a pale to bright olive-brown intercellular exudate (but hyaline at base of stipe), slightly to medium gelatinized, near base of t. angularis(-prismatica) oriented at a 70–90° angle to the surface, 20–35 µm thick, cells *6–9 × 4–6(–7) µm {2}; at flanks and margin of t. angularis-prismatica or t. porrecta, 15–25 µm thick at lower flanks, oriented at 10–45°; 5–15 µm thick near margin, oriented at 10°, marginal cortical cells *5–12 × 2–4 µm {4}. **VBs** present in terminal cells of paraphyses (sometimes also in 1–2 lower cells) and in marginal cortical cells {18}, 0.3–1.5 µm diam., globose, strongly refractive, hyaline, sparse to abundant (multiguttulate); 1–2 faintly yellow **LBs** (carotenoids) in cells of basal ectal excipulum, ~1–2 µm diam. **Exudate** over paraphyses ~1–4 µm thick, granular, dark olivaceous-green(-brownish), extending ± far down between the paraphyses, sometimes attached to lateral wall, individual granules 0.2–0.5(–1) µm diam., KOH-resistant (turning light reddish-brown-brass to ochraceous-olive), in PVA or other acids bright dirty blue-green to green, externally covered by a hyaline, refractive, continuous, 0.2–0.3 µm thick layer; over margin and flanks granular to continuous, ~0.5–2 µm thick (more cloddy near base); in hyaline apothecia only a thin hyaline layer present. **Anchoring hyphae** sparse to abundant, hyaline, *2–3.5 µm wide, walls 0.2–0.3 µm thick {3}, sometimes covered by a 0.7–1.5 µm thick gel sheath. — **ANAMORPH**: trinacrium-like (presumed, from natural substrate {4}). **Conidiophores** not observed. **Conidia** 2-armed (T-shaped), total size */†16–22 × (11–)15–25(–29) µm {4}, stipe */†15–19 × 2–3 µm, 2-septate, arms slightly to strongly tapering, bent downwards, */†9–15 × 2.3–3.2 µm, (0–)1–2-septate.

Habitat: on living trees or on fallen or cut trees or canopy parts, collected 1–4 m above the ground, recently dead (sometimes still-living), corticated, 8–80 mm thick branches, also 10–15 cm thick trunks, of *Larix decidua* {5}, *Larix* sp. {1}, *Picea abies* {14/1}, *P. ?sitchensis* {1}, *Pinus nigra* {1}, *P. sylvestris* {18}, in small or mostly large, sometimes very long, often strongly swollen canker-like wounds, on upperside or laterally, sometimes fully sun-exposed, on ± undecayed, rarely medium to strongly decayed, naked bark {14} and wood {3}, mostly on resin {> 38}, e.g., on central area of wound covered by abundant brown to black hyphomycetes (sometimes with green algae). **Associated**: *Amphosoma resinicola* {3}, *Capronia* sp. {2}, *Chrysodisca peziculoides* {1}, *Ciliolarina* sp. {3}, *C. pinicola* {6}, *Claussenomyces* sp. {1}, *C. olivaceus* {3}, *Crumenulopsis pinicola* {2}, *Diplolaeviopsis* sp. {1}, *Echinula resinicola* {2}, *Eustilbum aureum* {1}, *Evernia prunastri* {1}, *Hypogymnia physodes* {2}, *H. vittata* {1}, *Hysterium angustatum* {1}, *Lachnellula abietis* {1}, *L. occidentalis* {3}, *L. resinaria* {4}, *Lecophagus pini* {2}, *Lilapila oculispora* {3}, *L. oculisporella* {5}, *L. jurana* {1}, *Melaspileella proximella* {1}, *Mollisia lividofusca* {1}, *Mytilinidion gemmigenum* {1}, *Orbilia aristata* {1}, *O. cylindrospora* {1}, *O. eucalypti* {1}, *O. flagellispora* {2}, *O. ?graminis* {2}, *O. olivacea* {2}, *O. sphaerospora* {3}, *O. vinosa* {1}, *O. subvinosa* {1}, *Pragmopora* sp. {1}, *P. amphibola* {2}, *Propolis betulae* {1}, *Pseudohelotium sordidulum* {2}, *Resinomyces griseus* {6}, *R. kirschsteinianus* {16}, *Sarea difformis* {16}, *S. resinae* {4}, *Stictis* sp. {1}, *Tryblidiopsis pinastri* {1}, *Usnea* sp. {1}. **Desiccation tolerance**: fully tolerant for at least 6 weeks, after 2 months paraphyses and ectal excipulum still alive. **Altitude**: 350–1310 m a.s.l. (central Europe) or 743–1780 m (southern Europe). **Geology**: Lower to Upper Jurassic and Cretaceous sand-, lime- & marlstone, Pleistocene loess & silt, decalcified clay; granite, granodiorite, migmatite, mica schist, gneiss. **Phenology**: throughout the year (long-lived).

Phenology of *A. atroolivaceum*

Jan	Feb	Mar	Apr	May	June	July	Aug	Sept	Oct	Nov	Dec
2	1	1	4	0	0	3	11	9	7	3	1

Taxonomic remarks. *Amphosoma atroolivaceum* is readily distinguished from *A. resinicola* by its dark pigmentation. However, in one of the many collections studied, some apothecia were less strongly pigmented or sometimes completely whitish. The microscopic characters of these two species are quite similar, but the distinctly longer and more often clavate ascospores of *A. atroolivaceum* provide sufficient evidence that *A. resinicola* is not merely an albinotic form of *A. atroolivaceum*. The two species illustrate the comparatively low taxonomic value of pigmentation at higher levels.

Dry apothecia of *A. atroolivaceum* are impossible to detect under the dissecting microscope among the blackish-brown mould covering the resin. When rewetted they can be recognized by their shining, dark blue-green hymenium. The characteristic colour is more distinct when studying sections under transmitted light under the microscope.

Variation. *A. atroolivaceum* seems to be quite constant in its micromorphological characteristics, with little variation in ascus and spore size. As in *A. resinicola*, croziers were occasionally observed at the ascus base. In the collection from Gérardmer, one apothecium was pale blue-green and three whitish, while only three apothecia showed the typical dark pigmentation.

Anamorph. The observed trinacrium-like conidia are similar to those of *A. resinicola* but smaller. Since *A. resinicola* likewise inhabits resinous wounds of conifers and grew a single time in assocation with *A. atroolivaceum*, it cannot be excluded

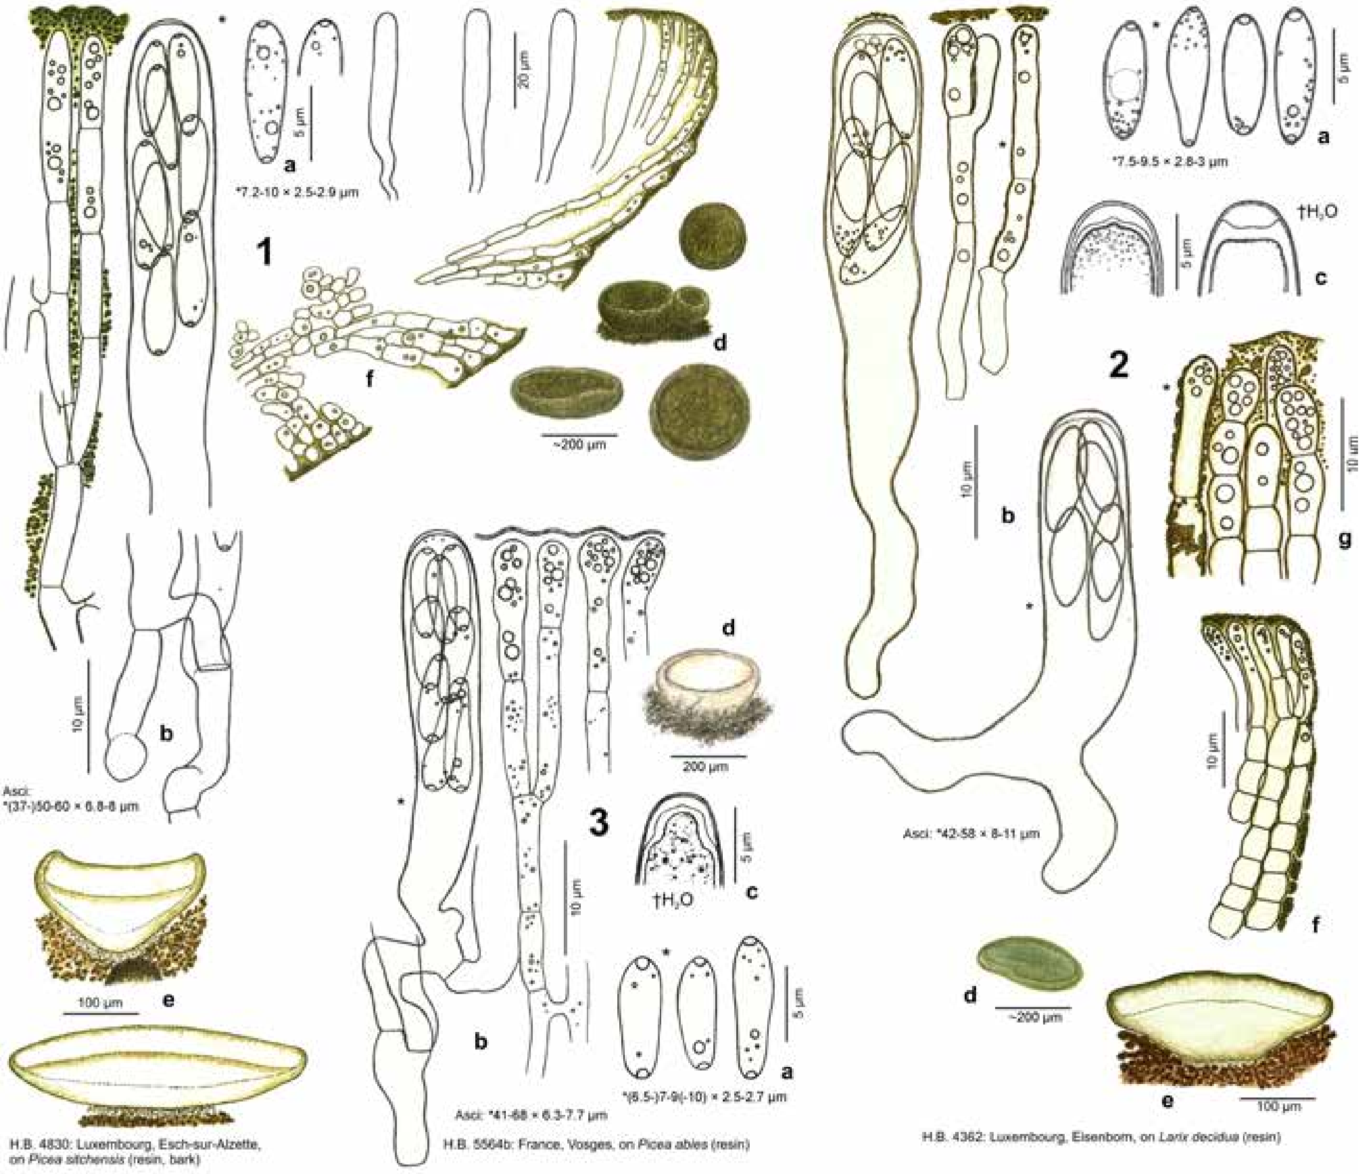

Plate 38. **1–3**: *Amphosoma atroolivaceum*. – **a**. ascospores; **b**. asci and paraphyses (containing VBs); **c**. ascus apices; **d**. rehydrated apothecia; **e**. apothecia in median section; **f**. median section of ectal excipulum and hymenium (lower flanks up to margin); g. ectal excipulum (margin, surface view), cells containing VBs.

that the observed conidia belong to that species. However, two of the four collections of *A. atroolivaceum* in which conidia were found originate from Luxembourg, whereas *A. resinicola* was so far recorded within central Europe only from the region of the Alps.

Phylogeny. Sequences were taken from apothecia of five specimens, four from the Southern French Alps (ITS: G.M. 2009-09-27.1; ITS+LSU: G.M. 2010-09-03.1, H.B. 9162b, 9631b), one from Vosges (SSU+ITS+LSU: G.M. 2017-11-05.1). Four of them (including Vosges) cover enough of the 3'-end of SSU, in which the S1506 intron is always absent. Those from the Alps are fully identical in the ITS and LSU (H.B. 9162b consists only of fragments of ITS and LSU and appears to be uncertain at the few deviating positions in the ITS1 and LSU). The sample from Vosges deviates by 15 nt (3.2 %) in the ITS and 2 nt (0.3 %) in the LSU D1–D2. Regrettably no morphological data were available for this sample. If it represents the northern genotype of the species aggregate, then morphological differences appear to be absent, similar as in *Lilapila*. For the distance to *A. resinicola* see p. 276.

Ecology. Like *Amphosoma resinicola*, *A. atroolivaceum* was exclusively found on resinous wounds of dead or living, undecayed xeric branches and trunks of gymnosperms, on which it grew especially on old resin blackened by hyphomycetes. No preference among the coniferous host trees was noted. *A. atroolivaceum* was collected in submontane to subalpine mixed conifer forests in cold- to orotemperate subcontinental humid central Europe (Eifel, Luxembourg, Vosges, Schwarzwald, Central Sudetes, High Tatras) and orotemperate to orosubmediterranean humid or sometimes suprasubmediterranean semihumid southern Europe (Southern French Alps, Massif central).

Specimens included. **POLAND**: **Lower Silesia**, Central Sudetes, 9 km SSW of Stronie Śląskie, 0.9 km NNE of Śnieżnik, 1125 m, branch of *Picea abies*, on resin, 9.IX.2009, P. Perz (P.P. 20090909-3, doc. vid.). — **SLOVAKIA**: **Prešov**, Carpathian Mts., Vysoké Tatry, 8.7 km SSW of Tatranská Javorina, Bielovodská valley, 1310 m, branch of *P. abies*, on resin, 12.VII.2018, A. Polhorský (A.P. 18/96, doc. vid.). — **LUXEMBOURG**: **Gutland**, **Mersch**, 6 km SW of Mersch, 1.2 km NE of Lorentzweiler, Haereboesch, 380 m, branch of *Larix decidua*, on bark & resin, 24.XI.1990, G. Marson (H.B. 4342, G.M. 4381). – 8 km NE of Mersch, 1 km E of Nommern, W of Kéngertsbësch,

Amphosoma macrosporum Baral & G. Marson, **sp. nov.**, MB 813482 — Pl. 40

Etymology: according to the comparatively large ascospores.
Typification: USA, Utah, Cedar City, branch of *Pinus edulis*, 24.VIII.1994, G. Marson (ex H.B. 5181b, M-0276402, holotype).

Latin diagnosis: *Differt ab* Amphosomate resinicola *ascis et sporis multo majoribus. Habitat ad corticem putridum rami sicci* Pini edulis *in zona temperata subhumida Americae septentrionalis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.12–0.35 mm diam., up to 0.23 mm thick (receptacle 0.13 mm), whitish to pure pale rose, also pale yellowish-cream, round; disc flat, margin even; with a distinct stipe 0.1 × 0.16 mm, superficial. **Asci** *81–90 × 10.5–11 µm, †75–95(–115) × (7.5–)8–9 µm, 8-spored (often only 5–7 spores developed), spores biseriate; **apex** (†) ± hemispherical, dome †1.8–2.3 → 1.2 µm thick (complete wall deep lilac-violet in CRB), with slight apical chamber; **base** with thick, flexuous stalk, unbranched or h- to H-shaped. **Ascospores** *11–15(–17.5) × 3.5–4.5(–5) µm, †10.3–14.5 × 3.3–4.5 µm; (sub)cylindrical, homopolar, ends rounded or very slightly papillate, straight or very slightly curved, overmature with 1, rarely 3 transverse septa, up to 5.5–7 µm wide; **SBs** *(0.7–)0.9–1.2 × 1.1–1.3 µm, plug-shaped, broadly attached to wall at both ends; with several small to medium-sized LBs (up to 1.7 µm). **Paraphyses** apically slightly to strongly clavate-capitate, terminal cells *6.5–15 × 3–6 µm, lower cells *6–15 × 1.8–2.2 µm (near base –2.6 µm); frequently di- or trichotomously branched at apex. **Medullary excipulum** not examined. **Ectal excipulum** hyaline, at base of irregular textura angularis 40 µm thick, at lower and mid flanks 15–20 µm thick, of (?)thin-walled, horizontal t. prismatica; at margin 15 µm thick. **Anchoring hyphae** sparse, *4–6 µm wide, walls *0.2–0.5 µm thick. **VBs** present in paraphyses (in all cells but a little more dense in upper cells) and in marginal cortical cells, globose, 0.2–0.5(–1) µm diam., strongly refractive, abundant (multiguttulate), often trembling. **Exudate** over paraphyses absent; at flanks continuous, yellowish-brass-coloured. **— ANAMORPH**: unknown.

Habitat: ~0.5 m above the ground, on corticated, 9 mm thick branch of *Pinus edulis*, on strongly decayed bark (periderm), greyed, covered by green algae, not associated with resin. **Associated**: ?*Venturia* sp., remotely with *Orbilia macroasca*. **Desiccation tolerance**: fully tolerant for at least 2.5 months. **Altitude**: 1815 m. **Geology**: Upper Cretaceous sedimentary rock. **Phenology**: VIII.

Taxonomic remarks. *Amphosoma macrosporum* is closely related to *A. resinicola*, from which it differs in much larger asci and ascospores, and in the latter being more cylindrical and becoming 1–3-septate when overmature.

Ecology. The species is only known from the holotype collection. It grew on rotten bark of a dead xeric branch of *Pinus edulis*. Unlike the other two conifericolous species, *A. macrosporum* was not associated with resin. It was found in a dry riverbed in the cold-temperate subhumid pinyon-juniper woodland of the Dixie Forest (Utah Mountains, western North America).

Specimens included. **USA**: **Utah**, Utah Mts., Dixie Forest, ~1.5 km ESE of Cedar City, 1815 m, branch of *Pinus edulis*, on bark, 24.VIII.1994, G. Marson (ex H.B. 5181b; M-0276402, **holotype**).

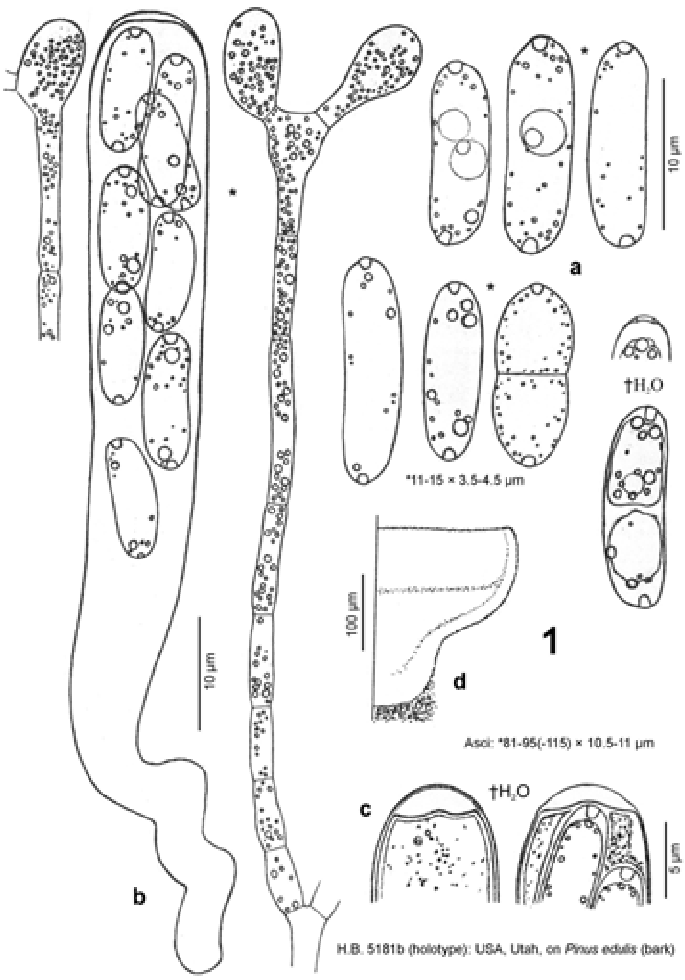

Plate 40. **1**: *Amphosoma macrosporum*. – **1a**. ascospores (lower right: spore bodies persistent in dead state, or spores with a polar pore); **1b**. ascus and paraphyses (containing VBs); 1c. ascus apices; **1d**. apothecium in median section.

Retiarius D.L. Olivier, Trans. Br. Mycol. Soc. 71: 193 (1978)

Type species: *R. superficiaris* D.L. Olivier (see p. 241)

Etymology: named after a Roman gladiator armed with a cast net (referring to the ability of the fungus to capture pollen).

Description (according to Olivier 1978 and Magyar et al. 2017a): — **TELEOMORPH**: unknown. — **ANAMORPH**: **Mycelial hyphae** †1.5–4 µm wide, hyaline. **Colonies** salmon or flesh-coloured, slow-growing (oatmeal agar, *R. superficiaris*, *R. bovicornutus*). **Conidiophores** integrated, reduced or sympodial, †1.5–5 up to 9–14 × 1.5–2.5 µm, conidia developing singly or also on lateral scars. **Conidia** multicellular, staurosporous, dichotomously branched, main axis (10–)13–30(–36) µm long [stipe (8–)10–27(–33) µm], 1–3-septate, either with consistently two arms (trinacrium-like), or with predominantly 3–4 arms (dwayaangam- or tripospermum-like), arms straight or slightly to medium curved upwards, 20–90 µm long. **Trapping hyphae**: capturing pollen grains by erect, attenuated, 12–35 µm long hyphae and by conidial arms.

Habitat: forming small colonies on adaxial surfaces of living leaves or on xeric bark of living branches and trunks of trees, parasitic on pollen grains of both gymno- and angiosperms.

Recognized species: *R. bovicornutus*, *R.* aff. *bovicornutus*, *R. goenczoelii*, *R. revayae*, *R.* aff. *revayae*, *R. superficiaris* (all without known teleomorph).

Taxonomic and ecological remarks. Olivier (1978) described the genus based on two species (*R. superficiaris* and *R. bovicornutus*) from South Africa growing on living leaves of *Eryobotrya japonica* and *Brabejum stellatifolium* on which they trap pollen. In her experiments, Olivier worked with pollen of *Pinus radiata*, but she did not mention whether pollen captured in the field was also from conifers. Magyar et al. (2017a) added two species from Hungary to the genus (*R. goenczoelii*, *R. revayae*), which grew on bark of living trees of *Platanus* and *Taxus* where they parasitize pollen grains of *Picea*, unidentified *Pinaceae*, but also *Tilia*.

Cultivation on artificial media was unsuccessful in *R. revayae* and *R. goenczoelii* (Magyar et al. 2017a). Olivier's two species (*R. superficiaris* and *R. bovicornutus*) were cultivated on oatmeal agar (OA).

During the present study, conidia similar to *R. bovicornutus* or *R. revayae* were found on different trees at several occasions, sometimes in association with pollen grains (Pl. 41–43, see also IVV).

Phylogeny. Magyar et al. (2017a, b) gained sequences (ITS, LSU) from Olivier's two ex-type cultures and from *R. revayae*. The S1506 intron region is not fully covered because the ITS1 primer was used (not the ITS1F as stated by Magyar et al.), but in the reverse direction the position of the intron is just reached in *R. bovicornutus* and *R. superficiaris*, and it seems that here the intron is present, unlike any other related taxon. In Magyar et al.'s Bayesian analyses of ITS+LSU the genus formed a strongly supported group that nested in the *Lilapila-Lecophagus-Amphosoma* clade sister to *Amphosoma*. In our ML analyses of SSU+ITS+LSU, ITS, and LSU (Phyls 2–4), the three species always clustered in a monophyletic clade, with high (SSU+ITS+LSU), low (LSU), or lacking support (ITS). *Retiarius* always nested in the *Lecophagus-Amphosoma* clade (see p. 253). The distance to *Lilapila* ranges around 20–26 % in the ITS region and 7.5–8.3 % in the LSU (D1–D3), but also within *Retiarius* it lies at 16.5–17.5 % in the ITS and 6–6.3 % in the LSU.

Specific nucleotide positions. *Retiarius* shows specific nucleotides in the region of the '*Orbiliales*-specific' primers (Smith & Jaffee 2009) (Tabs 18–19). In the primer Orb5.8s1F it concurs with *Lilapila*, *Amphosoma*, *Lecophagus*, *Vermispora* clade of *Hyalorbilia* etc., and in the primer Orb5.8s3F only with some of them. In the entire 5.8S region *R. bovicornutus* concurs with various environmental samples, including some which cluster in analyses of ITS or ITS+LSU in the *Amphosoma* clade (A1–A5). Two variants are observed in the primer Orb28s2R: *Retiarius* concurs here with various non-orbiliaceous ascomycetes, *R. superficiaris* and *R. bovicornutus* also with *Lecophagus* and some other orbiliaceous taxa, and *R. revayae* with *Amphosoma resinicola*. However, this primer region is badly sequenced in *Retiarius* and leaves some doubts about the correct motifs. In stem-loop B8 at 3'-end of 5.8S *R. superficiaris* and *R. revayae* concur with *Amphosoma* spp., whereas *R. bovicornutus* concurs with various uncultured clones related to *Amphosoma* (A1–A5) and deviates from the former by 2 nt. Some nucleotide positions in the LSU D3 domain separate *Retiarius* from *Amphosoma* (see p. 273).

Retiarius superficiaris D.L. Olivier, Trans. Br. mycol. Soc. 71: 194 (1978) — Pl. 20: a

Etymology: probably according to the superficial, epiphyllous growth.

Description of holotype (Olivier 1978, modified): Conidia 37–60 × 44–66 µm, (2–)3(–4)-armed; stipe (8–)10–15 × 4–4.5(–5.5) µm, tapering towards base, 1–2(–3)-septate; arms (20–)25–35(–45) × 4.5–6 µm, straight, tapering towards the ends, 4–7-septate.

Key to species of *Retiarius* (only anamorph known)

1. Conidia predominantly 3-armed, tripospermum-like, also 2- and 4-armed, arms straight, 20–45 × 4.5–6 µm, 4–7-septate; South Africa, on *Eriobotrya* leaves .... ***R. superficiaris***, p. 282
1. Conidia consistently 2-armed, trinacrium-like 2

2. Arms straight to flexuous, †42–90 × 2–2.5 µm, 5–8-septate, stipe 19–33 µm long; Hungary, on *Platanus* bark ..... ***R. goenczoelii***, p. 286
2. Arms curved upwards, up to 40–55 µm long 3

3. Arms (25–)30–45(–50) × 4–5.5 µm, stipe 12–25 × 3.5–5.5 µm, (1–)2–3-septate; South Africa, on *Brabejum* leaves (± similar records from Peru, Japan, and Europe on bark and leaves of angiosperms) .... ***R. bovicornutus***, p. 283
3. Arms and stipe narrower, 2–3.5(–4) µm wide 4

4. Arms †22–30 × 2–3(–3.5) µm, stipe †14–22 × 2–3.5 µm, 3–5(–7)-septate; Hungary, on *Taxus* bark (similar records from South Africa on bark of *Fabaceae*) .... ***R. revayae***, p. 285
4. Arms *33–70 × 3–3.5 µm, stipe * 20–24 × 3–4 µm, 2-septate; Luxembourg, on *Cytisus* and *Sambucus* .... ***R.* aff. *revayae***, p. 285

The 3-armed conidia resemble those of *Tripospermum*, the 4-armed conidia those of *Dwayaangam*, and the 2-armed conidia those of *Trinacrium*.

Specimens included. **SOUTH AFRICA**: **Western Cape**, 47 km S of Cape Town, 58 km SW of Stellenbosch, Cape of Good Hope, leaves of *Eriobotrya japonica*, parasitic on pollen, 15.IX.1974, D.L. Olivier (IMI 223459, **holotype**, doc. vid., sq.: KY352467).

Retiarius bovicornutus D.L. Olivier, Trans. Br. mycol. Soc. 71: 195 (1978) (Pls 20: b; 41–42; 43: 5)

Etymology: after the conidial arms resembling horns of cows.

Description of holotype (Olivier 1978, modified): Conidia 47–50 × 45–55 µm, 2-armed; stipe (12–)15–20(–25) × 3.5–4.5(–5.5) µm (in situ), tapering towards base, (1–)2–3-septate; arms (25–)30–45(–50) × 4–5 µm, curved upwards, tapering towards ends, (2–)4–5-septate.

Taxonomic remarks. The conidia of *R. bovicornutus* resemble those of *Trinacrium*, but deviate from typical members of that genus in the two arms being curved upwards. We have seen several records of conidia with upwards curved arms which appear to belong in the relationship of *R. bovicornutus*: one from Germany on wood of *Salix* (Pl. 43: 5) shows a strong resemblance in conidial shape (arms *30–32 × 5–5.5 µm, total size *38 × 43 µm) and appears to be conspecific.

Not included collections. A British sample on living leaves of *Rhododendron* with infected *Pinaceae* pollen (Pl. 42: 1) deviates from the type mainly in slightly longer arms (*45–55 × 5–6 µm, total size *52–60 × 65–86 µm) and a narrower, more cylindrical stipe. Also two samples from Luxembourg on branches of *Clematis* (Pl. 42: 2) and *Salix* (Pl. 41: 1) are very similar to *R. bovicornutus* but resemble the British sample in the stipe. The latter sample consisted of only one incomplete conidium having captured a pollen grain of probably *Salix*. Two samples from France on branches of *Pinus* deviate among another: in Pl. 42: 3 conidia are similiar to *R. bovicornutus* but insufficiently documented, whereas in Pl. 41: 2 they concur rather well, including a basally tapered stipe. A sample from Luxembourg on *Robinia* bark (Pl. 43: 4) showed distinctly smaller conidia (total size *27–31 × 27–29 µm, arms *15–17 × 4–4.5 µm) which, however, closely concur with *R. bovicornutus* in shape.

Ando & Tubaki (1984c, 2005) described a collection under the name *R. bovicornutus* from Japan (in rainwater draining from *Pinus*, total size 36–44 × 27–56 µm, arms 20–33.5 × 3.5–5.2 µm), and Matsushima (1993) one from Peru (on decaying palm petioles, total size 19–35 × 25–50 µm, arms 12–27 × 4–5 µm). Particularly in the latter sample the conidial arms are reported distinctly shorter than in the type.

Specimens included. **SOUTH AFRICA**: **Western Cape**, 47 km S of Cape Town, 58 km SW of Stellenbosch, Cape of Good Hope, leaves of *Brabejum stellatifolium*, parasitic on pollen, 30.VIII.1976, D.L. Olivier (IMI 223460, **holotype**, doc. vid., sq.: KY352466). — **GERMANY**: **Bayern**, **Oberbayern**, Kocheler Berge, 6.5 km WSW of Lenggries, NW of Latschenkopfhütte, S of Vorderer Kirchstein, 1600 m, branch of *Salix caprea*, on wood, 21.VI.2005, P. Karasch & B. Fellmann (H.B. 7830b ø, anam. only).

Not included. ***Retiarius* cf. *bovicornutus***: **GREAT BRITAIN**: **Yorkshire**, **South Yorkshire**, Barnsley, Wentworth Castle, *Rhododendron* leaves, on *Pinus* pollen, 175 m, 26.VI.2016, C. Yeates (CSVY/F/2698, anam. only). — **LUXEMBOURG**: unlocalized, branch of *Clematis vitalba*, 4.I.2014, G. Marson (ø, anam. only). – **Gutland**, 1.5 km SW of Cessange, Bois de Cessange, 305 m,

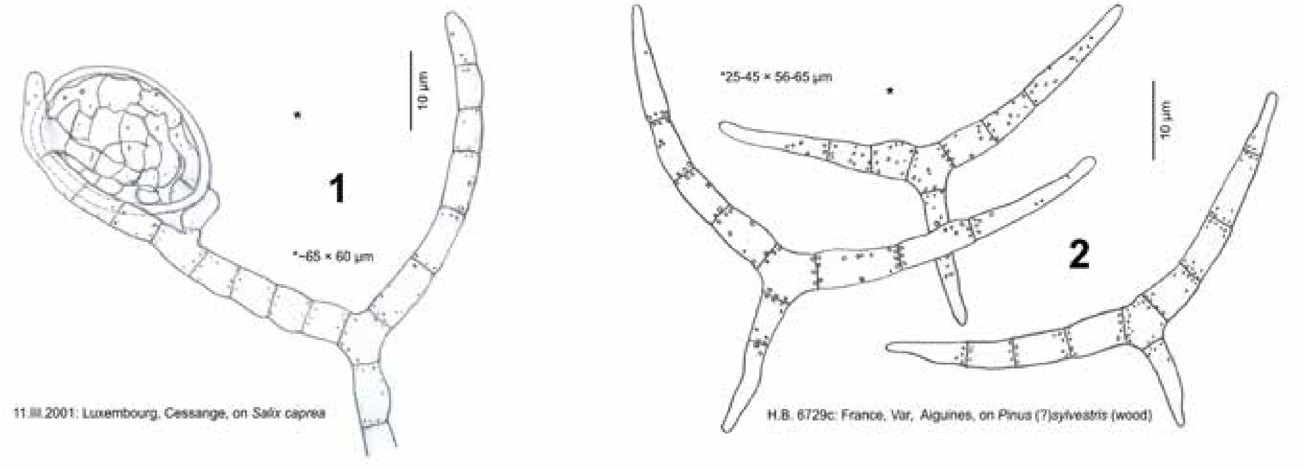

Plate 41. **1–2**: *Retiarius* cf. *bovicornutus*. – Conidia from natural substrate.

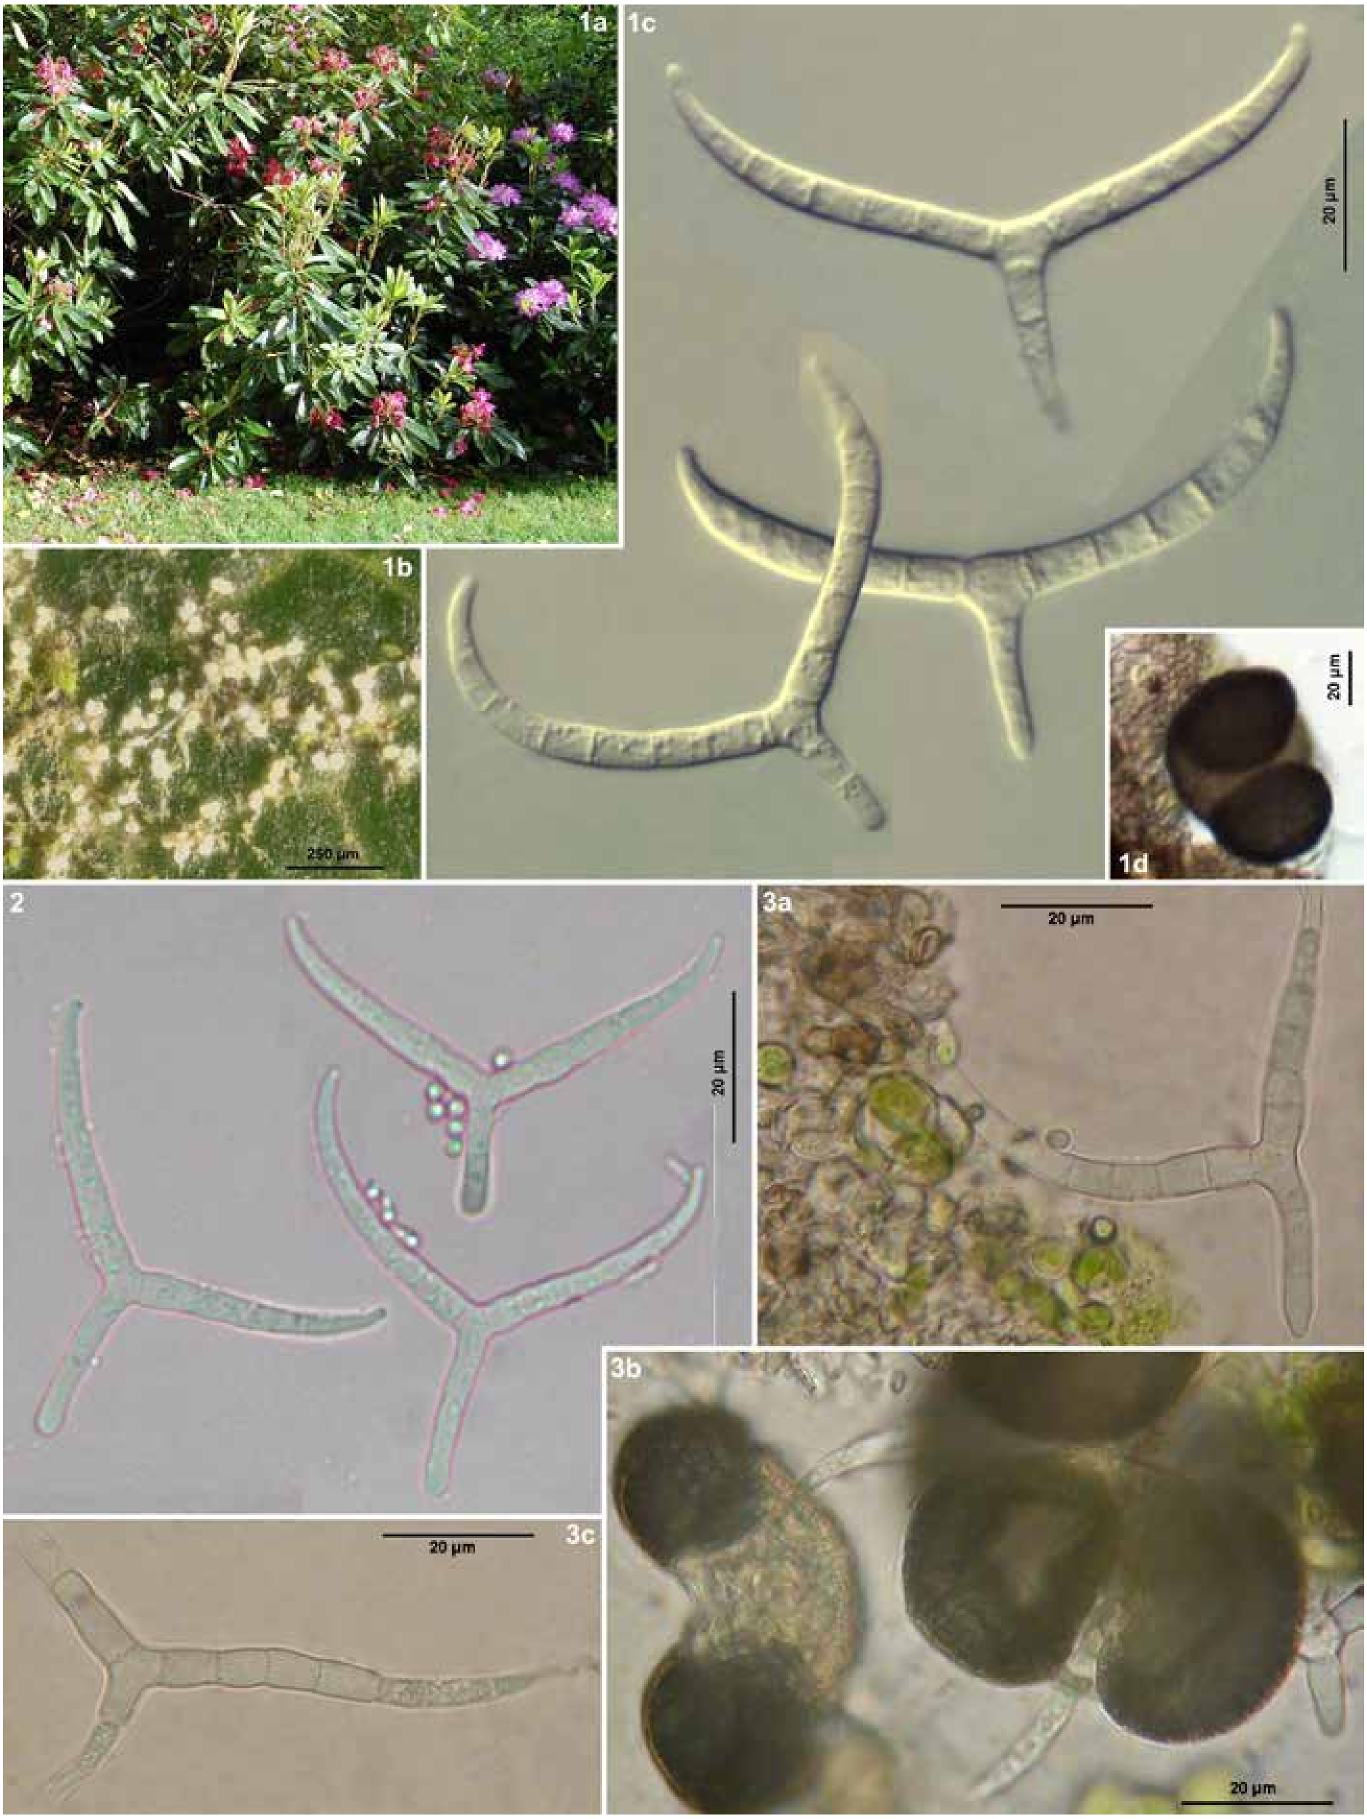

Plate 42. **1–3**: *Retiarius* cf. *bovicornutus*. – **1a**. *Rhododendron* shrubs in a park; **1b**, **d**. *Pinus* pollen grains in fungal mesh on the upper side of a *Rhododendron* leaf; **3b**. *Pinus* pollen grains with *Retiarius* conidia; **1c**, **2**, **3a–c**: conidia from natural substrate. Living state. – **1a–d**: phot. C. Yeates. — **1a–d**. 26.VI.2016: Great Britain, Barnsley, on *Rhododendron*; **2**. 4.I.2014: Luxembourg, on *Clematis*; **3a–c**. H.B. 9173: France, Bedoin, on *Pinus*.

branch of *Salix caprea*, on ?*Salix* pollen, 11.III.2001, G. Marson (ø, anam. only). — **FRANCE**: **Provence-Alpes-Côte d'Azur**, **Var**, Aiguines, branch of *Pinus sylvestris*, 5.VIII.1999, G. Marson (H.B. 6729c ø, anam. only). – **Vaucluse**, 9.5 km NE of Bedoin, 1.5 km NW of Mt. Ventoux summit, Mt. Serein, 1385 m, branches of *P. sylvestris*, on wood and *Pinus* pollen, 13.VIII.2009, G. Marson, H.O. Baral & B. Liu (mixtum in *Orbilia subvinosa* H.B. 9173b, anam. only). ***Retiarius* aff. *bovicornutus***: **LUXEMBOURG**: **Gutland**, 0.5 km W of Echternach, Troosknеppchen, 220 m, trunk of *Robinia pseudoacacia*, on bark, 6.VI.2004, G. Marson (ø, anam. only). — **PERU**: **Madre de Dios**, Tambopata, petioles of a palm, V.1989, T. Matsushima (MFC-9P086). — **JAPAN**: **Honshu**, **Ibaraki**, campus of University of Tsukuba, rainwater draining from *Pinus densiflora*, 27.X.1983, K. Ando (TKB-C-1298).

Retiarius revayae D. Magyar & Z. Merényi, Nova Hedwigia 105(3–4): 413 (2017) — Pl. 20: c, Pl. 43: 2–3

Etymology: in honour of Ágnes Révay, Hungarian mycologist on staurosporous fungi.

Description of holotype (Magyar et al. 2017a, modified): Conidia †26–40 × 32–48 µm (in situ), 2-armed; stipe †14–22 × 2–3.5 µm, cylindrical, tapered only at very base, 3–5(–7)-septate; arms †22–30 × 2–3(–3.5) µm, curved upwards, tapering towards ends, (3–)4–7-septate.

Taxonomic remarks. The conidia of *R. revayae* resemble those of *R. bovicornutus* but differ in narrower arms and in longer stipes with more septa, a combination which does not fit any of our samples, except for two from South Africa, each with only one observed conidium (Pl. 43: 2–3).

Not included collections. The two South African samples have rather long and narrow, ~3-septate stipes of 15–30 × 3 µm and could be conspecific with *R. revayae*. Magyar et al. (2017a) gave the arms as 22–38 × 2–4 µm, but the figured conidia do not attain that size, even when including the curvature.

Gönczöl & Révay (2004: fig. 11, Révay & Gönczöl (2010: figs 2–4, 2011: figs 1–8) reported conidia under the name *R. bovicornutus* which they observed in 85 % of the bark samples of twigs attached to various living trees in Hungary and Sweden. In Magyar et al.'s (2017a, pers. comm.) opinion, however, figs 3–4 in Révay & Gönczöl (2010) and figs 3–4 in Révay & Gönczöl (2011) belong to *R. revayae* and the fourth conidium from left in Gönczöl & Révay (2004) represents typical *R. revayae*, whereas, e. g., the third conidium from left seems to be of uncertain identity because of much too wide arms (~5 µm), and Révay & Gönczöl (2011: fig. 1) concerns *R. goenczoelii*.

An unlocalized sample on *Cytisus* (Pl. 43: 1) deviates in distinctly narrower arms and stipes and resemble *R. revayae* except for the short, 2-septate stipes which are more reminiscent of *R. bovicornutus*. In their total size (*50–75 × 50–76 µm, arms *33–70 × 3–3.5 µm) these conidia exceed the types of *R. bovicornutus* and *R. revayae*.

Specimens included. **HUNGARY**: **Pest**, Budapest, 110 m, trunk of *Taxus baccata*, on bark, parasitic on pollen of *Pinaceae* and *Tilia*, 7.I.2014, D. Magyar (BP 108633, **holotype**, doc. vid., sq.: KY352465). – ibid., 23.I.2014 (KMD174/5).

Not included. ***Retiarius* cf. *revayae***: **SOUTH AFRICA**: **KwaZulu-Natal**, 210 km NE of Durban, 55 km NE of Richards Bay, 1 km SE of Santa Lucia, St. Lucia Estuary, Sugarloaf Rest Camp, 10 m, branch of indet. angiosperm (?*Pterocarpus*), on bark, 25.II.2006, V. Kummer (mixture with *Amphosoma natalense*, ex H.B.

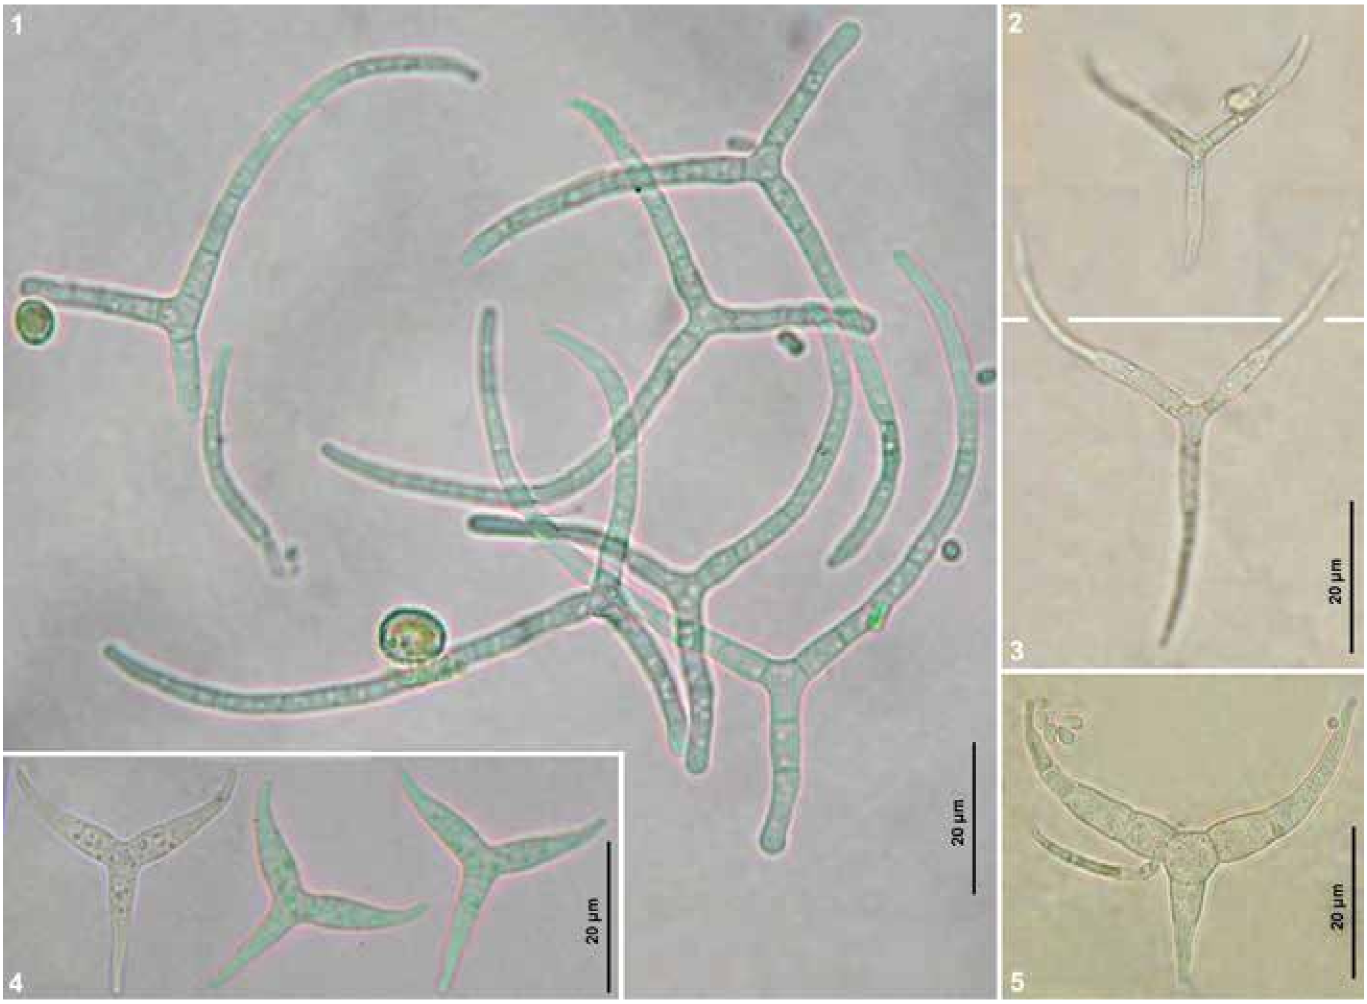

Plate 43. **1**: *Retiarius* aff. *revayae*; **2–3**: *R.* cf. *revayae*; **4**. *R.* aff. *bovicornutus*; **5**. *R. bovicornutus*. – Conidia from natural substrate. Living state but conidia in **3** and **5** with some dead cells, **2** in dead state. — **1**. Luxembourg, on *Cytisus*; **2**. Retiarius goenczoelii D. Magyar, in Magyar et al., Nova Hedwigia 105(3–4): 416 (2017) — Pl. 20: d

Etymology: in honour of János Gönczöl, Hungarian researcher on canopy fungi.

Description of holotype (Magyar et al. 2017a, modified): Conidia †37–70 × 100–150 µm, 2-armed; stipe †19–33 × 1.7–2.5(–3) µm, cylindrical, often constricted at base, (2–)3(–5)-septate; arms †42–90 × 2–2.5 µm, straight to ± flexuous, slightly tapering towards ends, 5–7(–8)-septate.

The conidia of *R. goenczoelii* have long and thin, straight to ± flexuous arms, and the stipe has a foot-like basal swelling due to a subbasal constriction. Unfortunately, this species is without sequence data, therefore, its affiliation in *Retiarius* is not assured.

Specimens included. **HUNGARY**: **Pest**, Budapest, 110 m, trunk of *Platanus* × *acerifolia*, on bark, parasitic on pollen of *Pinaceae* etc., 14.V.2014, D. Magyar (BP 105173, **holotype**, doc. vid.). – ibid., 23.I.2014 (KMD07/36).

Mycoceros D. Magyar & Merényi, in Magyar et al., Mycol. Prog. 17(1–2): 36 (2017),

Type species: *Mycoceros antennatissimus*

Etymology: referring to the shape of the conidia resembling horns.

Recognized species: *M. antennatissimus* (without known teleomorph).

Mycoceros antennatissimus D. Magyar, in Magyar et al., Mycol. Progr. 17(1–2): 37 (2017) — see p. 239–240 and Pl. 44

Etymology: referring to the multibranched shape of the conidia.

Description of genus and species (according to Magyar et al. 2017b): — **TELEOMORPH**: unknown. **— ANAMORPH**: **Mycelial hyphae** †1.2–2.5 µm wide, hyaline. **Cultivation** on artificial media unsuccessful. **Conidiophores** integrated, reduced, †~2 × 2 µm. **Conidia** multicellular, staurosporous by repeated dichotomous branching, ~55–90 × 70–190 µm, stipe †2–4(–8.5) × 2–3 µm, non-septate, primary arms 1(–3)-septate, straight, secondary arms 1–4-septate or sometimes higher-septate when without tertiary arms, tertiary arms 1–6-septate, secondary and tertiary arms straight, or flexuous when getting longer. **Trapping organs**: capturing pollen grains by erect, attenuated, 20–135 µm long hyphae or conidial arms (assumed).

Habitat: forming small colonies on bark of living trees, parasitizing pollen grains.

Taxonomic remarks. Magyar et al. (2017b) proposed the new genus for a single species from Hungary. In its staurosporous conidia and mode of life, *Mycoceros* (Pl. 18) resembles the genus *Retiarius* (Pl. 20). However, trinacrium-like conidia were not observed, and those lacking tertiary arms recall the genus *Dwayaangam*, e.g. the presumed anamorph of *Orbilia arachnovinosa* (Pl. 269), from which they differ in the relative length of the conidial main axis and its branches: in *Mycoceros* the main axis is much shorter than the primary branches, whereas in dwayaangam-like conidia of *Retiarius* and *Orbilia* the primary branches are much shorter than the main axis. Moreover, the conidia of *Mycoceros* are 3-dimensional regarding their secondary and tertiary arms.

The protologue gives the conidial stipes as 0(–2)-septate, but all illustrated conidia have no septa, including that of 8.5 µm length (Magyar et al. 2017b: fig. 2g).

Phylogeny. The genus *Mycoceros* was mainly erected for molecular reasons. Magyar et al. (2017b) gained four sequences from four individual conidia, ITS from two and LSU from two (the S1506 intron is absent). In their phylogenetic analysis, *Mycoceros* clustered with support within the *Orbiliomycetes* as a basal sister clade to all other genera. In our combined ML analysis, however, *Mycoceros* nested with low support as a sister group to the *Lecophagus*-*Amphosoma* clade (Phyl. 2). The genus shows a high distance to any other taxon, the lowest in the ITS region being 23–26 % to *Lilapila* (LSU D1–D3: 9.3–9.8 %) and 27–31 % to *Retiarius* (LSU D1–D3: 10.8–11 %).

Specific nucleotide positions. *Mycoceros* concurs in the region of the '*Orbiliales*-specific' primers (Smith & Jaffee 2009) with some other orbiliaceous taxa: in Orb**5.8s**3F with *Lilapila* and the majority of *Orbilia* (Tab. 18), and in Orb**28s**2R with

Plate 44. **1**: *Mycoceros antennatissimus*. – Conidia from natural substrate, living state. – Unlocalized (Europe), host unknown

Lilapila oculispora and two species of *Orbilia* (Tab. 19). In the primer Orb**5.8s**1F, however, *Mycoceros* deviates at one position (pos. 56, T vs. C) from all other orbiliaceous taxa, except for one uncultured basal *Orbiliomycetes* (KY687855, U3). In comparison with non-orbiliaceous fungi, *Mycoceros* concurs in two of these primers (Orb**5.8s**1F, Orb**28s**2R) with various other ascomycetes, in Orb**5.8s**1F also with basidiomycetes, whereas in Orb**5.8s**3F only a few ascomycetous yeasts and basidiomycetes concur (Tab. 18). In stem-loop B8 of 5.8S (pos. 117–138) *Mycoceros* matches *Lilapila* and some *Hyalorbilia* spp. (Tab. 18). A remarkable deviation is observed at the border between SSU and ITS1: in *Mycoceros* it is **ATCATT–**GAAA, whereas in *Retiarius* it is **ATCATTA**GAAA and in *Lilapila* and *Amphosoma* p.p. **ATCATTA**AAAA. Characteristic positions occur in the LSU: for instance, in the D1 domain pos. 80 is TTGCC**C**CAGTA, whereas all other *Orbiliomycetes* have **T**, and pos. 332 and 346 are **G**GAGACCGATAGCG**A** vs. **A**GAGACCGATAGCG**C** or **G**GAGACCGATAGCG**C** in any other *Orbiliomycetes*.

Ecology. *M. antennatissimus* was detected on xeric bark of living *Elaeagnus*, *Platanus*, and *Taxus* where it parasitizes *Pinaceae* pollen grains. During the present study, young 4–6-armed conidia of *Mycoceros* cf. *antennatissimus* formed on hyphae emerging from conifer and other pollen were found in a sample from cold-temperate, semiarid western USA (IVV: 15.VI.1996). Similar mature 4-armed conidia were observed in a European sample without known location (?Luxembourg), substrate, or association with pollen, which morphologically fits *M. antennatissimus* (Pl. 44).

Specimens included (all parasitic on pollen of *Pinaceae*): **HUNGARY**: **Pest**, Budapest, 110 m, trunk of *Platanus* × *acerifolia*, on bark, 6.V.2014, D. Magyar (BP 105172, **holotype**, doc. vid.). – ibid., 9.V.2011 (KMD07/4). – ibid., 12.V.2011 (KMD07/5). – ibid., 6.V.2016 (KMD07/7b). – ibid., trunk of *Elaeagnus angustifolia*, on bark, 10.IV.2007 (KMD07/2). – ibid., *Taxus baccata*, on bark, V.2010, D. Magyar (ø). – ibid., 29.II.2016, D. Magyar (ø). – **?Luxembourg**: unlocalized, substrate not noted, ?V.–VI.2002, G Marson.

Not included. **USA**: **Colorado**, ~5 km S of Great Sand Dunes, ~2430 m, branches of *Fallugia paradoxa*, on bark and wood, 15.VI.1996, G. Marson.

Lecophagus M.W. Dick, Mycol. Res. 94: 351 (1990),

Type species: *L. fasciculatus* M.W. Dick [= *L. muscicola* (G.L. Barron et al.) Tanabe et al.]

Etymology: referring to the capture of rotifers of the genus *Lecane*.

Emended diagnosis: **TELEOMORPH**: **Apothecia** minute, white, sessile to short-stipitate, margin smooth. **Asci** arising from croziers or simple septa, never furcate, apex hemispherical with a small lens-shaped wall thickening, 8-spored. **Ascospores** ellipsoid to subglobose, with a globose to broadly tear-shaped spore body attached to the spore apex by a short, thin or thick connecting part. **Paraphyses** simple, not or slightly inflated above, straight or sometimes curved. **Ectal excipulum** of indistinctly horizontally oriented textura angularis, cells near base *8–35 × 7–28 µm. **Anchoring hyphae** *5–17 µm wide. **Exudate** absent. — **ANAMORPH**: **Conidiophores** short and thick, unbranched. **Conidia** formed synchronously and terminally in a fascicle, large, slightly to strongly curved (C-shaped), multiseptate. **Trapping organs**: adhesive pegs for capturing rotifers and tardigrades, also adhesive knobs for capturing nematodes. — **SCBs**: All types of vegetative cells of both teleomorph and anamorph containing small, refractive, globose to cubical (crystalloid) bodies in their centre.

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.08–0.25 mm diam., 0.07–0.16 mm thick, white throughout, glassy translucent, non-gelatinous; disc flat, margin thin, not protruding, exterior glabrous; subsessile or often with a short stipe, superficial. **Asci** *29–68 × 6.5–9.5 µm, †26–48 × 5.5–8 µm, turgescent asci ± equalling the paraphyses, 8-spored, spores uni- to biseriate inside living asci, some of the spores usually inversely oriented (often oblique or in lateral direction); **apex** (†) ± hemispherical to slightly mammiform irrespective of the viewing direction, with distinct, small, lens-shaped dome 0.8–1.4 µm thick, without apical chamber; **base** with ± short and thick stalk, arising from croziers (some with small perforation) or simple septa, never furcate. **Ascospores** *3.8–8 × 3–4.6 µm, non-septate, smooth, ellipsoid to subglobose; **SBs** apically attached to spore wall, 1.5–2 × 0.9–1.8 µm, strongly refractive, (sub)globose (to broadly tear-shaped), apically ± abruptly narrowed to a short, ± thick filum 0.2–0.8 × (0.1–)0.15–0.25 µm. **Paraphyses** apically uninflated or sometimes slightly clavate, straight or slightly to strongly curved, *2.5–7 µm wide, ± equidistantly septate but terminal cells sometimes 2–5 × longer than lower cells, never branched at upper septum. **Medullary excipulum** of dense textura angularis with indistinct orientation, without intermingled hyphae, very indistinctly delimited. **Ectal excipulum** of indistinctly horizontally oriented t. (prismatica-)angularis(-globulosa), (*) thin- to slightly thick-walled (common walls 0.3–0.8 µm thick), cells near base *(8–)10–20(–35) × (7–)9–18(–28) µm, at mid flanks and margin of horizontally oriented t. prismatica-angularis, marginal cortical cells *7–10 µm wide, wall †0.3–3 µm thick, refractive, **glassy processes** and **hairs** absent. **Anchoring hyphae** restricted to base, *(5–)6–13(–17) µm wide, densely septate, often ± constricted at septa, wall *0.2–0.3 µm thick, smooth. **SCBs** refractive, hyaline, cubical to almost globose, 0.4–2 µm diam., present in most vegetative cells, usually in centre of cell, rarely near the septa, accompanied by a few to many minute hyaline **LBs** (carotenoids absent); **WBs** close to septal pores minute (~0.1–0.3 µm diam), globose, rarely seen. **Exudate** absent, **gel** only present as a thin layer on the cell walls, staining distinctly lilac in CRB (but almost negative for ascus wall), paraphyses and asci easily separable. — **ANAMORPH**: **Mycelial hyphae** *(4–)6–9(–11) µm wide, hyaline. **Colonies** slow-growing, greyish to brownish, with aerial mycelium; *L. navicularis* (see also below). **Conidiophores** */†(11–)15–30(–45) × (3.5–)5–7 or 7–14 µm, unicellular, unbranched, cylindrical to slightly capitate above, also clavate or dumbbell-shaped, conidiogenous loci inconspicuous, not protruding, 1–30 conidia synchronously formed at apex in a fascicle. **Conidia** */†28–228 × 6–15(–18) µm, slightly falcate to canoe-shaped, 3–11-septate. **Trapping organs for rotifers and tardigrades**: cylindrical to lageniform adhesive pegs, often with a small, slightly enlarged globose head, unicellular, */†10–24 × 3.5–12 µm, covered by a very thin adhesive gel, entire peg surface staining lilac in CRB; **for nematodes**: sessile globose adhesive knobs. Small refractive cubical **SCBs** occurring in all cells of anamorph. **Chlamydospores** observed in *L. vermicola*.

Habitat: teleomorph on xeric, ± decayed bark and wood of living or dead branches and trunks of angiosperm trees and shrubs, also on gymnosperms in association with resinous wounds; anamorph growing aquatic, in lakes or water-filled treeholes, hygric in soil, manure and moss, or on xeric bark and wood. **Desiccation tolerance**: mature asci survive for a few weeks or over 3 months, mycelial hyphae at least 4 months, conidia at least 2 weeks. **Distribution**: rare, though probably worldwide, in humid to semihumid, hemiboreal to submediterranean areas.

Recognized species: *L. ellipsoideus*, *L. longisporus**, *L. muscicola**, *L. navicularis**, *L. pini*, *L. subglobosus*, *L. vermicola** (* = without known teleomorph).

Taxonomy of teleomorph. The genus *Lecophagus* is characterized by tiny, white, subsessile apothecia, 8-spored asci with short and thick, non-furcate stalks arising either from a simple septum or a crozier, ellipsoid to subglobose spores with a single (sub)globose spore body at one end being attached to the spore wall by a short, rod-like connecting part (filum), and by angular excipular cells and a similarly constructed, hardly delimited medullary excipulum. The genus differs from others of the class in asci with hemispherical to submammiform apices and lens-shaped apical thickenings (dead state, the shape of apex does not depend on the viewing direction), extraordinarily wide anchoring hyphae, characteristic cubical SCBs in anchoring hyphae, ectal and medullary excipulum, and paraphyses, and the capability to capture rotifers and tardigrades, or nematodes.

The cubical SCBs are a characteristic trait of the living vegetative cells of *Lecophagus*. They also occur in the anamorph (see Fig. 89a–e), and have so far not been observed by us in any other genus of the *Orbiliomycetes*, nor in any other class of *Ascomycota*. We classify these cytoplasmic inclusions in the category SCBs because they disappear in KOH and are not stained in CRB. Judging from their crystalloid shape and small size, they might derive from Woronin bodies.

Delimitation from other genera. The ascospores and SBs of *Lecophagus* strongly resemble those of *Orbilia* section *Ovoideae*, but all the other features mentioned above suggest that *Lecophagus* is not closely related to this group, which is confirmed by molecular data. The genus *Hyalorbilia* might be related to *Lecophagus* owing to its hemispherical ascus apices, presence of croziers, and often comparatively wide anchoring hyphae. Species of *Lecophagus* resemble particularly *H. erythrostigma* and similar taxa with broadly ellipsoid but smaller spores. Even a possible connection to a rotifer was observed in a single species of *Hyalorbilia* (see below). However, *Hyalorbilia* differs from *Lecophagus* in the presence of VBs in the living paraphyses, and in the hymenial elements being conglutinated in gel and covered by a thin exudate, also in the absence of cubical SCBs in the anchoring hyphae. Very similar but more or less globose SCBs occur in the living conidia of *Hyalorbilia* and sometimes also in the excipular cells (see, e.g., Pl. 92: 1d, 2e, 3g), and might be homologous to the cubical SCBs in *Lecophagus* (see p. 94–95).

Anamorph (see p. 237–239). Four of the seven accepted *Lecophagus* spp. are only known from their anamorph and two only from the teleomorph. Only for *L. ellipsoideus* both morphs have been observed so far, and only on the natural substrate by emerging from common hyphae.

In *L. navicularis* slow-growing greyish to brownish colonies on PDA were reported by Tzean & Barron (1983), whereas in *L. vermicola* cultivation was unsuccessful (Magyar et al. 2016). Strains of *L. longisporus* (type strain, CBS) and *L. muscicola* (ATCC) exist in culture collections (CBS and ATCC), but no information on colony characteristics was available to us.

The genus *Lecophagus* is named after the capability to prey on rotifers, although tardigrades are likewise captured, whereas a recently described species (*L. vermicola*) traps nematodes. The five known species with anamorph are very similar in their short conidiophores that form large curved phragmoconidia, while they differ in their adhesive pegs (see Fig. 105, Pl. 16). The broad mycelial hyphae resemble the anchoring hyphae of the known teleomorphs not only in their extraordinary width, but also in containing the same cubical SCBs, as can be seen on light micrographs of Tzean & Barron (1983, figs 1–2), Barron et al. (1990, figs 13, 18), Morikawa et al. (1993, fig. 11), and in populations of the anamorphs studied by us (Pl. 47: 2c–h; Pl. 51: 1g, k–m, o; Pl. 52: 1–6). They are also seen in the genus *Haptocara* (Pl. 53: 1–2).

Contrary to the above-mentioned LM observations, TEM micrographs do not always clearly show cubical SCBs. Morikawa et al. (l.c.: figs 2, 7–8) stressed the abundant occurrence of electron-dense vesicles mainly in the upper part of adhesive pegs, but also in the cytoplasm of the hyphae. Groups of small refractive granules are visible under the LM in the apices of living adhesive pegs (Pls 51: 1g,), but it seems that only some of the many electron-dense vesicles seen with the TEM correspond to these refractive granules. Also in *Zoophagus insidians* (*Zoopagales*) Morikawa et al. (1993) reported electron-dense, ± globose vesicles. Yet, crystalloid electron-dense 'vacuoles' reported in *L. muscicola* (erroneously as *Zoophagus insidians*) by Powell et al. (1990, figs 16, 21; see Fig. 89e) appear to represent cubical SCBs.

Based upon the mentioned morphological similarities and the adaptation to rotifers and nematodes, together with molecular results about the relationship of *Lecophagus* with the *Orbiliaceae* (Tanabe et al. 1999, see also p. 239), we conclude that anamorph-typified species recognized in *Lecophagus* and the here reported teleomorphs belong to one genus. The observation by D. Magyar (pers. comm.) and G. Marson of adhesive pegs on broad mycelial hyphae emerging from apothecia of *L. ellipsoideus* (Pl. 46: 2) supported this hypothesis. The occurrence of apothecia and adhesive pegs of *L. ellipsoideus* on xeric bark corresponds to the desiccation tolerance observed by us in *L. muscicola* collected on *Elodea* in an ephemeral pond.

A sequence taken from apothecia of *L. ellipsoideus* confirmed a close relationship to sequenced anamorphs of *Lecophagus*. Therefore, we here adopt the name *Lecophagus* for the holomorph of these fungi. However, a clear connection of a teleomorph-typified species to one of the known anamorph-typified species could not be established so far, particularly because the ascospores did not germinate on agar. Therefore, and because our sequence of *L. ellipsoideus* shows a high distance to *L. muscicola* and *L. longisporus*, we here erect new names for the three recognized teleomorph-typified species.

The genus *Haptocara* Drechsler (see below) is believed here to be closely related to *Lecophagus*, based on its broad hyphae, similar conidiophores and conidia, presence of cubical bodies, and the capability to trap invertebrates, but molecular data were not available. *Haptocara latirostrum* and a similar undescribed species of that genus resemble *L. vermicola* in having sessile adhesive knobs which are formed directly on the conidia (Pl. 53), but differ in a hyphal appendage at the terminal conidial cell. Like *L. vermicola*, *H. latirostrum* is known to trap nematodes instead of rotifers.

Adaptation to rotifers. In several collections of the teleomorph of *Lecophagus*, dead rotifer bodies being completely colonized by hyphae were found in very close proximity to apothecia (*L. ellipsoideus*, Pl. 45: 1d, 2e, IVV: collection on *Betula*, 27.IX.1999). The similarity between hyphae emerging from rotifers and anchoring hyphae emerging from apothecia leave no doubt that these mycelia represent a single fungus: the hyphae correspond not only in their unusual width, but also in the cubical SCBs in all cells of these hyphae. This clearly indicates that *L. ellipsoideus* is able to grow endoparasitically in rotifers, although in some other records of this species as well as in *L. pini* and *L. subglobosus* no trace of a rotifer could be discovered. The adaptation to rotifers seems quite unique within the *Orbiliomycetes*. Only in one collection of a *Hyalorbilia*, apothecia occurred in close association with an infected dead rotifer body (Pl. 145: 2). This rotifer contained distinctly narrower hyphae than known in *Lecophagus*, therefore, these hyphae appeared to be part of the closely associated apothecium, for which reason this species was named *H. rotifera*. Only a few further reports of exceptional rotifer capture other than by *Lecophagus* came to our notice (*Drechslerella bembicodes*, *Gamsylella gephyropaga*), and one case in which eggs of rotifers are infected (*Dwayaangam heterospora*) (see p. 214 ff.). In any case, the parasitic lifestyle of *Lecophagus* is not surprising within the *Orbiliomycetes*, and indicates that trapping capabilities are not restricted to species of *Orbilia* section *Arthrobotrys*.

In *L. ellipsoideus* we observed anchoring hyphae of one apothecium emerging from a single dead rotifer body. A direct connection from an infected rotifer to an apothecium could almost completely be traced in CRB by the selective lilac stain of the hyphal wall. The anchoring hyphae form a loose network within the algal layer and emerge from the rotifer body, which is more or less buried within this biofilm. The rotifer jaws (trophi) inside the pharynx are still clearly visible within the cadaver (Pl. 45: 1j–k, Pl. 46: 2c). The cuticle is either intact, though mostly somewhat crumpled or disintegrated. The cadaver is completely colonized by branched assimilative hyphae of the fungus.

The distance between apothecia and rotifers was 0–0.2 mm, and it seemed that each apothecium is formed by the digestion of a single rotifer body. This is suggested by a similar size of apothecia and dead rotifers, the latter measuring about 0.13–0.2 × 0.12–0.15 mm. Although the apothecia are seated on an algal mat over rotten parts of wood or bark, they appear to be formed predominantly by the consumption of the rotifer: the wide anchoring hyhae are few in number and, due to their width, they do not seem to be adapted to enter cells of woody substrate.

Trapping organs were rarely observed in collections from xeric substrate studied by us. Infection could instead have taken place by ingestion of ascospores, or the trapping organs and their supporting hyphae have disappeared during digestion of the rotifer body. The trapping of rotifers by adhesive pegs could be studied by us in the specimen of *L. muscicola* from a pond (Pl. 51). The wall surface of hyphae and adhesive pegs was here found to be covered by a thin gel layer that stains light lilac in CRB. This gel layer is not thicker at the peg apex. When a rotifer was captured, a hypha grows out from the apex of the adhesive peg, and the peg apex may get more distinctly capitate by increasing up to *6.8–7.3 µm in width. Several branches of assimilative hyphae finally colonize the rotifer body.

Phylogeny. Sequences from five strains of *Lecophagus* were available, three of which comprising SSU and five ITS and LSU. *L. ellipsoideus* and *L. vermicola* were sequenced by G. Marson from apothecia or conidia, respectively. The S1506 intron was consistently absent in all five strains. Some environmental samples from GenBank clustered in the genus and comprise mainly SSU or ITS+LSU (Phyl. 3, L1–L5).

Our molecular analyses confirm the results of Tanabe et al. (1999) who found *Lecophagus* to form a clade with orbiliaceous taxa here recognized in *Orbilia* section *Arthrobotrys*. However, a high distance in the LSU region is noted between *Lecophagus* and the genera *Hyalorbilia* and *Orbilia*, while a closer relationship to *Amphosoma*, *Retiarius*, *Lilapila*, and *Bryorbilia* can be recognized (Phyls 1–2, see also Magyar et al. 2016).

Based on our data, the genus *Lecophagus* forms a strongly supported clade (Phyls 2–4), which clustered within the *Lecophagus*-*Amphosoma* clade with strong support sister to the clade with *Amphosoma* and *Retiarius* (Phyl. 2), but with a high distance in the LSU (D1–D2) to the other included genera (5.2–7.2% to *Amphosoma*, 6.8–9.3% to *Retiarius*, 8.7–10.5% to *Lilapila*, and 11–12% to *Bryorbilia.* Also between the four sequenced *Lecophagus* species a distance of 2.2–3.1% is observed, in spite of their close morphological similarity.

Specific nucleotide positions. *Lecophagus* is characterized in the SSU V9 at pos. 227 by TGGC**C** vs. TGGC**T** in any other *Orbiliomycetes*. At pos. 258–259 and 266–267 (Tab. 60), a variable region which forms a loop by base pairing, *Lecophagus* and *Amphosoma* have AT+AT, whereas other orbiliaceous taxa mainly have TC+GA (*Lilapila*, *Bryorbilia*, *Orbilia*) or GG+CC (*Hyalorbilia*), rarely TT+GA or TT+AA. Also in stem-loop B8 near the 3'-end of 5.8S occur specific positions: pos. 119–120 is TC in *Lecophagus* instead of CT or CC in all other orbiliaceous taxa tested, and pos. 135–136 is GA instead of GG or AG, except for *D. haptotyla* which has also TC and GA but differs at 4–5 positions between 120 and 135 (see also Tab. 18). In the LSU D1–D2 three *Lecophagus*-specific motifs were found: pos. 168–170 GG**TTC**GGAC vs. **TTT**, **TTG**, **CAC** and other combinations, 242–243 TCTC**GT** vs. **TT**, **CT**, **CG**, **GA** and other combinations, and pos. 308 AAAT**G**TC vs. **T** (Tab. 58). A further nucleotide (pos. 396) is diagnostic for *Lecophagus*, *Hyalorbilia*, and *Microdochiella* (AAA**A**AGT), whereas the rest of *Orbiliomycetes* have mostly AAA**C**AGT or sometimes AAA**T**AGT (but never **A**).

In the region of the three '*Orbiliales*-specific' primers (Smith & Jaffee 2009), *Lecophagus* concurs with different other genera of *Orbiliomycetes* (Tabs 18–19). For primer Orb5.8s1F and Orb28s2R this is mainly *Amphosoma*, *Lilapila*, and *Retiarius*, for the former also *Bryorbilia* and the *Vermispora* clade of *Hyalorbilia*. In the primer region of Orb5.8s3F *Lecophagus vermicola* deviates from other *Lecophagus* spp.

Table 58. Specific nucleotides and motifs of *Lecophagus* in the 5.8S (stem-loop B8, see Tab. 18), ITS2, and LSU D1 of rDNA, in comparison with other basal genera and remaining *Orbiliomycetes* (*Hyalorbilia*, *Orbilia*). Position numbers starting with AAAACTTT (5.8S), after GAGCGTC (ITS2), and with TGACCT (LSU, here by omitting predominant gaps in alignment of all groups of *Orbiliomycetes*). Y = C or T, K = G or T, R = A or G. Numbers in brackets give number of species (* = *A. resinicola*, '*A. persooniae*', *A.* aff. *resinicola* G.M. 2015-09-15.2).

Ecology. Apothecia of *Lecophagus* have so far only been found on hanging, periodically dry woody substrates, and mostly in small quantities. They completely tolerate desiccation for over 3 months, and the mycelium for at least 4 months. Bdelloid rotifers on which *L. ellipsoideus* preys likewise live on these xeric substrates and similarly overcome drought in a cryptobiotic state of complete water loss. A few dormant, uninfected rotifers were observed on the branches in two of the collections. These individuals rapidly revived and started creeping after spraying with water (Pl. 45: 1l). They possess the very same trophi as those dead infected individuals, and appear to represent the same species.

Mycelia and conidia of *L. ellipsoideus* were observed on xeric substrate at several occasions, e.g., on still-attached bark of *Fagus* and *Platanus* (Pl. 47). Likewise, the so far purely anamorphic *L. vermicola* forms conidia on xeric substrate. This species was found to prey on nematodes which, like bdelloid rotifers, may live on xeric bark and survive drying (Magyar et al. 2016, see under *L. vermicola*, p. 299).

The remaining three accepted species of *Lecophagus* without a known teleomorph were isolated from environments that are continuously moist or wet for a much longer period of time (see p. 237–239). The here studied *L. muscicola* (Pl. 51) formed its adhesive pegs and conidia submerged under water in a pond where it captured a very different type of loricate planktonic rotifer of the ploimoid genus *Lecane*, but exceptionally also a bdelloid rotifer, possibly of the family *Philodinidae*. Mycelium and adhesive pegs in this collection were found to tolerate desiccation on the dry slide for at least 2 weeks, similar as in *L. ellipsoideus* and *L. vermicola*, although the rotifers, protozoans and algae in this aqueous sample did not survive for a single day in the dry state. This result could be explained in a way that the life cycle of *Lecophagus* encompasses an aquatic anamorphic and a terrestrial teleomorphic phase. However, in the here reported samples of teleomorphs of *Lecophagus*, no stagnant or running water was seen in the near surroundings, even after intense rainfalls. It appears, therefore, that only *L. muscicola*, *L. longisporus*, and *L. navicularis* are adapted to a semiaquatic habitat. Whether they are able to form apothecia is unknown.

Key to species of *Lecophagus* based on the teleomorph

1. Spores subglobose, *3.8–4.5(–5) × 3–3.7(–4) µm; paraphyses apically often uncinate; asci *29–39 µm long, arising from croziers, pars sporifera *15–18 µm long; bark of *Ulmus*, mesosubmediterranean (semi)humid, atlantic Europe .... ***L. subglobosus***, p. 296
1. Spores ellipsoid-ovoid, predominantly > 4.5 µm long; paraphyses straight or only sometimes curved at apex; asci *30–68 µm long, pars sporifera *20–40 µm long.. 2

2. SBs with a 0.3–0.8 µm long filum which is ~2–3× longer than wide; spores *(4–)4.5–6.5(–7.3) × (3–)3.3–4(–4.3) µm, ± biseriate within the living asci; asci arising from simple septa or croziers, *(30–)35–45(–55) µm long, pars sporifera *20–36 µm long; marginal cortical cells with †0.3–0.5 µm thick walls; paraphyses apically straight to curved, *3.3–4.5(–5) µm wide; bark & wood of angiosperms, temperate to orotemperate humid Europe .... ***L. ellipsoideus***, p. 291
2. SBs with a 0.2–0.4 µm long filum which is ~1.2–1.5× longer than wide; spores *5–6.3 × 4–4.6 µm, ± uniseriate within the living asci; asci arising from croziers, *45–68 µm long, pars sporifera *37–40 µm long; marginal cortical cells with †1–3 µm thick walls; paraphyses apically straight, *(3.5–)5–6(–7) µm wide; resinous bark of *Pinus*, orosub- to suprasubmediterranean (semi)humid Europe .... ***L. pini***, p. 295

Key to species of *Lecophagus* and *Haptocara* based on the anamorph

(adhesive peg width measured at their base, conidial length straight distance from end to end)

1. Trapping organs elongate cylindrical to conico-lageniform adhesive pegs, apex not or slightly inflated; conidiophores with 1–30 conidia; capturing rotifers and tardigrades in the mouth region..2
1. Trapping organs sessile (sub)globose adhesive knobs; conidiophores with 1–3 conidia; capturing nematodes by adhesion to the cuticle...5

2. Conidia *28–34 × 6–9 µm, (2–)3-septate, canoe-shaped, about 10–30 on each conidiophore; adhesive pegs ± conical, without inflated apex, formed on mycelium; from old manure in a cattle farm, temperate North America (Pl. 16: d) ....***L. navicularis***, p. 299
2. Conidia *73–228 µm long, 5–11-septate, ± falcate 3

3. Conidia *93–133 × 10.5–15.7 µm, 5–8-septate, ± strongly curved; adhesive pegs *20–30 × 7.5–11 µm, apically distinctly inflated; xeric bark & wood of angiosperms, temperate Europe (Pls 45–47)..***L. ellipsoideus***, p. 291
3. Conidia *73–228 × 6–11 µm, 7–11-septate, ± slightly curved; adhesive pegs *10–23 × 5.5–7.5 µm..4

4. Adhesive pegs *17–21 × 3.5–6.5 µm, apically distinctly inflated; conidia slightly curved at the ends, 73–200 × 6–12.5 µm (Pl. 16: a); from moss, soil, or aquatic plants, worldwide, temperate ....***L. muscicola***, p. 297
4. Adhesive pegs *(9–)11–16(–23.5) × (5–)5.5–6(–7.5) µm, apically not inflated; conidia medium curved at the apical end, slightly at the basal end, 125–228 × 8.5–10 µm (Pl. 16: b); from mossy soil or aquatic cyanobacteria, worldwide, arctic to subtropical............ ....***L. longisporus***, p. 299

5. Conidia 5–8-septate, *56–78 × 13–15 µm, distinctly curved (canoe-shaped), without hyphal appendage; often 2–3 adhesive knobs on each conidium (usually at their dorsal side); xeric bark of angio- (and gymno-)sperms, temperate to mediterranean Europe (Pl. 52) ....***L. vermicola***, p. 299
5. Conidia (2–)3(–4)-septate, slightly curved, with a long, narrow, subapically inserted hyphal appendage; one terminal adhesive knob on each conidium..6

6. Conidia slightly obclavate (narrowed towards apex), *24–38 × 9–11 µm, hyphal appendage mainly pointing downwards; from decaying plant material along a roadside, temperate North America (Pl. 53: 3) ....***Haptocara latirostrum***, p. 301
6. Conidia slightly clavate (narrowed towards base), *40–59 × 15–21.5 µm, hyphal appendage pointing laterally; xeric bark of angiosperms, temperate to mediterranean Europe (Pl. 53: 1–2) ....***H.* aff. *latirostrum***, p. 301

However, further evidence for the occurrence of *Lecophagus* in xeric habitats is provided by Hofstetter et al. (2007: 415, 421) who found by molecular methods that *L. muscicola* is present in association with thalli of various lichen genera. Desiccation-tolerant rotifers are known to live on thalli and to feed on the lichen's ascospores (Pyatt 1968), therefore, it can be assumed that *L. muscicola* preys on rotifers in these habitats, either by adhesive pegs or possibly by ingestion of ascospores which may have a similar size and shape as ascospores of many lichens.

The known distribution of the genus *Lecophagus* includes cold-temperate to subtropical, humid regions of Europe, eastern Asia, Australasia, and North America, also tundra vegetation in the Antarctic.

Unrelated genera that resemble anamorphs of *Lecophagus*. Some other genera that prey on rotifers may be confused with *Lecophagus*. The genus *Zoophagus* (*Zoopagales*) was earlier misapplied to species of *Lecophagus* (see p. 238–239) because of similar adhesive pegs and conidia. It differs in having non-septate mycelial hyphae without anastomoses, and another type of conidiophore (see Dick 1990, Morikawa et al. 1993 who observed anastomoses in *L. muscicola* and *L. longisporus*).

Members of two genera of the order *Hypocreales*, *Haptospora* Barron (Barron & Szijarto 1982, Barron 1991b) and *Rotiferophthora* Barron (Barron 1991a), grow endoparasitically in rotifers. In both genera conidiogenesis is phialidic. Their assimilative hyphae inside the dead rotifer body are ± strongly constricted at the septa, with the individual cells often broader at one end, which permits distinction from those of *Lecophagus* which are more rectangular and less constricted.

Lecophagus ellipsoideus Baral & G. Marson, **sp. nov.**, MB 813450 — Pls 45–47, Map 4

Etymology: named according to the ellipsoid ascospores.

Typification: Germany, Baden-Württemberg, Stuttgart, branch of *Lonicera ?tatarica*, 14.V.1994, H.O. Baral (ex H.B. 5078a, M-0276427, holotype).

Latin diagnosis: *Apothecia in statu rehydratato 0.08–0.35 mm diam., sessilia vel breviter stipitata. Asci *24–55 × 6.3–9.3 µm, apice rotundati, in basi non uncinati vel interdum uncinati. Ascosporae *4–7.3 × 3–4.3 µm, ellipsoideae vel ovoideae. Paraphyses sparsae, ad apicem rectae vel leniter curvatae, non vel leniter inflatae ad *3.3–4.5(–5) µm. Excipulum ectale cellulis ad basim *(9–)11–20(–28) µm latis. Hyphae basales *(7.5–)8.5–14(–17) µm latae. Habitat ad lignum vel corticem siccum angiospermarum, in rotiferas parasitans, in zona temperata ad orotemperata humida Europae.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated (0.08–)0.1–0.25(–0.35) mm diam., 0.08–0.18 mm high, white, round, soft, very scattered to subgregarious, rarely gregarious in small groups; disc flat, margin even or very slightly crenulate by the large cortical cells; subsessile on an obconical base or with a ± distinct stipe 15–70(–80) × 40–80(–120) µm, superficial; dry hardly visible, colour unchanged. **Asci** *(24–)29–42(–55) × (6.3–)7–8.5(–9.3)((–11.5)) µm {6}, fully turgescent *7.5–9.5 µm wide, †(23–)27–40(–48) × (5.8–)6–7(–8) µm {4}, 8-spored, spores (*) biseriate to subbiseriate, in lower part also uniseriate, (1–)3–5 upper spores inversely oriented {5} (often ± mixed, often obliquely or laterally oriented), pars sporifera *20–36 → 15–17 µm long (†23–25 µm); **apex** (†) ± hemispherical, slightly mammiform, dome immature or mature *0.8(–1.1) µm thick, mature with refractive inner delimitation, †0.8–1.3 µm thick, endotunica of low refractivity; **base** with ± short and thick stalk, arising from simple septa {6}, but also in some asci from croziers {4}. **Ascospores** *(4–)4.5–6.5(–7.3)((–8)) × (3–)3.3–4(–4.3) µm {6}, ellipsoid, rarely ovoid or slightly clavate, ends rounded, straight, rarely very slightly curved; **SBs** (1.5–)1.6–2(–2.2) × (0.9–)1–1.3(–1.4) ((–1.8)) µm {4}, (sub)globose to broadly tear-shaped, with a short and rather thick or rarely thin, cylindrical or tapering filum, (0.3–)0.4–0.7(–0.8) × (0.1–)0.15–0.25 µm. **Paraphyses** ± sparse, apically uninflated or slightly clavate, straight or sometimes slightly curved or flexuous, terminal cells *10–29 {3} or 30–36 {1} × (3.3–)4–4.5(–5) µm {3}, †2.8–4 µm wide {3}, lower cells *(8–)11–18(–27) × (2–)3–4.5(–5.5) µm {3}, very rarely branched at apex (antler-like), never branched in middle part. **Medullary excipulum** very indistinctly delimited, of dense textura angularis of indistinct orientation, cells guttulate as the ectal excipular cells, without hyphoid elements. **Ectal excipulum** near base of (*) comparatively thin-walled, indistinctly oriented t. angularis(-globulosa), cells *(9–)15–28(–35) × (9–)11–20(–28) µm {3}, at mid flanks and margin of t. prismatica-angularis oriented at a 0–10° angle to the surface, cells *9–18 × 8–12.3 µm {2}, 25–30 µm thick at margin, marginal cortical cells *10–25(–29) × 7–10(–13) µm {4}, wall †0.3–0.4(–0.5) µm thick, refractive. **Anchoring hyphae** sparse, restricted to base, individual cells *(14–)18–30(–35) {4} × (7.5–)8.5–14(–17) µm {5}, †8–12 µm wide, smooth or with an indistinct, very irregular incrustation, wall *0.2–0.3 µm thick {2}, cylindrical to ± moniliform, constricted at septa; individual cells of assimilative hyphae inside the rotifer *10–30(–60) × 5–10(–15) µm {2}. **SCBs** cubical or nearly globose {5}, in paraphyses 1–2 per cell, 0.4–1.2 µm diam., in ectal excipulum and anchoring hyphae ~2–4 per cell, (0.5–)1–1.7(–2) µm diam., in assimilative hyphae 0.5–1 µm diam. **LBs** present in all vegetative cells: small LBs abundant in basal ectal excipulum, sparse towards margin, also in medullary excipulum and paraphyses; sparse to abundant in anchoring and assimilative hyphae (in the latter also large LBs present). — **ANAMORPH**: lecophagus-like (affirmed from natural substrate {2}). **Conidiophores** not seen. **Conidia** strongly curved by ~150–180°, *133 × 15.7 µm {1, *Fagus*}, †90–98 × 10–11 µm {1, *Platanus*}, 5–8-septate. **Adhesive pegs** *(20–)22–28(–29.5) × 9.3–10.8 µm {2, *Clematis*}, †22–26 × 7–8.5 µm {1, *Platanus*}, apex *7.5–9.2 µm wide {2}, lageniform, slightly constricted in upper part, here abruptly thin-walled.

Habitat: collected 0.5–3.5 m above the ground on still-attached, corticated to ± decorticated, dead or sometimes still-living, undecayed, 10–40 mm thick branches but also thick trunks, of *Betula ?pendula* {1}, *Clematis vitalba* {2}, *Cornus sanguinea* {1}, *Fagus sylvatica* {1}, *Lonicera ?tatarica* {1}, *Platanus* × *acerifolia* {3}, *Salix* sp. {1}, *S. cinerea* {1}, on medium to strongly decayed, slightly to strongly eroded bark (bast) {9} and wood {2}, especially on the algae-covered side, often in fissures or old beetle galleries, along the edge between bast and wood, or hidden on inner surface of bark, sometimes on thick algal layer or on excrements of invertebrates, ± strongly greyed, often very close to dead, infected bdelloid rotifer bodies {5}. **Associated**: *Durella connivens* {1}, *Hyalorbilia erythrostigma* {1}, *H. latispora* {2}, *H. subfusispora* {2}, *Karstenia rhopaloides* {2}, *Orbilia clavuliformis* {1}, *O. eucalypti* {1}, *O. filiformis* {1}, *O. obtusispora* {1}, *O. pleioeuonymi* {1}, *O. ungulata* {1}, *O. vinosa* {1}, *O. vitalbae* {1}. **Desiccation tolerance**: fully tolerant for at least 2 weeks, mycelial hyphae for at least 4 months. **Altitude**: 115–1310 m a.s.l. **Geology**: Cambrian pelite, Upper Buntsandstein, Muschelkalk, Middle Keuper (gypsum), Lower Jurassic sandstone & shale, Pleistocene loess; gneiss, marble & amphibolite. **Phenology**: III, V–VII, IX, XI.

Taxonomic remarks. *Lecophagus ellipsoideus* is characterized by ellipsoid ascospores, the upper spores showing a distinct tendency to being inversely oriented within the asci, and by the predominant absence of croziers. However, croziers were present in some asci of four of the six collections with a teleomorph (from Luxembourg and Pyrenees), though only in a few of the tested apothecia. In one of the *Salix* collections (H.B. 6990d) only mycelium was found, and in that on *Fagus* only an infected rotifer and a detached conidium were seen (see below). The mesosubmediterranean *L. subglobosus* differs in subglobose ascospores with narrower SBs, asci consistently arising from croziers, and paraphyses with mostly strongly curved apex. For the more orosubmediterranean *L. pini* see below.

Variation. Ascus length varied among collections between *(24–)29–42 and *35–55 µm, and spore length between *4–

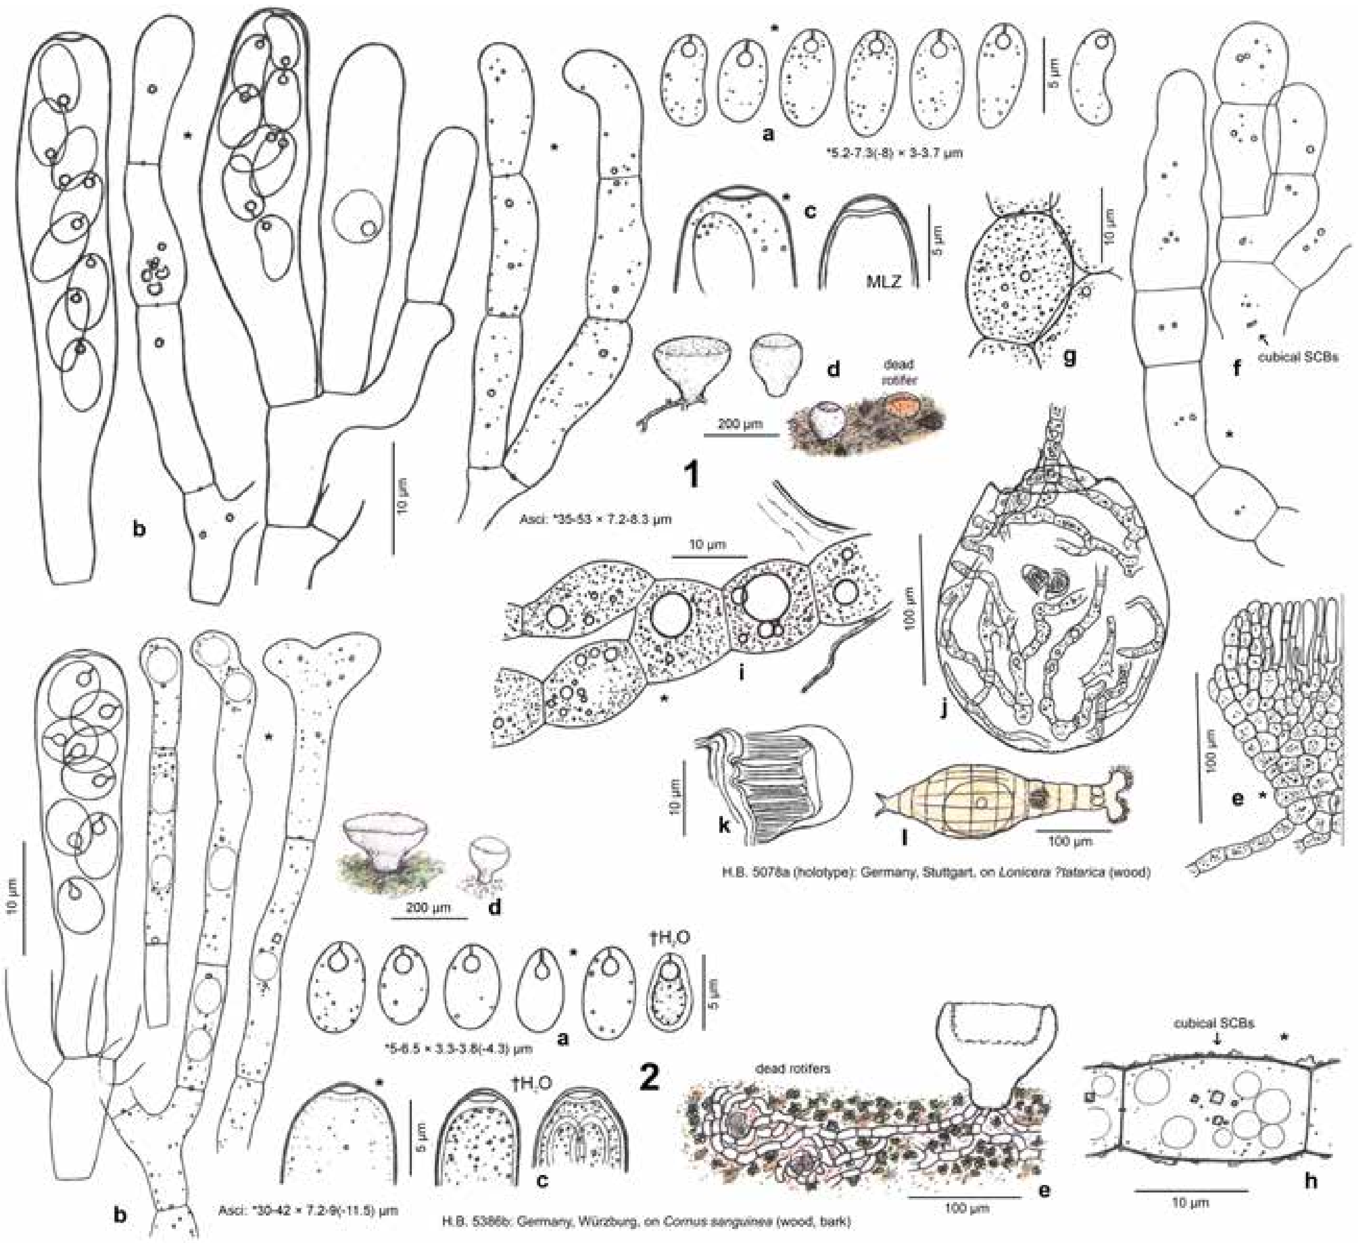

Plate 45. **1–2**: *Lecophagus ellipsoideus*. – **a**. ascospores; **b**. asci and paraphyses (**1b** young ascus with fusion nucleus); **c**. ascus apices; **d**. rehydrated apothecia; **e**. apothecia in median section; **f**. id., marginal ectal excipulum; **g**. ectal excipular cell at flanks; **h**. anchoring hypha; **i**. assimilative hypha within rotifer; **j**. dead rotifer with assimilative hyphae inside; **k**. trophi of infected dead rotifer; **l**. living rotifer found on same branch.

5.5 and 5.2–7.3(–8) µm, but some variation occurred also within a population. The most remarkable variation concerns the partial presence of croziers in some of the studied apothecia, but no basal protuberances were observed. The only montane collection (on bark of *Betula*, IVV: 28.IX.1999) comes close to *L. pini* with its large asci (*42–55 × 7.5–8.5 µm) and rather broad spores (*4.2–6 × 3.5–4.3 µm); in the anchoring hyphae the cubical SCBs attained here a maximum size of 2 µm, while the paraphyses and marginal cortical cells were not studied.

Anamorph. A purely anamorphic record with rather large conidia might represent *L. ellipsoideus*, judging from the occurrence on xeric substrate in temperate Europe: a single infected rotifer was found on the inner surface of bark of a standing trunk of *Fagus* 1 m above the ground (Pl. 47: 2). The assimilative hyphae contained cubical SCBs, and a single conidium was detected in vicinity of the cadaver (*133 × 15.7 µm, 8-septate), but no trapping organs, conidiophores, or apothecia. The large size of the conidium appears to exclude any of the described anamorph-typified species of *Lecophagus*.

A record from Hungary (on bark of a standing trunk of *Platanus*, D.M. 102/2) showed adhesive pegs and a few conidia (Pl. 47: 1). When studied by D. Magyar (pers. comm.) in the dead state, these were strongly curved (by ~150–180°) similar to that on *Fagus* but distinctly smaller (†90–98 × 10–11 µm, 5–7-septate). Again no conidiophores were seen. Another Hungarian sample on *Platanus* showed the same adhesive pegs on mycelium, but here connected to minute apothecia (IVV: D.M. 81/5). A detailed microscopic analysis of their asci and spores was not made, but their identity with *L. ellipsoideus* is assumed here. Also in the two apothecial samples from Luxembourg on xeric bark of *Clematis* (Pl. 46: 2–3) the anchoring hyphae carried adhesive pegs, either on the natural substrate or after some weeks of incubation at the lid of a Petri dish. The large size of the adhesive pegs excludes identity with *L. muscicola* or *L. longisporus* (see key p. 290). Ascospores shot on agar from the

two *Clematis* samples failed to germinate. Regrettably, conidia were so far never seen in association with any of the apothecial records of *Lecophagus* reported here.

Phylogeny. A sequence was gained from apothecia of one of the samples on *Clematis* (H.B. 9902a), comprising SSU V1–V9, ITS, and LSU D1–D5 & D9–D12. *L. ellipsoideus* clustered with

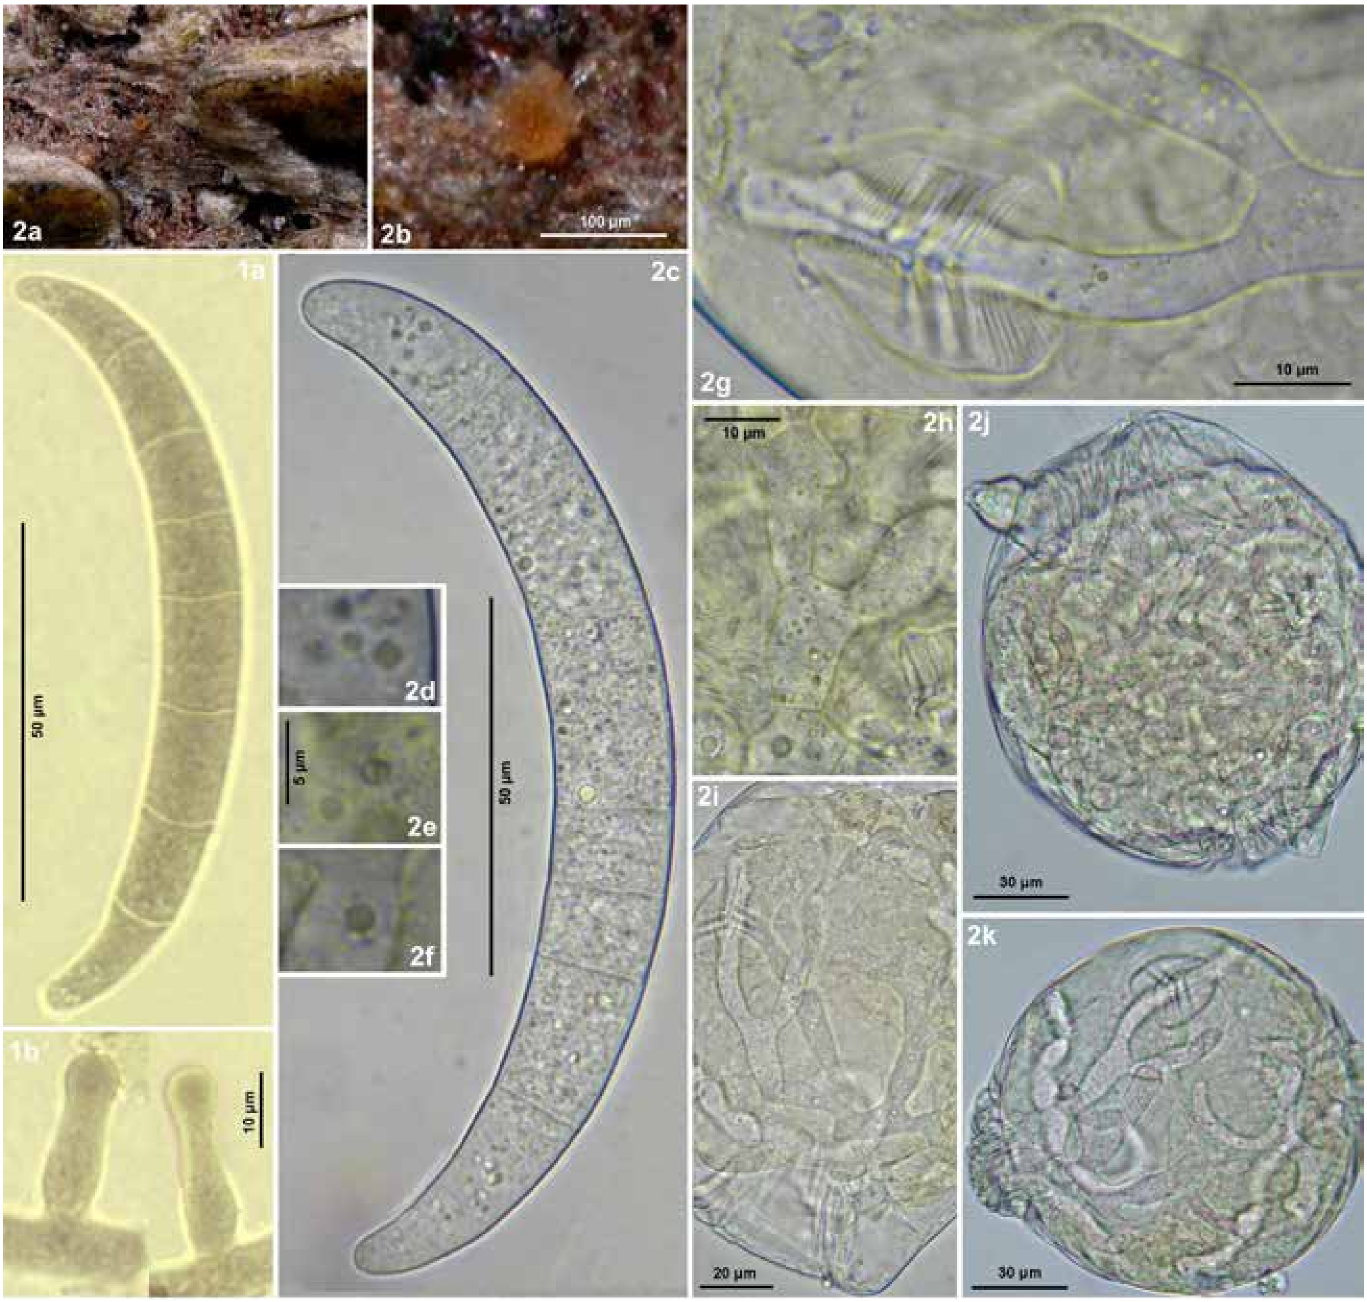

Plate 47. **1–2**: *Lecophagus ellipsoideus*. – **1a**, **2c**. conidia from natural substrate; **1b**. adhesive pegs; **2a–b**. infected rotifer; **2i–k**. rotifer with internal assimilative hyphae; **2d–f**. cubical SCBs in conidium (**2d**) and assimilative hyphae (**2e–f**); **2h**. assimilative hyphae with cubical SCBs; **2g**. assimilative hyphae growing through trophi of rotifer. – Living state, except for **1a–b**. — **1a–b**. high bootstrap support in a clade with *L. muscicola*, *L. longisporus*, and *L. vermicola* (Phyls 2–4). In the ITS region the distance of *L. ellipsoideus* to *L. muscicola* and *L. longisporus* is about 16–17% (15% between the two latter), and 21–23% to *L. vermicola*. Due to their strong distance, the four sequences are difficult to align. *L. ellipsoideus* and *L. vermicola* show 1 larger and 2 smaller inserts in the ITS1. In the LSU the distance of *L. ellipsoideus* to *L. longisporus* is 2.7%, to *L. muscicola* 2.9%, and to *L. vermicola* 3.2% (D1–D2, 633 nucleotides), while the distance between *L. muscicola* and *L. longisporus* is also 2.9%. When including 918 nt (D1–D3), *L. ellipsoideus*, *L. vermicola* and *L. muscicola* show a similar distance among each other (2.2–2.3%, D3 data for *L. longisporus* are lacking), because in the D3 domain *L. ellipsoideus* and *L. vermicola* deviate by only 1 nt (and 4 ambiguities), while *L. muscicola* deviates here by 3 nt from both.

An environmental sequence from Antarctica (MK537054, ITS1) fully matches *L. ellipsoideus*, but was published too late in order to be properly included in this study. Another from a freshwater lake (Lake Biwa) in Shiga, Japan (Bi-F-370) comprises mainly ITS2 and clusters strongly supported with *L. ellipsoideus* (Phyl. 3, L5), though with a distance of 7.5% (15 nt + 5 gaps).

Ecology. *Lecophagus ellipsoideus* was detected on ± decayed bark and wood of xeric branches or on bark of standing living trunks of different angiosperm trees and shrubs or climbers. The known collection sites include cold-temperate (often thermophilous) but also orotemperate areas in subcontinental humid central and southern Europe. A connection to infected cadavers of bdelloid rotifers in close proximity to the tiny apothecia is assumed to be obligatory, although not always easy to observe.

Specimens included. **GERMANY**: **Baden-Württemberg**, 6 km NW of Stuttgart, Weilimdorf, Raiffeisenstraße, 325 m, branch of *Lonicera ?tatarica*, on wood, with infected rotifers, 14.V.1994, H.O. Baral (ex H.B. 5078a, M-0276427, **holotype**). – **Bayern**, **Unterfranken**, 17 km NW of Würzburg, 2 km W of Zellingen, Hügelspitz,

Lecophagus pini Baral, **sp. nov.**, MB 813451 — Pl. 48

Etymology: named after the host tree, *Pinus sylvestris*.

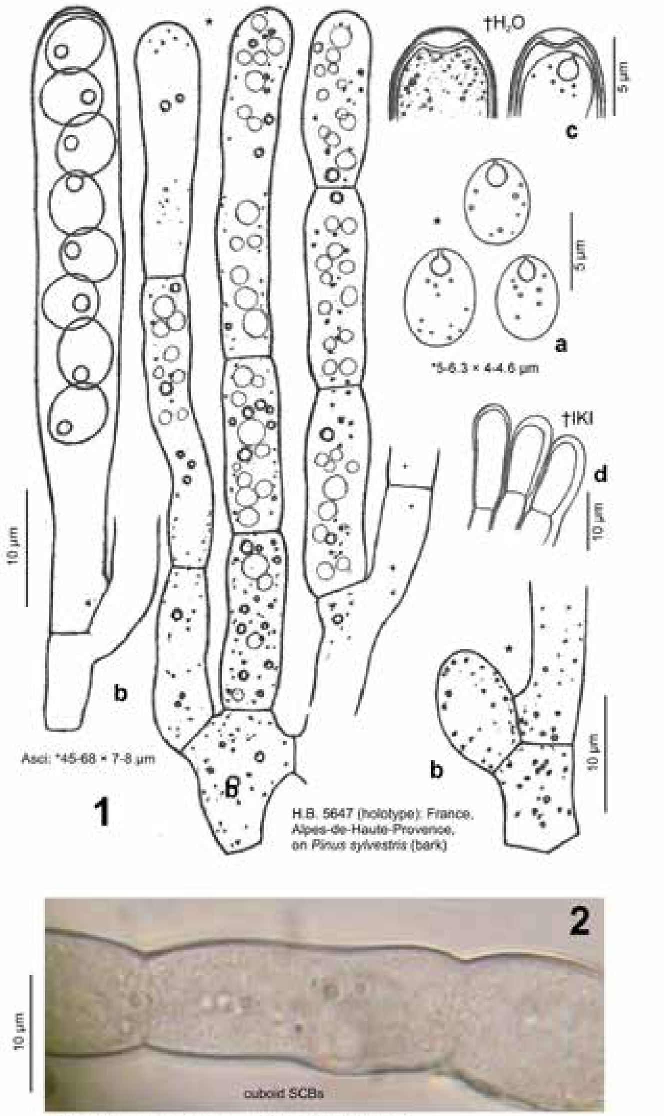
Typification: France, Alpes-de-Haute-Provence, Seyne-les-Alpes, branch of *Pinus sylvestris*, 24.VIII.1996, G. Marson (ex H.B. 5647, M-0276428, holotype).

Latin diagnosis: Lecophago ellipsoideo *similis, sed asci longiores*, *in basi uncinati, ascosporae uniseriatae, leniter latiores*, *paraphyses ad apicem rectae, *(3.5–)5–6(–7) µm latae, excipulum marginale cellulis crassitunicatis. Habitat ad corticem siccum* Pini *in zona orosubmediterranea Europae meridionalis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.12–0.15 mm diam., ~0.13 mm high (receptacle ~0.1 mm), white, round, scattered; disc flat, margin thin, not protruding, smooth; with a small stipe ~0.03 × 0.05 mm, superficial. **Asci** *45–68 × 7–8 µm {1}, 8-spored, spores (*) ± uniseriate, orientation irregular, pars sporifera *37–40 µm long; **apex** (†) hemispherical to slightly conical, dome †1.3–1.4 → 1–1.2 µm thick {1}; **base** with short to long, thick stalk, arising from croziers {1}. **Ascospores** *5–6.3 × 4–4.6 µm {1}, broadly ellipsoid(-ovoid), ends rounded (to obtuse); **SBs** *1.5–1.8 × 1.3–1.5 µm, globose to ovoid, with a very short and thick connecting part, 0.2–0.4 × 0.15–0.3 µm. **Paraphyses** apically uninflated, straight, terminal cells *(11.5–)14.5–34 × (3.5–)5–6(–7) µm {1}, lower cells *12–25 × 4–6 µm {1}; unbranched at upper septum. **Medullary excipulum** not examined. **Ectal excipulum** of (*) slightly gelatinized t. angularis-prismatica, cells *15–25 × 10–14 µm {1}, common walls *0.5–0.8 µm thick; marginal cortical cells †11.5–17 × 6–7 µm {1}, with up to 1–3 µm thick glassy wall. **Anchoring hyphae** individual cells *15–26 × 10–12.5 µm {1}. **SCBs** in paraphyses roundish to slightly angular, 0.7–1 µm diam., intermingled with non-refractive vacuoles. **Exudate** absent. **— ANAMORPH**: unknown.

Habitat: collected ~3 m above the ground, corticated, 40 mm thick branch of *Pinus sylvestris* {2}, on rather undecayed bark (periderm) {1}, very close to blackened resinous wound {1}, medium greyed, with many green algae. **Associated**: *Amphosoma atroolivaceum* {2}, *Bulbillomyces* sp. {1}, *Resinomyces kirschsteinianus* {2}, *Lilapila oculisporella* {1}, *Orbilia sphaerospora* {1}, *Propolis betulae* {1}, *Sarea difformis* {1}, *S. resinae* {1}. **Desiccation tolerance**: fully tolerant for more than 3 months. **Altitude**: 870–1350 m a.s.l. **Geology**: Cretaceous limestone. **Phenology**: VIII.

Taxonomic remarks. *Lecophagus pini* differs from *L. ellipsoideus* in slightly wider ascospores which are almost uniseriately oriented within the living asci, their SB-containing apex pointing rather irregularly in all directions. Besides, the SBs have a shorter filum, the asci and their pars sporifera are longer, the paraphyses wider and apically always straight, the marginal excipular cells more thick-walled. Finally, *L. pini* differs in the coniferous host and (oro)submediterranean region. Some of these features are only gradual. The ascus base (simple septate vs. croziers) appears to be variable in *L. ellipsoideus*, or perhaps indicative of the existence of further taxa. Because of the paucity of material, the mentioned characteristics of *L. pini* may actually show a higher variation than here reported.



H.B. 9143c; France, Vaucluse, on *Pinus sylvestris* (resin)

Plate 48. **1–2**: *Lecophagus pini*. – **a**. ascospores; **b**. ascus and paraphyses, ascus base; **c**. ascus apices; **d**. marginal cortical cells in median section; **2**. hypha containing cubical SCBs (living state).

Further observations on new records are necessary to clarify the taxonomic value and ecological amplitude of *Lecophagus* species.

A second record on *Pinus sylvestris* (Pl. 48: 2) consisted only of one anchoring hypha that undoubtedly represented a species of *Lecophagus*, probably *L. pini* because of the coniferous substrate. Here *Amphosoma atroolivaceum* grew in very close association.

Ecology. The holotype of *Lecophagus pini*, which consisted of only two apothecia, was found on rather undecayed bark of a xeric branch of *Pinus sylvestris*, on the border of an old resinous wound, at an eastnortheast-exposed steep slope 100 m above a mountain brook in an altimontane, orosubmediterranean humid mixed pine forest in the calcarean Southern French Alps. The mycelial record from Mont Ventoux was also in a resinous wound but at lower altitude in a suprasubmediterranean more semihumid pine forest.

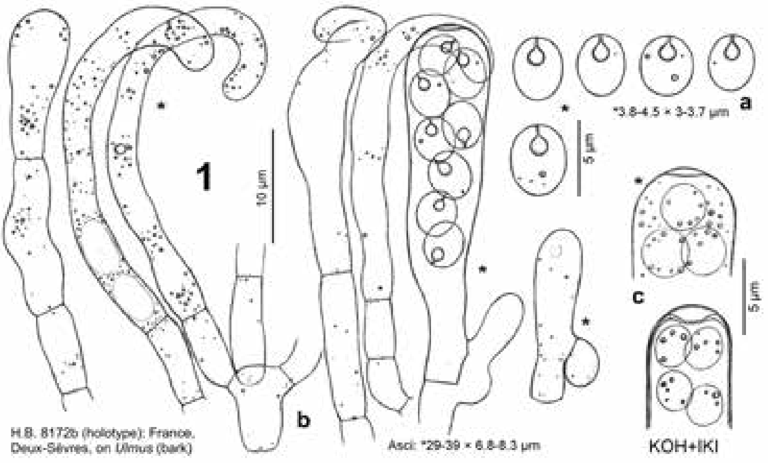


Plate 49. **1**: *Lecophagus subglobosus*. – **a**. ascospores; **b**. ascus and paraphyses; **c**. ascus apices.

Specimens included. **FRANCE**: **Provence-Alpes-Côte d'Azur**, **Alpes-de-Haute-Provence**, Mercantour, 13.5 km SE of Seyne-les-Alpes, 5.5 km SW of Tête de l'Estrop, SE of Vière, 1350 m, branch of *Pinus sylvestris*, on bark near resin, 24.VIII.1996, G. Marson (ex H.B. 5647, M-0276428, **holotype**). – **Vaucluse**, 10.5 km SE of Mont Ventoux, 3.5 km NW of Sault, 870 m, branch of *P. sylvestris*, on resin, 14.VIII.2009, H.O. Baral & G. Marson (H.B. 9143c ø, myc. only).

Lecophagus subglobosus Baral, B. Coué & M. Hairaud, **sp. nov.**, MB 813452 — Pls 49–50

Etymology: named according to the subglobose ascospores.

Typification: France, Deux-Sèvres, Clussais-la-Pommeraie, trunk of *Ulmus* sp., 6.V.2006, B. Coué (ex H.B. 8172b, M-0276429, holotype).

Latin diagnosis: *Differt ab* Lecophago ellipsoideo *ascis in basi uncinatis, ascosporis subglobosis, *3.8–4.5(–5) × 3–3.7(–4) µm, paraphysibus ad apicem plerumque valde uncinatis, cellulis excipuli minoribus, ad basim *7–12 µm latis, hyphis basalibus *5–9.5 µm latis. Habitat in cortice* Ulmi *in zona submediterranea Europae occidentalis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.1–0.2(–0.25) mm diam., 0.07–0.08 mm high, white, round, very scattered; disc flat, margin even or very slightly crenulate, not protruding, exterior glabrous; subsessile on an obconical base or with a short, ± sharply differentiated stipe 0.03–0.04 × 0.03–0.04 mm, superficial; dry hardly visible, colour unchanged. **Asci** *29–39 × 6.5–8.3 µm {2}, †26–35 × 5.5–6.2 µm {1}, 8-spored, spores (*) biseriate to subbiseriate, in lower part also uniseriate, a few lower spores inversely oriented {1} (often ± mixed, also some spores irregularly oriented), pars sporifera *15–18 µm long; **apex** (†) hemispherical, very slightly mammiform, dome immature or mature *0.4–0.7 µm thick, †0.9–1.1 µm; **base** with ± short and rather thick stalk, arising from croziers {1}. **Ascospores** *3.8–4.5(–5) × 3–3.7(–4) µm {1}, subglobose; **SBs** 1.5–2 × 1–1.2 µm {1}, globose to subglobose, with a short and thick connecting part, 0.5–0.7 × 0.15–0.2 µm. **Paraphyses** apically uninflated, rarely medium clavate, medium to very strongly curved (uncinate) {2}, rarely straight, terminal cells *(13–)25–40 × 2.5–5 µm {1}, lower cells *5–14 × 2.5–3.3 µm {1}, rarely branched at upper septum. **Medullary excipulum** not examined. **Ectal excipulum** near base of comparatively thin-walled textura angularis(-prismatica), cells *8–14(–20) × 7–12(–18) µm {1}, at flanks and margin of horizontally oriented t. prismatica-angularis,

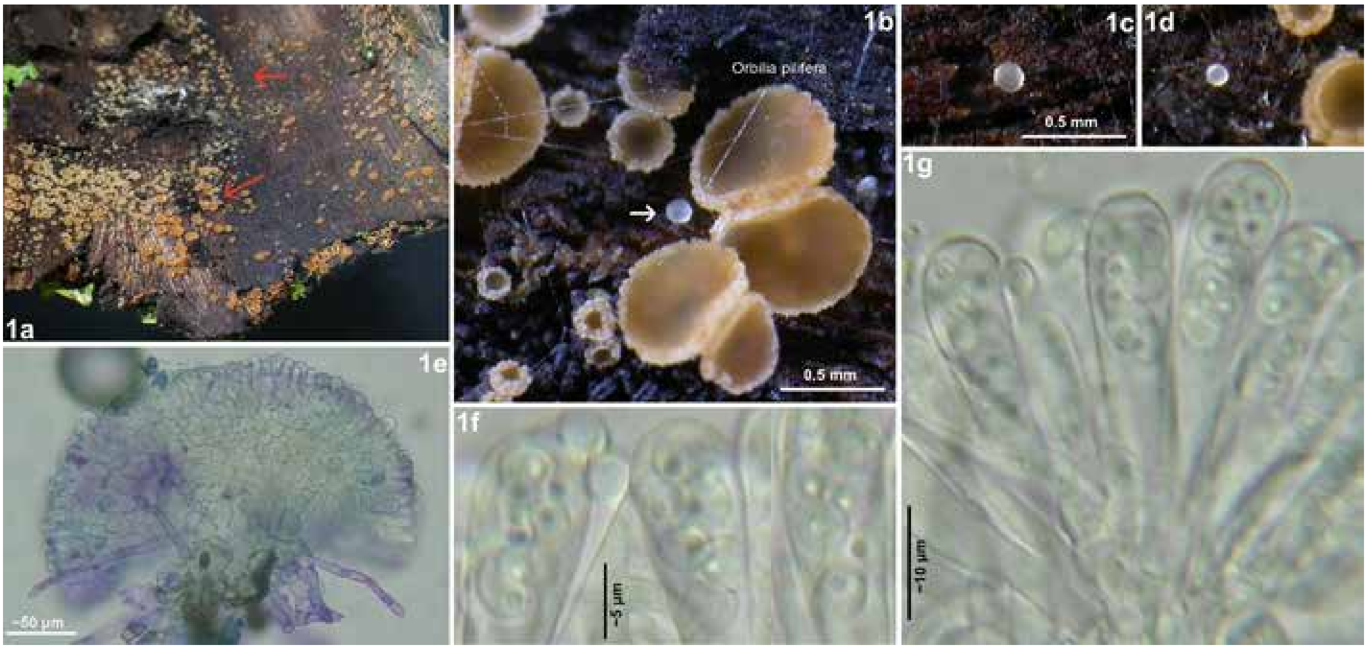

Plate 50. **1**: *Lecophagus subglobosus*. – **1a**. inner surface of xeric *Ulmus* bark, with abundant *Orbilia pilifera*; **1b–d**. rehydrated apothecia (between *O. pilifera*); **1e**. apothecium from below (in CRB); **1f–g**. asci with ascospores, paraphyses. – Living state. – **1e–g**: phot. B. Coué. — **1a–g**. H.B. 8172 (holotype): France, Deux-Sèvres, on *Ulmus*.

marginal cortical cells conglutinated by some gel, †10–12 × 6–11 µm {1}, wall †0.3–0.5 µm thick, refractive. **Anchoring hyphae** sparse, restricted to base, *(5–)6–8(–9) µm wide {1}. **SCBs** in paraphyses not observed, in centre of some excipular cells with globose-cubical SCB 0.5–1 µm diam.; **LBs** in paraphyses and excipular cells scattered, small. — **ANAMORPH**: unknown.

Habitat: on probably recently fallen bark detached from ~5–10 cm thick trunks of dead trees of *Ulmus* sp. {1}, *U.* (?)*minor* {1}, on medium decayed inner surface of bark {2}, ungreyed, without algae, no rotifers observed, outer surface with abundant foliose lichens. **Associated**: *Orbilia pilifera* {2}, *Physcia* sp. {1}, *Xanthoria parietina* {1}. **Desiccation tolerance**: fully tolerant for at least 1–2 weeks. **Altitude**: 130–158 m a.s.l. **Geology**: Tertiary clay over Jurassic and Tertiary limestone. **Phenology**: V, X.

Taxonomic remarks. *Lecophagus subglobosus* is similar to *L. ellipsoideus* and *L. pini*, from which it differs in shorter, subglobose ascospores and mostly strongly curved paraphyses, from the former also in the consistent presence of croziers.

Ecology. *L. subglobosus* was found on medium rotten xeric bark detached from branches of *Ulmus* in ± marshy areas in atlantic, mesosubmediterranean (semi-)humid western Europe. No rotifers or other invertebrates could be found in association with the apothecia.

Specimens included. **FRANCE**: **Poitou-Charentes**, **Deux-Sèvres**, 16 km ESE of Melle, 2 km ENE of Clussais-la-Pommeraie, E of Clussais, 130 m, trunk of *Ulmus*, on bark, 6.V.2006, B. Coué (ex H.B. 8172b, M-0276429, **holotype**). – 13 km ESE of Melle, Coudré, inside of village, 158 m, trunk of *Ulmus* (?)*minor*, on bark, 25.X.2006, B. Coué (ø, non vid.).

Lecophagus muscicola (G.L. Barron et al.) Tanabe, Nagah., Saikawa & Sugiy., Mycologia 91: 835 (1999) — Pl. 51

≡ *Cephaliophora muscicola* G.L. Barron, C. Morik. & Saikawa, Can. J. Bot. 68: 686 (1990)
= *Lecophagus fasciculatus* M.W. Dick, Mycol. Res. 94: 351 (1990)
?= *Lecophagus antarcticus* McInnes (as *L. antarctica*), Polar Biol. 26(2): 79 (2003), nom. inval., Arts 39.1, 40.1 ICN

Etymology: *muscicola*: isolated from mossy soil, *fasciculatus*: from the fasciculate clusters of conidia, *antarcticus*: isolated from Antarctic lakes.

Typification: New Zealand, North Island, from muddy soil in a ditch, 18.XII.1988, G. Barron (OAC 10848, holotype of ***Cephaliophora muscicola***). — USA, Washington, Woodinville, in a small pond, undated, collector unknown (IMI 335522, holotype of ***Lecophagus fasciculatus***, ex-type culture APCC 9000).

Description: — **TELEOMORPH**: unknown. — **ANAMORPH** (collection from Oberlausitz): **Mycelial hyphae** *6–8(–10) µm wide, hyaline. **Conidiophores** *17–17.5 × 6–7 µm, unicellular, unbranched, conidia formed in apical clusters of ~4–10 from broad inconspicuous loci, conidiogenesis synchronous. **Conidia** *83–145 × (9–)9.5–10.5(–12.5) µm, (6–)7–10-septate, fusoid, slightly to medium curved under a wide arch, cells of a conidium of quite different length, terminal cells often longest. **SCBs** in centre of living cells but also near septa, refractive, cubical, 1–1.3 µm diam., present in mycelial hyphae, conidiophores, and conidia. **Trapping organs**: adhesive pegs unicellular, *17–21 × 5.5–6.5 µm, apex *4.2–4.7 µm wide, forming a distinct globose head, sometimes moniliform.

Habitat: isolated from moss and organic debris in wet soil, also from aquatic plants (*Elodea*) in ephemeral ponds, capturing planktonic rotifers of the genera *Adineta* (*Bdelloidea*) or *Lecane* (*Ploima*), also tardigrades. **Desiccation tolerance**: conidia survive for at least 2 weeks. **Altitude**: ~10–300 m a.s.l.

Taxonomic remarks. The synonymy of *L. fasciculatus* with the one month earlier published *L. muscicola* was demonstrated by Morikawa et al. (1993) based on morphological criteria (see p. 238–239). *L. muscicola* and *L. longisporus* were both described in the genus *Cephaliophora* by Barron et al. (1990) and are morphologically as well as ecologically very similar. They are said to differ only in a few details: the adhesive pegs are in *L. muscicola* ± cylindrical, i.e., hardly inflated at the 3.5–5.5 µm wide base, and slightly constricted below the globose apex, whereas in *L. longisporus* they are more conico-lageniform, i.e., inflated to 5.5–7.5 µm at the base but not at the apex (see Pl. 16). The conidia are similar in size and number of septa, but in *L. longisporus* they tend to be more bent near the apex.

We have identified the here illustrated specimen as *L. muscicola* based on the shape of the distinctly subapically constricted adhesive pegs, although their width at the base would better fit *L. longisporus* (it is not quite clear if the measurements in the literature are from living or dead material). Moreover, in our specimen the conidia are never distinctly bent at the apex as is described for *L. longisporus*.

Magyar (2006: fig. 1) identified a fungus as *Cephaliophora muscicola*, sampled in Hungary in a water-filled treehole 1.5 m above the ground. The conidia measured *112–135 × 7.5–8.7 µm and the adhesive pegs *14–15.8 × 4.5–5.5 µm. There is, however, a slight error in these data: the conidia illustrated there and on additional photos kindly sent by D. Magyar (pers. comm.) measure 128–143 × 9–10.5 µm according to the scale, whereas the adhesive pegs on the undulating mycelium are reproduced about 8 % too small on the plate.

Not included collection: *L. antarcticus* was described as predacious on tardigrades (*Acutuncus antarcticus*) and bdelloid rotifers (*Philodina* and others) by McInnes (2003). The author distinguished the species from *L. muscicola* and *L. longisporus* by much broader vegetative hyphae (9 vs. 4–7.5 µm) and larger adhesive pegs (30–40 × 9 vs. 10.5–23.5 × 3.5–7.5 µm), also the conidia are given much wider (170–180 × 13.7–15.5 vs. 125–228 × 6.2–10 µm). However, the indicated dimensions are questionable because there are some striking discrepancies to the dimensions evaluated from the scale: the vegetative hyphae measure 8–9.5 µm from figs 2b and 3a–b and 10–12 µm from fig. 2c, but only ~6–8 µm from fig. 2e; the adhesive pegs measure 33–45 × 7–9 µm from figs 2b–c, but only 13–17 × 6–8 µm from figs 2e, 3a, and 3c; the conidia measure 168–200 × 10–11 µm when evaluated from figs 2e, 2f, and 3c.

Undoubtedly, some of the scales and measurements must be wrong. The illustrated morphology of *L. antarcticus* resembles that of *L. longisporus* and *L. muscicola*, and it is well possible that *L. antarcticus* is conspecific with one of them, when neglecting the very different climatic region from which it derives. In any case, the name *L. antarcticus* is invalid because it lacks a Latin diagnosis and statement where the type was deposited (which was sent to CABI, UK, S. McInnes pers. comm.). No molecular data of *L. antarcticus* was available.

Phylogeny. Sequences from three strains of the *L. muscicola*/*L. longisporus* complex were available in GenBank, comprising SSU (V1–V9), in two of them also ITS and LSU. In the 1769 overlapping nucleotides of SSU, *L. longisporus* (CBS 845.91, New Zealand, holotype) differs from *L. muscicola* (IAM 14638, Japan) by 5 nt, which is a 0.3 % distance in this gene region, whereas the third strain (*Lecophagus* sp., ATCC 56071, ?USA) differs from Japanese *L. muscicola* by only 1 nt and from *L. longisporus* by 4 nt. This appears to indicate that the two strains with a 1 nt distance represent the same species, *L. muscicola*.

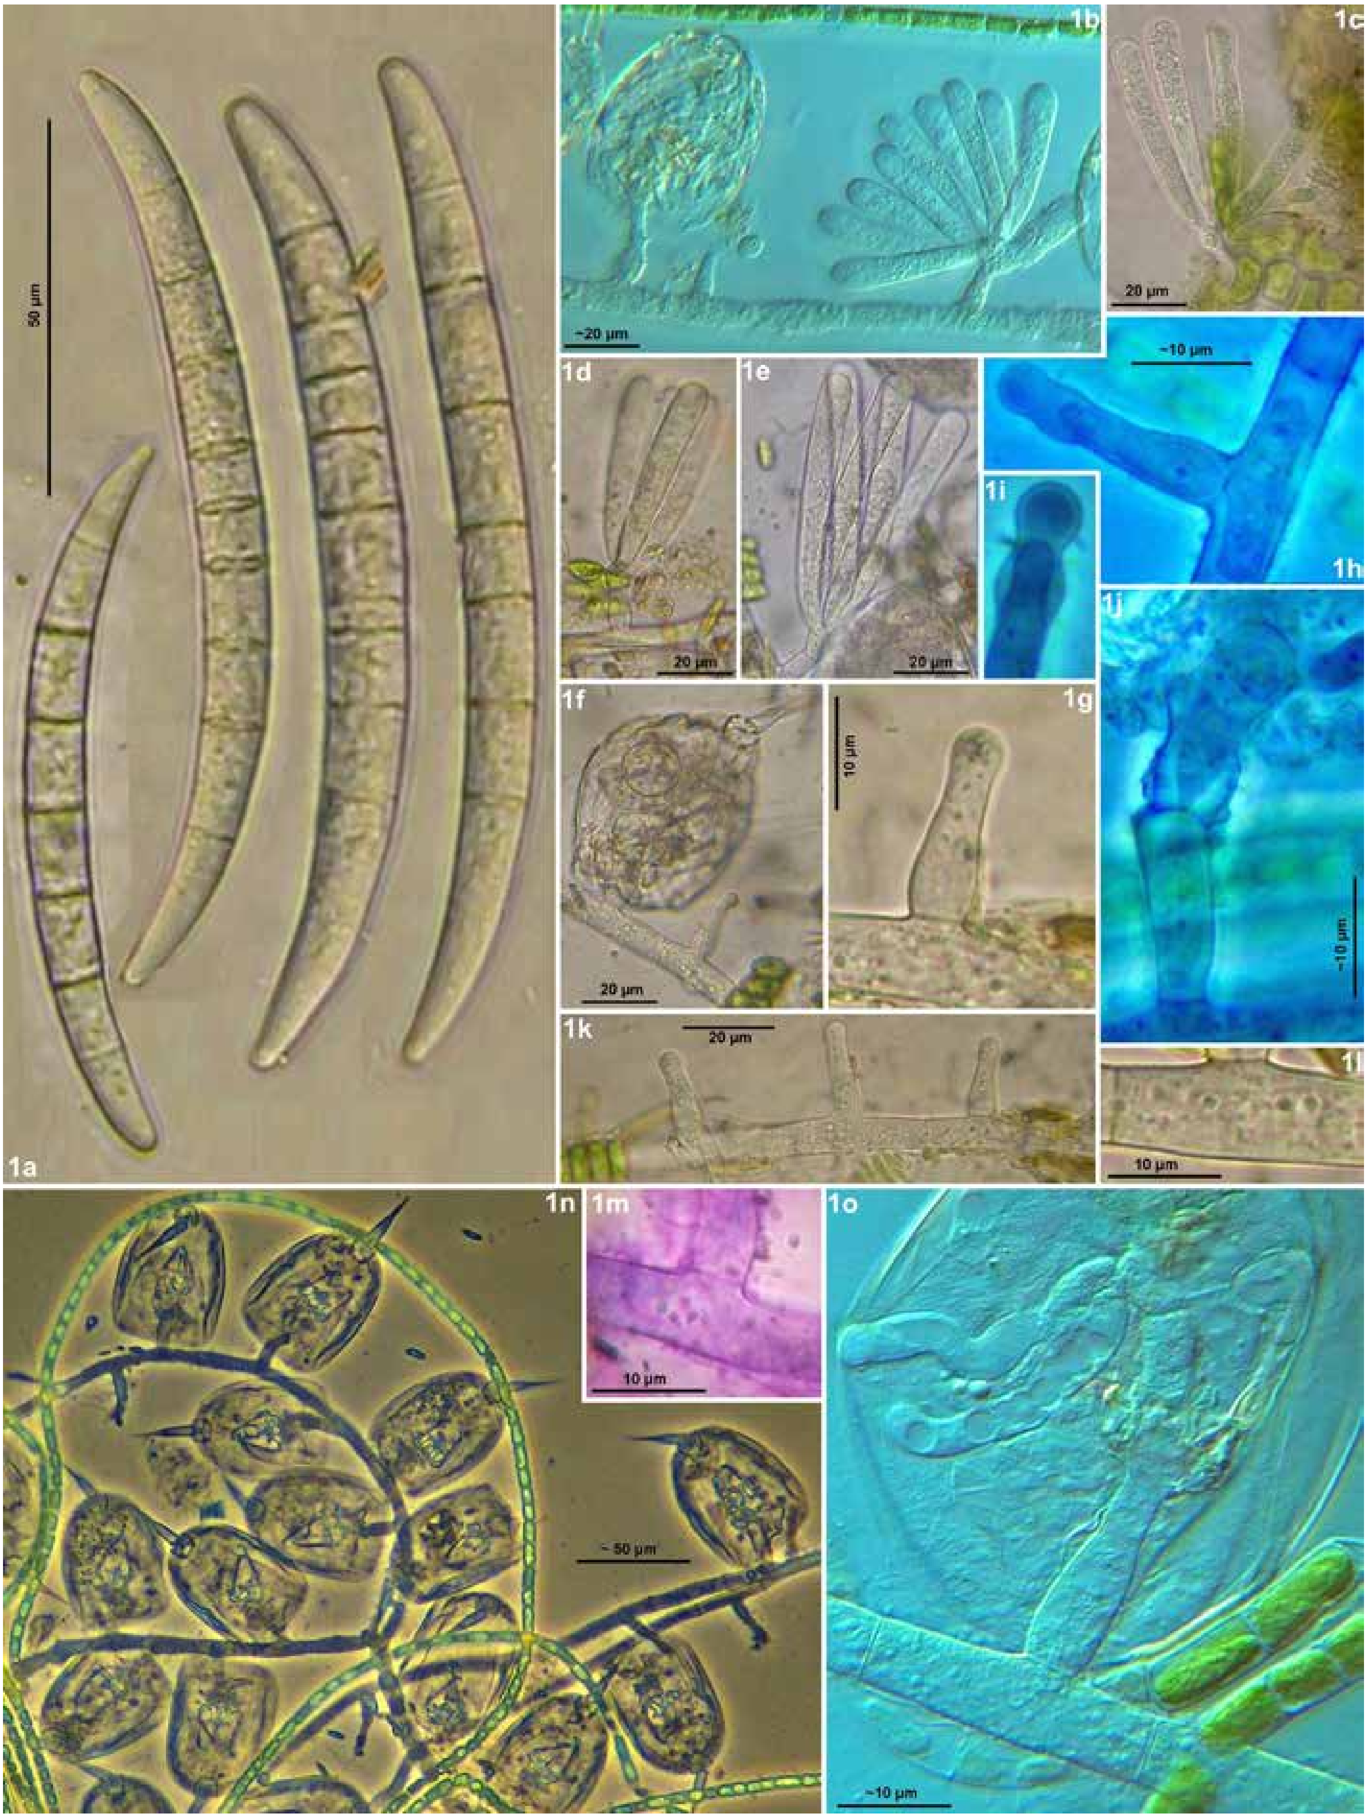

Plate 51. **1**: *Lecophagus muscicola*. – **1a**. mature conidia; **1b–e**. conidiophores with young conidia; **1b**, **f–k**, **n–o**. adhesive pegs (**1b**, **f**, **j**, **n–o** with captured ploimoid rotifers of the genus *Lecane* and assimilative hyphae within rotifer); **1l–m**. cubical SCBs in hyphae. – Living state in water (**1m** in CRB) except for **1h–j** (in CB_L), **n**. – **1b**, **h–j**, **n–o**: phot. P. Bergmann (**b**, **n–o**: DIC). — **1a–o**. Germany, Sachsen, Oberlausitz, Löbau, on *Elodea* (H.B. 7771)

In the LSU (overlapping 563 nt), the difference between *L. muscicola* (ATCC 56071) and the type of *L. longisporus* is 13 nt (2.3 %), and in the 5.8S rDNA it is 2 nt, whereas in the ITS1 and less so in the ITS2 the divergence is so high that an alignment is almost impossible (no data on ITS and LSU are available for the Japanese strain). The high distance of ~15 % in the ITS region confirms separation between *L. muscicola* and the morphologically similar *L. longisporus* at the species level. For the distances to *L. ellipsoideus* see p. 294.

Ecology. The population illustrated here was collected by Peter Bergmann (pers. comm.) in a garden pond in the region of Oberlausitz at the easternmost edge of Germany. The fungus occurred here in close association with trichomous algae attached to decaying shoots of *Elodea*. Barron et al. (1990, as *C. muscicola*) isolated the fungus from muddy soil in a ditch in Egmont Park on North Island (New Zealand), from muddy soil in a rainforest at Milford Sound, and from moss beside a woodland path at Geraldine (both on South Island), also from leaf mould in a subtropical lowland riverside bank of Agano river (Saitama, Japan). The type of *L. fasciculatus* was from a small pond at Woodinville at the cool-maritime westcoast of North America. *L. muscicola* was also recorded from a water-filled treehole on a standing trunk of *Acer platanoides* in Hungary (Magyar 2006, as *Cephaliophora muscicola*). For more details see also under Ecology of the genus *Lecophagus*, p. 290. All these records concern lowland areas with a more or less temperate, humid climate.

The not included *L. antarcticus* was isolated from benthic cyanobacterial mats and sediments in maritime Antarctic lakes in the tundra vegetation of Signy Island, a part of the South Orkney Islands in the Antarctic Ocean about 600 km NE of the tip of the Antarctic Peninsula (McInnes 2003).

Specimens included. **GERMANY**: **Sachsen**, Oberlausitz, 10 km SE of Löbau, Berthelsdorf, S of Zinzendorf Castle, 300 m, on *Elodea canadensis*, parasitic on *Lecane*, III.2005, P. Bergmann (H.B. 7771 ø). — **NEW ZEALAND**: **North Island**, Mt. Egmont Park, muddy soil in ditch, parasitic on *Adineta* and *Tardigrada*, 18.XII.1988, G. Barron no. 169 (**holotype** of *L. muscicola*, OAC 10848, doc. vid.). — **USA**: **Washington**, small pond near Woodinville, on twigs and leaves, parasitic on *Lecane*, date and collector not stated (**holotype** of *L. fasciculatus*, IMI 335522, ex-type culture APCC 9000). – ?**USA**: unlocalized, James et al. 2006 (AFTOL-ID 183, ATCC 56071, as *Lecophagus* sp.; sq.: AY635836, AY997058, DQ273799). — **JAPAN**: **Honshu**, **Tokyo**, Saitama, Agano, river side, leaf mold, M. Saikawa (IAM 14638, isolated by Morikawa et al. 1993, as *C. muscicola*; sq.: AB001108).

Not included. **ANTARCTICA**: **South Orkney Islands**, Signy Island, 0 m, parasitic on *Acutuncus antarcticus* and *Philodina* sp., undated, S.J. McInnes (CABI, **type** of *L. antarcticus*, doc. vid.).

Lecophagus longisporus (G.L. Barron, C. Morik. & Saikawa) Tanabe, Nagah., Saikawa & Sugiy. [as '*longispora*'], Mycologia 91: 835 (1999) — Pl. 16: b

≡ *Cephaliophora longispora* G.L. Barron, C. Morik. & Saikawa, Can. J. Bot. 68: 688 (1990)

Taxonomic remarks. *Lecophagus longisporus* differs from *L. muscicola* mainly in the shape and size of the adhesive pegs (see under *L. muscicola*, p. 297). However, the morphological distinction between the two species is not very clear.

Phylogeny. Sequence data exist in GenBank for the holotype of *L. longisporus* (CBS 845.91, New Zealand), showing to the Japanese strain of *L. muscicola* a distance of 0.3 % in the SSU, ~15 % in the ITS, and 2.3 % in the LSU D1–D2 (see p. 297).

Ecology. *Lecophagus longisporus* was isolated by G.L. Barron from mossy soil in a subtropical humid kauri wood at Birkenhead (Auckland, New Zealand, 25.XII.1988, CBS 845.91, holotype), also from moss on a rock in a cold-temperate humid region at Eramosa River bank near Guelph (Ontario, Canada), using tardigrades and rotifers of the genus *Adineta* as prey. Cultures earlier misidentified as *Zoophagus insidians* are APCC 9000 (H.C. Whisler), and ATCC 48646 (S. Warner no. 65-6) (Dick 1990, Morikawa et al. 1993), but their geographical origin is not indicated.

Lecophagus navicularis (Tzean & G.L. Barron) M.W. Dick, Mycol. Res. 94: 352 (1990) — Pl. 16: d

≡ *Cephaliophora navicularis* Tzean & G.L. Barron, Can. J. Bot. 61: 1345 (1983)

For a description see Tzean & Barron (1983).

Taxonomic remarks. The canoe-shaped conidia of *Lecophagus navicularis* resemble those of *L. vermicola* but are smaller and with only 3 septa. *L. navicularis* forms conical adhesive pegs in contrast to the globose ones of *L. vermicola*. No molecular data of *L. navicularis* was available.

Ecology. *L. navicularis* was reported as predacious on bdelloid rotifers of the genus *Adineta*, being isolated from old manure in a beef (cattle) farm near Toronto, Ontario, in cold-temperate (hemiboreal) humid North America.

Lecophagus vermicola D. Magyar, G. Marson, Z. Merényi & Baral, in Magyar et al., Mycol. Progr. 15: 1139 (2016) — Pl. 52

Etymology: named after the ability to prey on nematodes.

Typification: Hungary, Budapest, infected nematodes on trunk of *Platanus* × *acerifolia*, 24.VII.2011, D. Magyar (BP 107927, holotype).

Description: — **TELEOMORPH**: unknown. — **ANAMORPH**: **Assimilative hyphae** septate †(3–)5–7(–11) µm wide, completely colonizing the nematode's body, arranged longitudinally as 1 or 2 parallel, anastomosing threads. **Conidiophores** micronematous, mononematous, †11–13 × 8–9 µm {Hungary}, conical to clavate, 0–1-septate, with 2 conidiogenous scars. **Conidia** *56–86 × (11.5–)13–17 µm {12}, †(44.5–)50–55(–61.5) × (8–)10.5–11.5(–12.5) µm {Hungary} or †58–63 × 12–15 µm {Canada} (in situ, actual length *~65–90, †~55–75 µm), (3–)7(–8)-septate, fusoid to fusiform, canoe-shaped, slightly tapered at the slightly to medium curved base, sometimes forming a pedicellate 'foot-cell', straight in middle part, strongly tapered and curved (sometimes hooked) at the apex. **SCBs**: living cells containing small, globose to rectangular (cubical to hexagonal), refractive bodies 0.7–1.5 µm, rarely 2–3 µm diam. **Trapping organs**: capturing nematodes by globose sessile adhesive knobs formed on conidia or hyphae erupting from the host's body, 1–5 knobs at dorsal side of conidia, also on apical cell, sessile, globose, *7.5–9 µm diam. (†7–7.5 µm {Hungary}); adhesive knobs on assimilative hyphae breaking through the cuticle of the nematode, globose to elliptic, †8–12 × 6–8 µm, sometimes short-stalked with a broad basal cell. **Chlamydospores** globose, 16.5–36.5 µm diam. {Hungary}.

Habitat: ~1–2 m above the ground, on standing living trunks or dead, corticated, rarely decorticated, ~2–30 cm thick xeric twigs and branches of *Cercis siliquastrum* {2}, *Cornus* sp. {2}, *Elaeagnus angustifolia* {3}, *Fagus sylvatica* {1}, *Gymnocladus dioicus* {1}, *Platanus* × *acerifolia* {3}, *Populus ?balsamifera* {1}, *Salix* sp. {1/1}, *Sorbus aucuparia* {1}, *Taxus baccata* {1}, *Thuja plicata* {1}, on bark {10} or wood {1}, rarly boring dust {1}, mycelium repeatedly observed to emerge from infected nematodes. **Associated**: *Claussenomyces* sp. {1}, *Hyalorbilia helicospora* {1}, *Hysterobrevium mori* {1}, *Nitschkia broomeana* {1}, *Orbilia arachnovinosa* {1}, *O. cejpii* {1}, *O. cercidicola* {1}, *O. flagellispora* {1}, *O. gambelii* {1}, *O. myriolentiformis*

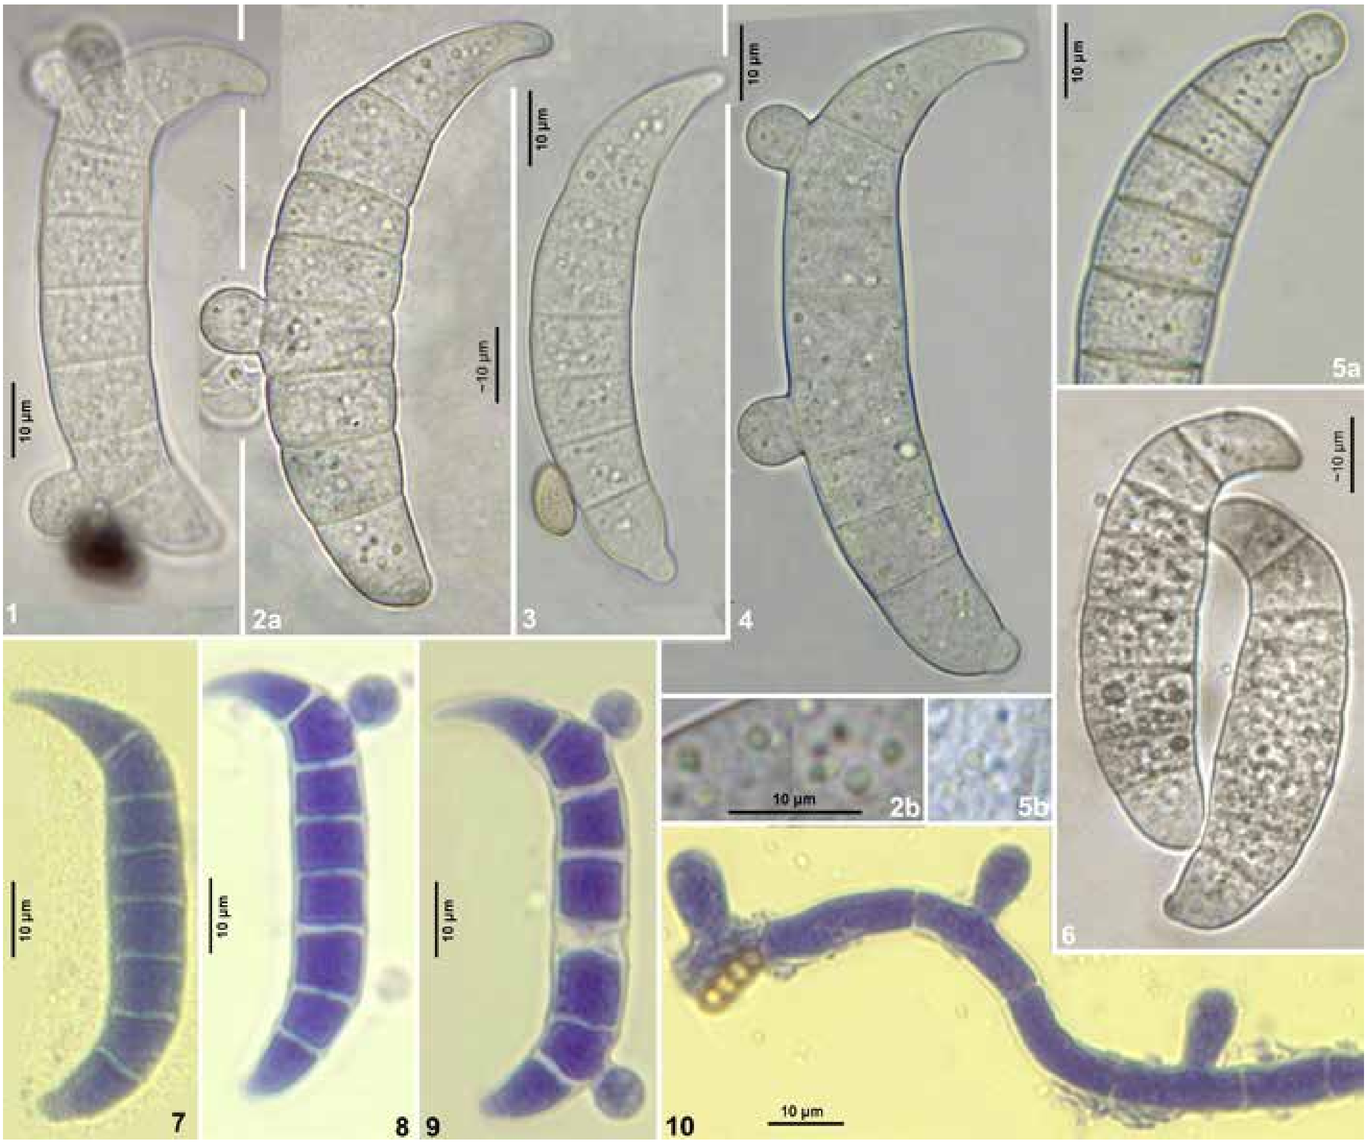

Plate 52. **1–10**: *Lecophagus vermicola*. – **1–9**. conidia with sessile adhesive knobs; **10**. hypha with adhesive knobs; **2b**, **5b**. cubical SCBs in conidial cells. – Living (**1–6**) and dead state (**7–10**, in methylene blue). — **1**. VIII.2005: Luxembourg, unlocalized, substrate unknown; **2a–b**. 9.X.2002: France, Venasque, on *Cornus*; **3**. 27.VII.2005: Luxembourg, Alzingen, on *Fagus*; **4**. H.B. 9151k: France, Nyons, on *Cercis*; **5a–b**. 19.III.2005: Luxembourg, Berchem, on *Thuja*; **6**. undated, unlocalized; **7–10**. BP 107927, Hungary, Budapest, on *Platanus* (holotype).

{1}, *O. myriosphaera* {1}, *O. ocellata* {1}, *O. subaristata* {1}, *O. subclavuliformis* {1}, *O. trapeziformis* {1}, *O. vinosa* {1}. **Drought tolerance**: conidia survive in the dry state for probably several months. **Altitude**: 114–485 m a.s.l. (Europe), 30 m (North America). **Geology**: Canada: Permian sedimentary rock; Europe: Keuper & Lower Jurassic sandstone & Minette, Cretaceous limestone, Miocene sandstone; granitoid granulite & gneiss. **Phenology**: I, III, V, VII–XI (throughout the year).

Taxonomic remarks. *Lecophagus vermicola* forms very large conidia which produce laterally or apically 1–5 sessile, globose adhesive knobs, apparently without presence of nematodes. Uninfected nematodes added to conidia on the natural substrate, which was rehydrated with distilled water, were trapped by the adhesive and got invaded by the fungus, while germination of conidia without presence of nematodes was not observed.

Conidia of *L. vermicola* resemble those of *Lecophagus navicularis* but are distinctly larger and have 5–8 septa instead of (2–)3, also they are formed in much smaller number on the conidiophores. Cubical bodies are regularly present in the living cells (Pl. 52: 2b, 5b). In the samples from Luxembourg and France only conidia were observed, which were detected by one of us (G.M.) on bark of xeric branches of various angio- but also gymnosperms (Pl. 52: 1–6). D. Magyar demonstrated that the fungus captures nematodes on xeric bark (Magyar et al. 2016). Apothecia of a presumed teleomorph could never be observed in association.

Haptocara latirostrum s.l. (see below) has similar conidia which deviate in having a single sessile adhesive knob at the apex when still on the conidiophore, and by forming a lateral hyphal appendage at their apical cell already before the knob appears.

Variation. The rather strong size difference between Hungarian and Luxembourg samples is in part due to the shrinking effect. The extent of shrinkage was so far only tested for conidia from Canada (A. Carter pers. comm.), measuring *~57–68 × 15–17(–19?) µm vs. †58–63 × 12.5–15 µm which is a ~3% shrinkage in length and 12–18% in width.

Phylogeny. A sequence of *L. vermicola* from Hungary comprising ITS and LSU falls in the *Lecophagus-Amphosoma* clade, showing in the ITS region a distance of 17–23 % to the so far sequenced typical species of *Lecophagus*, which is not higher than the distance between them (~15–17 %). In the LSU (D1–D2) the distance is 2.2–3.2 % to typical *Lecophagus* species (to other genera, e. g. to *Amphosoma*, the minimum LSU distance is 7 %).

Ecology. Conidia of *Lecophagus vermicola* were harvested on bark of xeric branches and trunks of different angio-, rarely gymnosperms in subcontinental, cold- to orotemperate humid and mesosubmediterranean semihumid Europe, and in cold-temperate humid eastern Canada.

Specimens included. **LUXEMBOURG**: **Gutland**, **Esch-sur-Alzette**, 8 km S of Luxembourg, 1 km NW of Berchem, Angelsbierg, 295 m, trunk of *Thuja plicata*, on bark, 19.III.2005, G. Haptocara Drechsler, Am. J. Bot., Suppl. 62: 1073 (1975)

Type species: *H. latirostrum* Drechsler

Etymology: *Haptocara*: from the capture of nematodes by means of an adhesive bulb at the conidial apex; *latirostrum*: referring to the broad adhesive bulb ('wide beak').

Description (according to Drechsler 1975, modified): — **TELEOMORPH**: unknown. — **ANAMORPH**: **Mycelial hyphae** *4–13 µm wide, septate, hyaline, scanty. **Colonies** slow-growing (maize-meal agar). **Conidiophores** *40–80 × 6.5–9 µm, apically not narrowed, septate only at base, unbranched, conidia formed in apical parallel clusters of ~3 from broad inconspicuous loci, conidiogenesis synchronous. **Conidia** phragmosporous, *(24–)30–38 × 9–10(–11) µm (excluding knob), with 2 septa near the middle, inequilateral to slightly curved, subapically forming 1 lateral, filiform, nonseptate **hyphal appendage** *24–34 × 1.7–2 µm directed ± downwards, apically later developing a broadly ellipsoid to subglobose **adhesive knob** of *8–9.5 × 6–7 µm, eventually (2–)3(–4)-septate. **Trapping organs**: capturing nematodes by small globose adhesive knobs on short lateral branches of the mycelium, or, more often, by the larger subglobose adhesive knobs on the conidia; extending an infection tube to the animal, producing only one endozoic hypha 4–13 µm wide.

Habitat: isolated from plant remains from a ruderal roadside, capturing nematodes. **Desiccation tolerance**: unknown. **Altitude**: 40 m a.s.l.

Recognized species: 1, plus 1 unnamed species.

Taxonomic remarks. The above description is based on the type species, *H. latirostrum* (Pl. 53: 3). A short generic characterization is given on p. 235. *Haptocara* is probably very closely related to *Lecophagus*, if not conspecific, but molecular data were not available. It is mainly the conidial hyphal appendage and the less curved conidia that distinguish *H. latirostrum* from *L. vermicola*, to which it is otherwise very similar.

Cubical bodies in the conidial cells are not or only indistinctly seen in Drechsler's (1975: fig. 12c) drawing which was undoubtedly made on living cells. In any case, they are clearly visible in another, apparently undescribed species of *Haptocara*, here referred to as *H.* aff. *latirostrum*, which has very similar

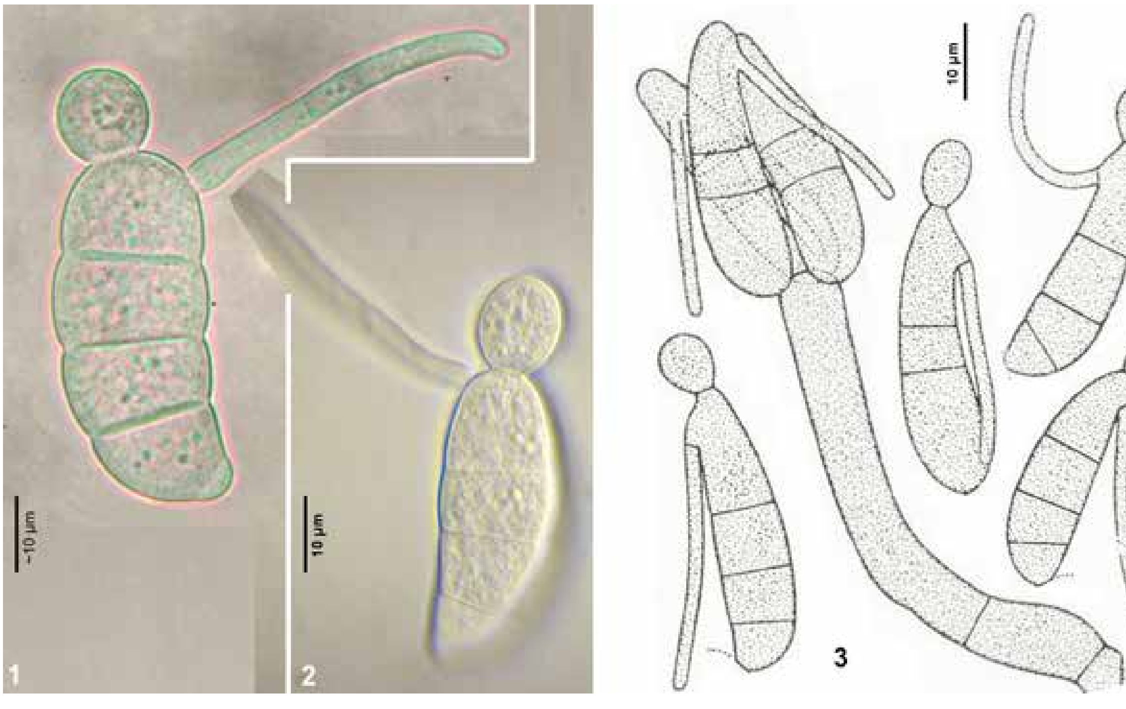

Plate 53. **1–2**: *Haptocara* aff. *latirostrum*; **3**: *H. latirostrum*. – Conidiophore and conidia with sessile adhesive knobs (**1–3**) and hyphal appendages (**1–3**; all in living state). — **1**. 3.II.2007: Luxembourg, Beaufort, on *Fagus*; **2**. 20.III.2003: France, Nyons, on *Cercis*; **3**. from Drechsler (1975), holotype.

conidia, differing in much larger (*~38–47 × 15–20 µm), consistently 3-septate conidia of a somewhat different shape, the hyphal appendage projecting more upwards and the knob of more (sub)globose shape (Pl. 53: 1–2).

Conidia of *H.* aff. *latirostrum* were found at least two times on xeric branches and trunks of angiosperms in cold-temperate humid and mesosubmediterranean semihumid Europe. Although conidiophores have not been seen, the conidia were undoubtedly formed on the xeric substrate and found to be viable when later examined, suggesting considerable drought tolerance of this species.

Haptocara latirostrum: **USA**: **Maryland**, 16 km NE of Washington DC, Beltsville, 0.5 km S of National Agricultural Library, roadside, 40 m, obtained from indet. plant material on agar, 28.V.1969, C. Drechsler (**holotype**, doc. vid.).

Haptocara* aff. *latirostrum: **LUXEMBOURG**: **Gutland**, **Echternach**, 10 km WNW of Echternach, 1.2 km SW of Beaufort, Längt, 340 m, trunk of *Fagus sylvatica*, on bark, 3.II.2007, G. Marson (ø). — **FRANCE**: **Rhône-Alpes**, **Drôme**, 1 km N of Nyons, le Devés, 460 m, branch of *Cercis siliquastrum*, ~20. III.2003, G. Marson (ø).

Bryorbilia Baral & E. Rubio, **gen. nov.**, MB 825640

Type species: *B. arenicola*

Etymology: referring to the associated growth with a moss and the relationship to the genus *Orbilia*.

Latin diagnosis: *Apothecia in statu vivo 0.4–0.5 mm diam., orbicularia, sessilia, tota alba, hymenio plano, margine subglabro. Asci fusoideo-clavati, apice conico-truncati, in statu emortuo maturitatem tenuitunicati sed immaturitatem ad latera crassetunicati, non amyloidei (IKI), octospori, stipitati, bifurcati. Ascosporae distichae in asco viventi, ellipsoideae, clavatae, vel ovoideae, aseptatae, hyalinae, in statu vivo plures corpuscula refringentia, globosa continentes. Paraphyses ad apicem plus minusve clavatae, flexuosae, plerumque rostratae, ramosae, corpusculum refringentem unum globosum continentes, exsudato hyalino tectae, non cohaerentes. Excipulum ectale e textura globulosa-prismatica tenuitunicata. Habitat ad solum argillaceum inter muscum* Ceratodonis purpurei *Europae occidentalis*.

Recognized species: *B. arenicola*.

Bryorbilia arenicola E. Rubio & Baral, **sp. nov.**, MB 825641 — Pls 54–55

Etymology: referring to the sandy soil on which it grows.

Typification: Spain, Asturias, Carcedo de Lomes, on sandy soil among *Ceratodon purpureus*, 11.III.2017, E. Rubio (ex E.R.D. 6987 & ex H.B. 10121, AH 52844, holotype, sq.: MK514443, MK514443).

Description: — **TELEOMORPH**: **Apothecia** rehydrated (0.2–)0.4–0.5 mm diam., 0.21 mm high, white, slightly translucent, subturbinate, round, non-gelatinous, scattered; disc flat, margin distinct, thin, finely rough; broadly sessile to substipitate. **Asci** *82–99 × 9.5–11 µm, †(60–)70–80(–93) × 6–7(–8) µm, 8-spored, fusoid-clavate, spores obliquely biseriate, lower spores not inverted, pars sporifera *~50 µm long, †27–35 µm; **apex** (†) conico-truncate irrespective of the viewing direction, thin-walled (in KOH 0.3 µm), entire lateral wall thick-walled when mounted in KOH (0.4–0.5 → 0.6–1 µm), immature with a ring-like plasmatic structure; **base** with (*) short and thick, (†) short to long and thin, often flexuous stalk, bifurcate (h- to H-shaped), arising from simple septa. **Ascospores** *9–13(–14) × (4–)4.5–5.2(–5.5) µm, †8.5–12 × 3.5–4.5(–5) µm, non-septate, smooth, narrowly ellipsoid to clavate-ovoid, both ends rounded to obtuse, straight; **SBs** numerous (~20–30), 0.5–1 µm diam., globose, attached to wall all over the spore, together with 1 **LB** 1–2.7 µm in each half; overmature *10–10.5 × 5.5–7 µm, †9.5–12.5 × 4.3–5.5 µm, during germination 0–1-septate, germ tubes moniliform and irregularly bent. **Paraphyses** apically uninflated or usually slightly to medium clavate to spathulate, often beaked, sometimes 2–3-lobed, always ± flexuous, terminal cells *17–27 × 2.5–4 µm, lower cells *(7–)10–14 × 1.7–2.5 µm; sometimes branched at upper septum, not immersed in gel. **Medullary excipulum** 80–110 µm thick, of dense, small-celled non-gelatinized textura angularis-intricata, medium sharply delimited from ectal excipulum by a thin t. prismatica. **Ectal excipulum** at base and lower flanks of (*) thin-walled t. globulosa-prismatica, 35–40 µm thick, oriented at a (10–)30–50(–80)° angle to the surface, cells *7–14 × 4.5–9.5 µm, 20 µm at mid flanks and margin, of t. prismatica oriented at 10–50°, cells *10–24 × 7–12 µm, marginal cortical cells *9–15 × 3–5 µm, †9–13 × 2.5–4.3 µm, *thin-walled, in KOH slightly gelatinized; **glassy processes** and **hairs** absent. **Anchoring hyphae** medium abundant at base, hyaline, †1.5–2.5 µm wide, walls 0.2 µm thick, smooth. **VBs** absent. **SCBs** globose, 2–2.8 µm diam., subapically and singly in each paraphysis. **Exudate** over paraphyses and marginal excipulum 0.7–1.5 µm thick, cloddy, loosely attached, hyaline. **— ANAMORPH**: unknown.

Habitat: on burnt, sandy soil under *Ceratodon purpureus*, green algae abundant below apothecia. **Associated**: *Octospora rustica*. **Desiccation tolerance**: probably desiccation-intolerant, dead in all parts after 3 months in dry state. **Altitude**: 692 m a.s.l. **Phenology**: III. **Geology**: Neoproterozoic sandstone, slate & greywacke.

Taxonomic remarks. *Bryorbilia arenicola* resembles members of *Helotiales* in shape of ascospores and upper part of asci, but it discloses its genuine relationship in having a bifurcate, h- to H-shaped ascus base (Pl. 55: 1i), apically inflated and flexuous paraphyses with globose SCBs (Pl. 55: 1j–l) reminiscent of, e. g., *Orbilia* section *Ovoideae*, and KOH-soluble guttules (SBs) in the spores (Pl. 55: 1m). The large spore drops sometimes seem to be situated in the middle of each spore half, but in such cases they are actually out of focus while under another viewing direction they appear closely associated with the lateral spore wall. On the other hand, in a later reexamination two large drops remained visible in KOH (Pl. 55: 1p), suggesting that they were LBs, whereas other spores appeared in H_2O or IKI like vacuolated (Pl. 55: 1n–o). No tests with KOH or CRB were undertaken when studied in the fresh state (E. Rubio pers. comm.). In order to better understand the nature of the small and large drops in the spores, future collections should be studied in different reagents.

The inamyloid ring-like structure at the ascus apex (Pl. 55: 1e) was only seen in a few immature asci. Because of its obviously cytoplasmic nature it cannot be homologous with amyloid or congophilous apical rings which always represent a component of the ascus wall.

Phylogeny. A BLAST search for ITS or LSU yields only *Orbiliomycetes* as closest hits, although in the ITS region solely the 5.8S did align. When analysing SSU+ITS+LSU, *B. arenicola* clustered with *Amphosoma, Retiarius*, *Lecophagus*, and *Lilapila* in a weakly supported clade (Phyl. 2), whereas in separate analyses of ITS and LSU it stands unresolved (Phyls 3–4). In our analysis of LSU, seven uncultured fungus clones from Papua New Guinea, Madagascar, Panama, Puerto Rico, and Chile, submitted by Tedersoo et al. (2017) to GenBank, comprising LSU, ITS and mostly SSU, and one by Mueller et al. (2014) from North Carolina (only LSU), belong to at least four unknown species and cluster in the strongly supported *Bryorbilia* clade (Phyl. 4, B2–B5), though with a distance in the D1–D2 domain of 7–18% to each other (called GS33 clade by Tedersoo et al.). Also when analysing the ITS region, they cluster together but with only low support (Phyl. 3).

Various further uncultured fungus clones from America and one from Australasia, from the studies by Hartmann et al. (2009, 'LTSP_EUKA'), Jumpponen et al. (2010, 'OTU'), Mueller et al. (2014, 'NCD_LSU_otu'), Tedersoo et al. (2017, 'GL'), and Urbina et al. (2010, 'OTULB'), comprise ITS2 and/or LSU

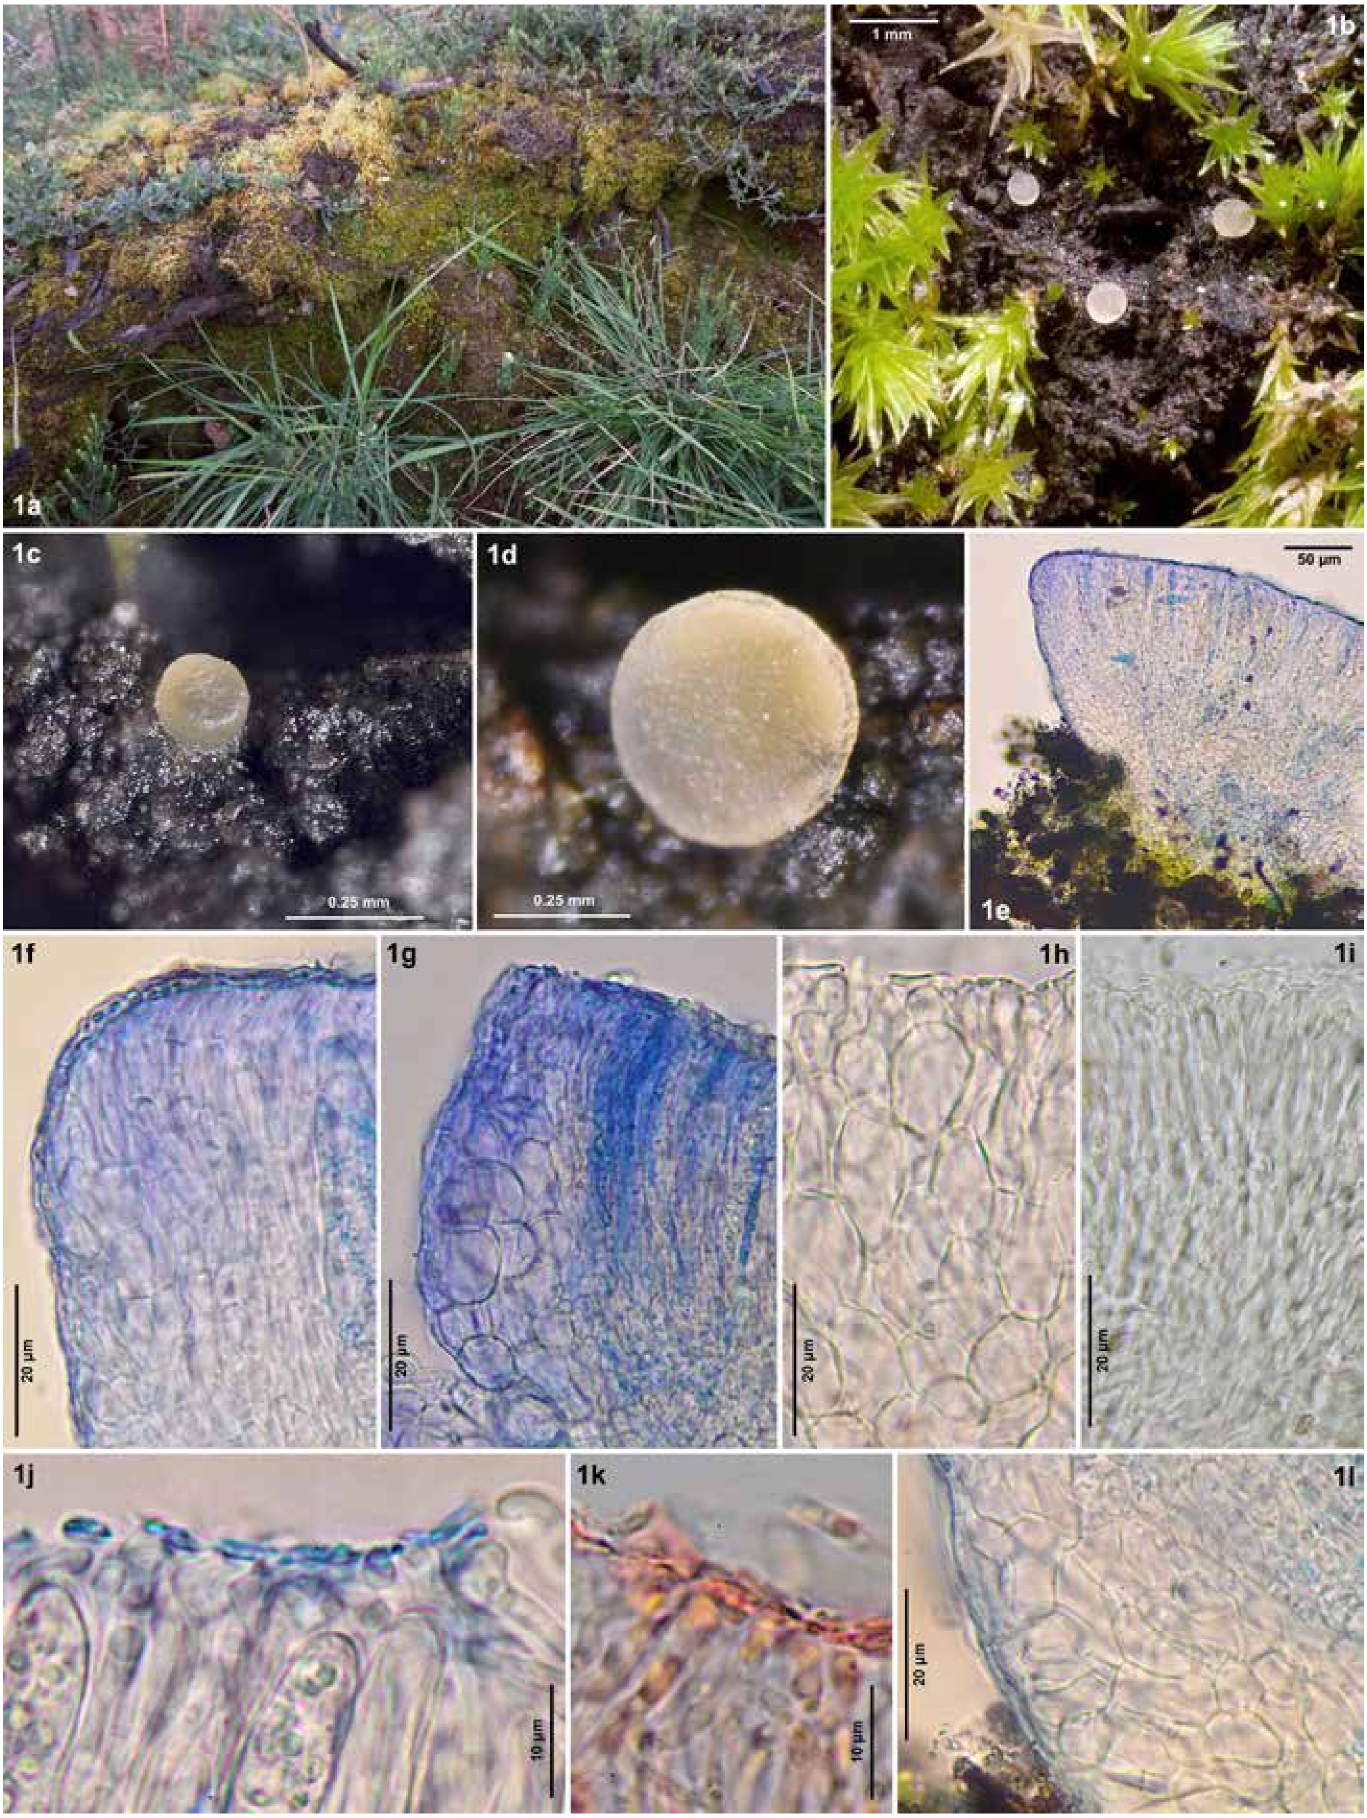

Plate 54. **1**: *Bryorbilia arenicola* (holotype). – **1a**. E. Rubio. — **1a–s**. E.R.D. 6987: Spain, Asturias, on soil.

and clustered unresolved and distant from the *Bryorbilia* clade (U1–U4, U7). That they belong to *Orbiliomycetes* is supported by their motifs in the *Orbilia*-specific primer regions (Tabs 18–19) and by BLAST searches for each gene region. In our phylogenetic analyses a strongly supported clade is obtained (Phyls 3–4, U1 clade) which Tedersoo et al. named GS32 clade, but some other strains clustered separate hereof.

Specific nucleotide positions. In the Orb5.8s1F primer region, *B. arenicola* concurs with members of *Amphosoma*, *Lecophagus*, *Lilapila*, *Retiarius*, and the *Vermispora* clade of

Hyalorbilia, whereas in the other two *Orbilia*-specific primers and in stem-loop B8 of 5.8S it differs from all other taxa of *Orbiliomycetes* in at least 1 nucleotide position, and in and around the LR4 primer even in 5 positions (Tab. 21).

Five of Tedersoo's seven uncultured clones match *B. arenicola* in the Orb5.8s1F primer, while two (KY687745, KY687746, [B2]) differ at 1 position (Tab. 18). In the Orb28s2R region most of them concur with *Hyalorbilia erythrostigma* and a majority of *Orbilia*, and also in Orb5.8s3F they deviate by 1–3 nt from *B. arenicola* (Tabs 18–19). Very remarkable is that all those four clones which cover the D3 domain, including the L4 primer region, fully match *B. arenicola* in all 5 aberrant nucleotides around this primer, two of them being part of the primer region (Tab. 21). Only a few members of *Dothideomycetes*, *Lecanoromycetes*, *Leotiomycetes*, and *Xylonomycetes* were found to concur with *Bryorbilia* at the 2 aberrant positions within the LR4 primer. The paired change of nucleotides in this primer region, which is also observed in *Orbilia septispora*, though at adjacent positions, is due to base pairing between reverse-complementary motifs in a stem-loop, here the stem-loop H700 of LSU (see Gillespie et al. 2005).

Other motifs specific to the *Bryorbilia* clade are difficult to find. Predominant motifs in the LSU are CT**T**GGATGCT or CT**C**GGATGCT in the D2 (pos. 605) and **GA**CTGTTGGGA in the D3 (pos. 784–785) vs. mostly CT**A**GGATGCT (D2) and **AG**CTGTTGGGA or sometimes **GG**CTGTTGGGA (D3) in other *Orbiliomycetes*.

Ecology. *Bryorbilia arenicola* grew on poor acidic sandy soil among the moss *Ceratodon purpureus*, together with apothecia of *Octospora rustica*. The soil was burned 2 years ago and is now colonized by *C. purpureus*, *Funaria hygrometrica*, and other pioneer mosses. Before the fire, the place was covered with *Quercus robur* and *Betula celtiberica*, now young *Ulex europaeus* is growing. Whether a connection between *Bryorbilia* and *Ceratodon* exists was not investigated. The holotype now contains only a single apothecium without the moss, but it seemed clear in the field that the fungus has close relations to it. The location lies in the suprasubmediterranean slightly semihumid atlantic Cantabrian Mountains of Asturias (southwestern Europe).

Specimens included. **SPAIN**: **Asturias**, Allande, 3.5 km NNW of Cangas del Narcea, 1.2 km WSW of Carcedo de Lomes, 692 m, on burnt, sandy soil among *Ceratodon purpureus*, 11.III.2017, E. Rubio (ex E.R.D. 6987, ex H.B. 10121, AH 52844, **holotype**, sq.: MK514443, MK514443).

Pseudorbilia Ying Zhang, Z.F. Yu, Baral & K.Q. Zhang, Fungal Diversity 26: 306 (2007)

Type species: *Pseudorbilia bipolaris* Ying Zhang et al.

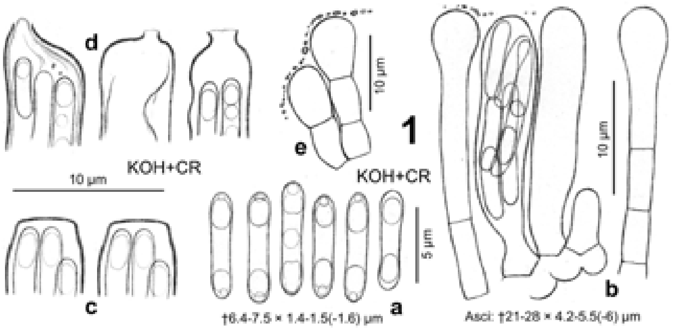
Etymology: named after its similarity to the genus *Orbilia*.

Recognized species: *P. bipolaris*.

Pseudorbilia bipolaris Ying Zhang, Z.F. Yu, Baral & K.Q. Zhang, Fungal Diversity 26: 307 (2007) — Pls 56–57

Etymology: referring to the bipolar arrangement of the spore bodies within the ascospores.

Typification: China, Yunnan, Yi Liang, wood of gymnosperm, IX.2005, Y. Zhang (ex H.B. 8310, M-0140896, holotype).



H.B. 8310 (holotype): China, Yunnan, on indet. coniferous tree (wood)

Plate 56. **1**: *Pseudorbilia bipolaris*. – **1a**. ascospores; **1b**. asci and paraphyses; **1c–d**. ascus apices (**d** apically opened); **1e**. marginal ectal excipulum (median section). All elements in dead state.

Description: — **TELEOMORPH**: **Apothecia** 0.09–0.2(–0.35) mm diam., ~0.07–0.1 mm thick (receptacle 0.055–0.07), whitish to pale cream-yellowish, medium translucent, gregarious to fasciculate in small groups; disc flat to slightly convex, margin thin, smooth to very finely rough; superficial or with ± immersed, obconical, stipe-like base, dry light ochraceous. **Asci** *23.5–34 × 5.5–6.8 µm {2} or *31–41 × 7.5–8.5 µm {1}, †20–28 × 4.2–5.5(–6) µm {2}, 8-spored, spores (*) 2–4-seriate, pars sporifera *(9–)13–17(–19) {2} or *19.5–21 {1} µm; **apex** (†) medium to strongly truncate, but hemispherical to slightly or strongly conical in profile view, without apical thickening, rupturing by a central or eccentric pore; **base** with short, thick stipe, arising from croziers (without perforation) {2}. **Ascospores** *6.8–8.5 × 1.5–1.8 {T} or *(4.5–)5–6(–7) × 1.3–1.8(–2) {France} µm or *6.5–7.8 × 1.6–2.1 µm {Norway}, †6.4–7.5 × 1.4–1.5(–1.6) {T} or †5–6 × 1.3–1.5 {France} µm, cylindric-bacilliform to very slightly dumbbell-shaped, rounded at both ends, straight or sometimes very slightly curved; containing 2 ± lens-shaped refractive **SBs** broadly attached to the terminal spore wall, one at each end, *0.6–1 × 1.3–1.8 µm {2}, *0.4–0.5 × 0.9–1.1 µm {1}, inner surface of SBs ± flattened; containing also 2 subterminal, large, ellipsoid, non-refractive **vacuoles**, one in each half, selectively staining violet in CRB (Pl. 15 Fig. 1g), vacuoles in dead spores still visible when mounted in KOH+IKI (light yellowish-brown, refractive) or KOH+CR (light purplish-red, Fig. 1f, h). **Paraphyses** not embedded in gel, apically (*) uninflated or slightly capitate-clavate (†slightly to medium so), terminal cells *12–19 × 3.8–4.5 µm {1}, †11–19 × 3–5 µm {2}, lower cells †(2–)4–7(–10) {2} × 2–2.2(–3) {T} or 2.5–3(–4.5) {1} µm. **Medullary excipulum** hyaline, ~10–15 µm thick, of dense, not or ?slightly gelatinized t. intricata. **Ectal excipulum** pale yellowish-ochraceous near base (very pale so at flanks), of (†) ± thin-walled, indistinctly (?vertically) oriented t. globosa-angularis from base to mid flanks, ~10–30 µm thick, cells †6–18 × 5–11 µm {2} (in surface view partially tangentially elongated), at margin 6–8 µm thick, of t. prismatica-angularis oriented at a ~10–30° angle to the surface, marginal cortical cells †5–9 × 4–6 {T} or †11–15 × 5–7 {1} µm, thin-walled, **glassy processes** and **hairs** absent. **Anchoring hyphae** sparse, †1.2–2.5 µm wide, wall 0.1–0.2 µm thick {2}, sparsely septate. **VBs** in terminal cells of paraphyses large, very elongate, hyaline, refractive. **Exudate** over paraphyses and margin absent or scattered, granular, 0.2–0.5 µm thick, hyaline, at lower flanks continuous, 0.2–0.3 µm thick, pale yellowish-ochraceous. **— ANAMORPH**: unknown.

Habitat: lying on the moist ground, decorticated, thick branch of unidentified conifer {T}, on deeply very decayed wood (ungreyed, no algae) {1}; on necrobiotic leaves of ?*Hypnum cupressiforme* {1}, on 1 cm thick branch of *Ulex* sp. {1}, droppings of *Capreolus capreolus* {1}. **Associated**: *Orbilia rubrovacuolata* {1}. **Desiccation tolerance**: no elements viable after 3 weeks in the dry state. **Altitude**: 24–285 m a.s.l. (Europe), 1843 m (China). **Geology**: China: Paleozoic sedimentary rock; France: Ordivician sand- & siltstone; Norway: granite & quartzite. **Phenology**: III, IX–X.

Taxonomic remarks. *Pseudorbilia bipolaris* is easily recognized in the living state by its cylindrical ascospores containing two lens-shaped spore bodies, one at each end. The species includes characters typical of *Orbilia* (ectal excipulum of globose

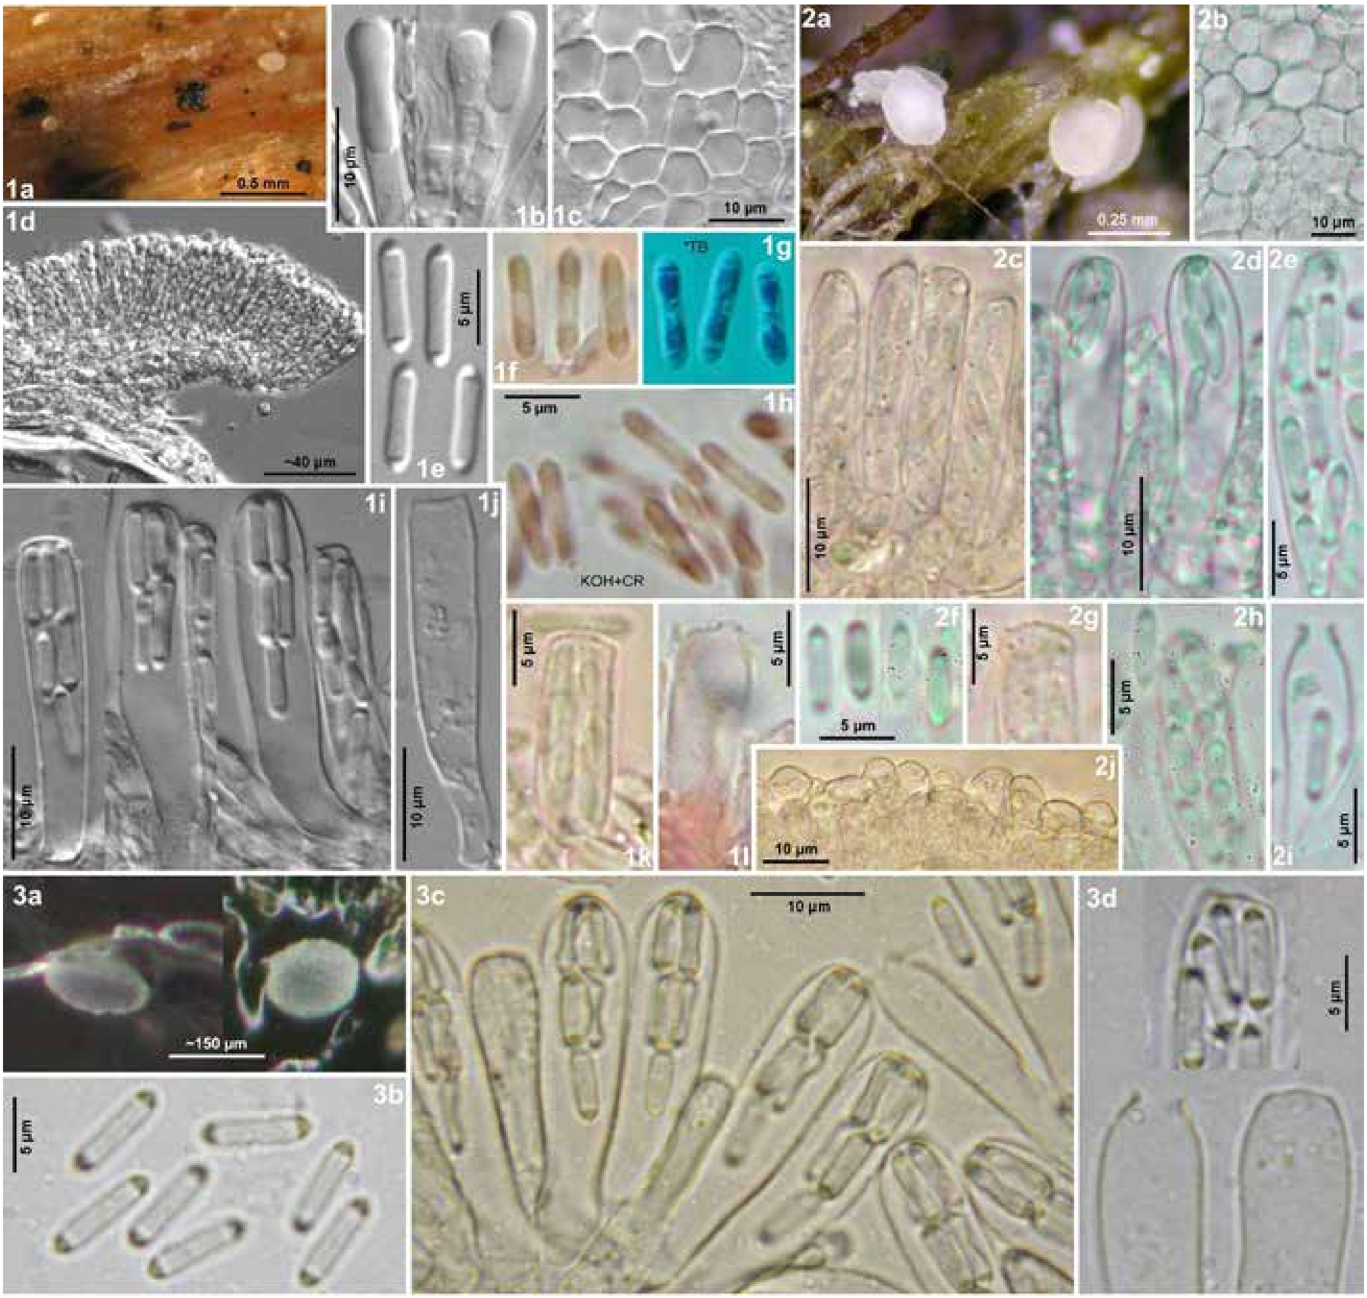


Plate 57. **1–3**: *Pseudorbilia bipolaris*. – **1a**, **2a**, **3a**. fresh apothecia; **1d**. apothecium in median section; **1c**, **2b**. ectal excipulum in external view; **2j**. margin in top view; **1b**. paraphyses; **1i**, **2c–d**, **3c**. mature asci; **1j**. young ascus; **1k–l**, **2g**, **i**, **3d**. ascus apices; (**1l**, **2i**, **3d**, below, emptied); **1e–h**, **2e–f**, **h–i**, **3b**. ascospores. – Living state, except for **1d**, **j**, **2j**, **3d** (asci) (in H_2O); **1k**, **2c**, **g** (in KOH); **1f**, **h**, **l** (in KOH+CR), right ascus in **1i**, asci in **2e**, **2h–i**. – **1a–e**, **g**, **i–j**: phot. Y. Zhang (DIC, p.p. in Zhang et al. 2007); **2a–b**, **d–f**, **h–i**: phot. J.P. Priou; **3a–d**: phot. M. Depont. — **1a–l**. H.B. 8310 (holotype): China, Yunnan, on indet. gymnosperm; **2a–h**. H.B. 8794: France, Bretagne, on ?*Hypnum*; **3a–d**. 3.X.2014: Norway, Arendal, on *Capreolus* dropping.

to angular cells, asci with a truncate, shouldered apex, hymenial elements not embedded in gel), but also characters typical of *Hyalorbilia* (asci arising from croziers, paraphyses containing large refractive vacuoles, spores with bipolar SBs). The genus *Amphosoma* resembles *P. bipolaris* in the bipolar arrangement of the lens-shaped SBs, but differs in rounded, mostly thick-walled ascus apices, the predominant absence of croziers, ellipsoid spores, and multiguttulate VBs in the paraphyses. Therefore, *P. bipolaris* is recognized in a separate genus.

Pseudorbilia bipolaris may easily be mistaken for a member of the *Helotiales*. The whitish translucent apothecia resemble genera of *Hyaloscyphaceae* such as *Calycellina*. The truncate, biradial-symmetrical ascus apex and the characteristic SBs in the living ascospores are the reason for including this species in the *Orbiliomycetes*.

Variation. The spores in the holotype vary between cylindrical and dumbbell-shaped with a very slight median constriction. The European collections fit quite well the holotype, particularly that from Norway, which differs in longer asci with a longer pars sporifera, although the spore characters are quite similar, and the apothecia only slightly smaller (90–150 µm diam. vs. 150–200 µm). The collection from France on bryophyte differs in shorter, not dumbbell-shaped spores with smaller SBs, longer marginal cortical cells, and the bryophilous habitat; also the apothecia tend to be larger (~150–350 µm). It might well represent a different species, but this cannot be decided at present based on the three sparse collections.

A correction is necessary for fig. 2 in the protologue (Zhang et al. 2007): the bar is not 10 µm as stated in the legend but 15 µm. Hardly any apothecia remain in the holotype, whereas the entire specimen from France was lost during examination, and that from Norway got destroyed in the mails.

Ecology. *Pseudorbilia bipolaris* is only known from three very sparse collections. The holotype was detected on a decorticated, very decayed hygric branch of a coniferous tree in a shady subtropical humid (winter-dry) forest in southeastern Asia. The two European collections were from a living moss on a hygric branch of an *Ulex* shrub in mesotemperate humid, atlantic western Europe and from excrements of *Capreolus* in hemiboreal northern Europe, both on acidic soil.

Specimens included. **CHINA**: **Yunnan**, **Kunming**, 37 km ESE of Kunming, 8.5 km WNW of Yiliang, Xiaobailong Forest Park, 1843 m, on wood of indet. gymnosperm, IX.2005, Y. Zhang (ex H.B. 8310, M-0140896, **holotype**). — **FRANCE**: **Bretagne**, **Morbihan**, 4.5 km SE of La Gacilly, 2.6 km E of Cournon, Pinguily, 24 m, branch of *Ulex europaeus*, on ?*Hypnum cupressiforme*, 19.III.2008, J.P. Priou (J.P.P. 28039 ø, H.B. 8794 ø). — **NORWAY**: **Aust-Agder**, 29 km NW of Arendal, NW of Ytre Lauvrak, 285 m, on droppings of *Capreolus capreolus*, 3.X.2014, J. Fournier, vid. M. Delpont (ø, doc. vid.).

Etymology: *Brachyphoris*: after the short conidiophores; *Curucispora*: referring to the cross-shaped conidia; *Dwayaangam*: named after the conidia with normally 4 arms formed by repeated dichotomous branching (from Sanskrit: 'dwaya' = 2, 'angam' = branch); *Hyalorbilia*: referring to the pale-coloured, ± translucent apothecia and the relationship to *Orbilia*; *Microdochiella*: after the morphological similarity with *Microdochium*; *Spirospora*: with curled ascospores (but Velenovský referred here taxa with falcate spores); *Vermispora*: after the worm-shaped conidia.

Description: — **TELEOMORPH**: **Apothecia** fresh (0.05–)0.1–2(–5) mm diam., (0.03–)0.05–0.25(–0.4) mm thick [receptacle (0.03–)0.05–0.13(–0.2) mm], whitish to often pale cream-chlorinaceous (chlorinaceous-yellow under LED), also light (to bright) yellowish- or orange-ochraceous, often ± translucent, not or very slightly to rather strongly gelatinous, sessile on a broad or narrow base but often substipitate on an obconical base, or with a distinct cylindrical stalk (0.01–)0.02–0.2(–0.5) × 0.04–0.4(–0.7) mm, disc cup- to saucer-shaped, or flat, finally sometimes convex, margin usually ± even, in large apothecia often undulating or notched, rarely crenulate or denticulate, exterior glabrous but sometimes hairy due to anchoring hyphae which are often seen (mainly in dry state) as a whitish subiculum, especially near the base, superficial, dry hardly to strongly contracted with incurved margin, more intensely ochraceous or yellow, sometimes red-brown. **Asci** *(13.5–)16–40(–50) × (3–)3.5–7(–8) µm, †(9–)12–40(–53) × (2.6–)3–6(–7) µm, 8-, rarely 16-spored, inverse spore orientation only rarely observed (if spores with 1 eccentric SB, or heteropolar in shape); **apex** of dead asci hemispherical or slightly (rarely medium) truncate or often subconical to submammiform, apical wall thin- to firm-walled (†0.2–0.4 µm); **base** with or without short, thick, not or only slightly flexuous stipe, consistently arising from croziers (some with a round to slit-like, rarely large, medaillon-shaped perforation). **Ascospores** *(2–)3–14(–17.5) × 0.7–2.8(–3.8) µm, non-septate, smooth, of various shape (cylindrical, fusoid to fusiform, fusoid-clavate, ellipsoid, subglobose to ovoid), never consistently heteropolar in shape, straight or slightly to strongly curved (falcate to helicoid); living spores with 1–4(–5) low- to high-refractive, globose (rarely subglobose, tear-, or lens-shaped) **SBs** in each half, especially near the ends, 0.2–1.2(–1.5) × 0.2–1(–1.5) µm, sometimes without SBs or only 1 eccentric SB present, attachment by a filum only exceptionally seen, if hemispherical then broadly attached to wall; usually a few minute **LBs** present; **glycogen** not observed; spores in senescent apothecia never seen to germinate or to form a septum. **Paraphyses** apically uninflated or slightly to medium, rarely strongly clavate(-capitate), terminal cells (1–)1.5–4(–5.5)× as long as lower cells, unbranched or often dichotomously branched (usually only in their lower part), anastomoses rarely seen near the base. **Subhymenium** not differentiated. **Medullary excipulum** hyaline, (5–)10–50(–110) µm thick, of non- or slightly to strongly gelatinized textura angularis-prismatica of small to medium-sized cells of usually indistinct orientation, partially also mixed with hyphae or purely t. intricata, indistinctly to very sharply delimited. **Ectal excipulum** hyaline, near base (10–)20–150(–250) µm thick, of ± vertically oriented t. angularis or t. prismatica, from lower flanks up to margin of horizontally oriented t. prismatica-porrecta, sometimes t. prismatica-angularis, exceptionally t. angularis (mainly in *H. subfusispora*, *H. resinae*, *H. rotifera*); texture in external view with a distinct radial orientation, individual cells never tangentially elongated (never wider than long); cells at flanks *(4–)8–45(–80) × (3–)6–25(–40) µm, walls (†) non- or slightly to strongly gelatinized (common walls †0.3–3 µm thick); 10–40(–80) µm thick at flanks, (5–)10–20(–30) µm thick at margin, marginal cortical cells narrowly cylindrical (t. porrecta) or often clavate to obovoid (vesiculous), exceptionally globose and thick-walled by forming denticulate protrusions; **glassy processes** absent, exceptionally with glassy caps (*H. nodulosa*); **septate hairs** absent. **Anchoring hyphae** sparse to often abundant at base, sometimes also at lower flanks, usually long and straight, radiating ± vertically from excipular surface, (1.3–)2–5(–10) µm wide, sparsely to rather densely septate, partially branching, sometimes anastomosing, walls smooth, 0.2–1(–2) µm thick. **Globose SCBs** usually absent (but refractive SCBs inconsistently observed in the excipulum in a few species, partially ring- or irregularly shaped); **crystalloid SCBs** rarely present in excipulum and anchoring hyphae (*H. ulicicola*); **VBs** usually abundant in paraphyses and marginal cortical cells, globose, medium-sized, slightly to medium refractive, hyaline to often pale chlorinaceous, later fusing to form large, angular or elongate bodies (also from the beginning large and elongate); **carotenoids** in LBs of paraphyses rarely present (*H. erythrostigma*, *H. anonyma*). **Exudate** forming a continuous, refractive, (0.1–)0.2–0.6(–1.2) µm thick layer over hymenium and marginal excipulum, exterior of exudate either ± smooth or usually densely covered by minute, angular, pale chlorinaceous granules or clods; paraphyses and asci usually conglutinated with the paraphyses in a hymenial **gel** (gel invisible, staining faintly to distinctly lilac in CRB), in some species freely separable. — **ANAMORPH**: mainly brachyphoris-like, also trinacrium-, curucispora-, or dwayaangam-like (the latter is presumed). **Mycelial hyphae** *1–5 µm wide, hyaline. **Colonies** ± slow-growing, whitish to yellowish or brownish, with ± aerial mycelium. **Conidiophores** emerging from mycelial hyphae, 1.5–50(–100) µm when unbranched, (1.5–)2–4(–7) µm wide at the base, (1–)1.3–2(–2.5) µm at the tip, up to 95(–200) µm when branched. **Conidiogenous cells** monoblastic or sometimes sympodial with 2–4 lateral nodules or denticles. **Conidia** predominantly unbranched (brachyphoris-like), cylindrical to narrowly-ellipsoid, or often fusoid to fusiform, straight or only slightly curved towards their ends, rarely flexuous to S-shaped, *(12–)20–96(–120) × (2–)3–8(–10) µm, (0–)3–8(–12)-septate; rarely branched: T-, Y- to K-shaped or 4-armed, *(10.5–)15–45 × 10–25 µm (in *H. quadridens* *75–95 × 61–77 µm), branches (1.2–)2–4(–4.5) µm wide, 0–2(–4)-septate, arms ± tapering, straight, also strongly curved (C-shaped); living cells often containing refractive globose **SCBs** 0.4–2 µm diam. aggregated in small groups (so far only seen in unbranched conidia); large **glycogen** regions sometimes present; wall surface either lilac or hardly stained by CRB.

Chlamydospores absent or present. **Trapping organs**: capturing rhizopods with adhesive knobs (so far known only in a few species), also invading nematode eggs and cysts, rotifers, and oospores of *Pythium*.

Habitat: saprobiontic on dead bark and wood, rarely woody fruits or herbaceous stems of mono- and dicots, often on dead or living fungal fruitbodies (perennial polypores, gelatinous basidiomycetes, pyrenomycetes, apothecia of *Orbilia* spp.), exceptionally on dung; substrate usually ± decomposed (optimal to often final stage), when fungicolous then partially parasitic; substrate permanently moist (hygric) or periodically dry (xeric, then sometimes in tight association with green algae and black yeasts); sometimes capturing testaceous rhizopods or parasitic on nematode eggs and oomycete oospores. **Desiccation tolerance**: mature asci intolerant or tolerating 1 week up to 3 months, immature asci rarely up to 11 months, excipular cells, ascospores and conidia a few days up to 1–5 months, rarely 11–17 months. **Distribution**: worldwide, in boreal-montane, temperate, subtropical or tropical, humid to semihumid, rarely semiarid climates, the highest species number observed in temperate to tropical (semi)humid regions, recorded from arctic-alpine areas so far only by DNA isolates.

Recognized species: 44 (7 of them without known teleomorph), plus 7 unnamed species (‘affinis’).

Generic concept. The genus *Hyalorbilia* forms a comparatively small, natural group within the *Orbiliomycetes*, being easily recognizable in almost every case. In the present monograph we accept 44 species, 7 of which being only known from their anamorph and 7 further unnamed taxa mentioned as *affinis* (aff.) under the related species. *Hyalorbilia* is sharply delimited from *Orbilia* based on various characteristics (Tab. 59), some of which occur with high consistency across the genus. The most important are: (1) spore bodies usually near both ends of the ascospores; (2) croziers always present at the ascogenous hyphae, sometimes perforated; (3) paraphyses and asci usually firmly embedded in gel; (4) numerous minute angular clods of exudate usually covering the gel surface on hymenium and margin; (5) ascus apex in dead state never distinctly truncate or thick-walled; (6) ectal excipulum at flanks of a horizontally oriented textura (angularis-)prismatica.

Morphologically, the anamorphs of *Hyalorbilia* and *Orbilia* are not easily distinguishable. Yet, many species of *Hyalorbilia* possess a rather uniform and quite diagnostic type of fusiform phragmoconidia, which were described under the names *Dactylella passalopaga*, *D. lignatilis*, *Brachyphoris oviparasitica*, and *B. brevistipitata*. In addition to their shape, these conidia often contain refractive, small, globose SCBs which are unknown in *Orbilia*, and which appear to be homologous to the cubical SCBs in *Lecophagus*.

The genera *Pseudorbilia* and *Amphosoma* resemble *Hyalorbilia* in some micromorphological characteristics, e. g., in their bipolar-symmetrical spore bodies (see Tab. 56), but they share also features with *Orbilia* (*Amphosoma*: furcate ascus base, *Pseudorbilia*: truncate ascus apex).

Within *Hyalorbilia*, a division into a small group of species with globose to subglobose ascospores and a large group with elongate ascospores could be made. However, the two groups are not clear-cut (see Pl. 58), and a correlation with features of the anamorph is not recognizable. Since the genus is rather poor in morphological characteristics, correlations of features are difficult to detect, and further subdivisions can hardly be made based on morphology alone.

With some experience the genus *Hyalorbilia* can be recognized in the field by the usually pale yellowish-chlorinaceous-brownish, often translucent, substipitate apothecia with a thin margin. By external appearance alone, however, *Orbilia* species with hyaline apothecia, such as *O. leucostigma*, can easily be confounded with members of *Hyalorbilia*. At the time the

Table 59. Comparison of characters of the teleomorph between *Hyalorbilia* and *Orbilia*.

		Hyalorbilia	*Orbilia*
1a	Asci	*(13.5–)16–40(–55) × (3–)3.5–7(–8) µm, 8(–16)-spored	*(24–)30–100(–140) × (2.8–)4–11(–15.3) µm, 8–128-spored
1b	Ascus base	unstalked or with short and thick stalks, arising from croziers	with short to very long, often thin and flexuous, usually furcate stalks arising from simple septa
1c	Apex of dead asci	hemispherical to slightly (rarely medium) truncate or conical, shape scarcely depending on the viewing direction, never with distinct internal wall thickenings	either hemispherical and ± thick-walled (often with an apical chamber), or ± saddle-shaped (truncate but hemispherical in profile view) and then usually thin-walled
2a	Ascospores	shape never predominantly heteropolar, never with a tail	shape homo- to strongly heteropolar, with or without a tail
2b	Spore bodies (SBs)	spore guttulation bipolar-symmetrical (one or more SBs near each spore end), rarely one eccentric SB per spore but then spores subglobose or ovoid, no clear inverse spore orientation	spore guttulation unipolar-asymmetrical (1 SB per spore), SBs inserted in spore apex, rarely laterally, inverse spore orientation frequent
3	Paraphyses	uninflated to slightly, rarely strongly capitate, not distinctly protruding beyond hymenial surface, terminal cells usually longer than lower cells, rarely of ± equal length	uninflated to strongly capitate, sometimes spathulate-lanceolate and then often distinctly protruding beyond hymenial surface (sometimes only the cap-like exudate), terminal cells longer than lower cells or ± equal with them
4a	Ectal excipulum	at flanks of horizontally oriented textura prismatica, rarely t. globulosa-angularis (cells isodiametric)	at flanks of vertically oriented t. angularis(-prismatica), very rarely of horizontally oriented t. prismatica
4b	Medullary excipulum	composed of isodiametric to prismatic cells, partly intermingled with hyphoid elements, sometimes purely of interwoven hyphoid elements	composed of interwoven hyphae, usually intermingled with inflated cells that form chains, sometimes purely of isodiametric cells
4c	Anchoring hyphae	usually ± straight, rarely forming strands, (1.3–)2–5(–10) µm wide	usually irregularly oriented, ± undulating, often forming a thick loose or dense layer or strands, (1.5–)2–3.5(–6) µm wide
5	Intercellular gel	hymenial elements often embedded in abundant gel, mostly very difficult to separate, medullary and ectal excipulum gelatinized or not	hymenial elements with a thin gel layer on the wall surface, therefore usually easy to separate, medullary and ectal excipulum rarely gelatinized
6	Exudate on exterior of apothecium	mostly present, hyaline to often pale yellowish-chlorinaceous, forming minute, ± angular granules or clods on a firm continuous layer, ~0.2–1 µm thick	present or absent, hyaline or pale to light yellow, rarely dark olive, continuous to granular or often cloddy, also forming individual caps, (0.2–)1–3(–5) µm thick
7	SCBs	rarely present, crystalloid or globose (in anchoring hyphae and excipular cells)	globose and/or crystalloid SCBs frequently present in the living paraphyses and excipular cells
8	VBs	regularly present in paraphyses and marginal cortical cells, rarely absent	irregularly present in desiccation-sensitive taxa, absent in desiccation-tolerant taxa

concept of the genus was established, exclusively European material was available for study. Later examined collections from other continents and even from tropical regions fully supported this concept.

Ad (1a). *Hyalorbilia* has shorter asci on average compared to *Orbilia*, due to the lack of a distinct ascus stalk and because polyspory occurs only exceptionally (asci 16-spored in *H. pleioerythrostigma*). The shortest asci were noted in *H.* cf. *japonica* (†9–17 µm, H.B. 7994a), *H. ulmi* (†12–17 µm), and *H. inflatula* (*13–21 µm, H.B. 8221), the longest in *H. anonyma* (†40–53 µm) and *H. fusispora* (*30–50 µm).

Ad (1b). Though not very easily visible, the consistent presence of croziers in *Hyalorbilia* provides a valuable feature which none of the many examined species of *Orbilia* have. Nevertheless, some variation must be mentioned. On the one hand, the occurrence of perforated, medaillon-shaped croziers in some species of *Hyalorbilia* may simulate a bifurcate ascus base, especially if the perforation is large (e.g., in some collections of *H. fusispora*, Pl. 114: 5b). On the other hand, in a few species of *Amphosoma* and *Orbilia* the two legs of the bifurcate ascus base of a few asci may be connected to form a medaillon-shaped crozier (e.g., in *A. resinicola*, Pl. 34: 1b).

Ad (1c). The apex of dead asci is typically rounded, but often it tends to be somewhat conical or truncate. Its shape apparently does not or only slightly depend on the direction of view. Sometimes the ascus wall is distinctly more thick-walled at the apex compared to the lateral wall, but a low-refractive endotunica was never observed in dead asci.

Ad (2a). Ascospore shape diversity in *Hyalorbilia* is confined to a few types, ranging between globose, ellipsoid, cylindrical, and fusiform, with only a slight tendency towards heteropolar (Pl. 58). Depending on the species, the spores vary between straight and strongly curved. In contrast to this, spore shape in *Orbilia* is much more diverse, comprising also strongly heteropolar, clavate to tailed, or highly asymmetrical spores.

Ad (2b). The general bipolar-symmetrical arrangement of SBs in living ascospores (2 or more SBs per spore) provides a valuable characteristic to recognize the genus *Hyalorbilia*. Only in three species with subglobose spores (*H. erythrostigma*, *H. anonyma*, *H. ulmi*) there is only a single eccentric SB in each spore. The generally small, globose SBs in *Hyalorbilia* (in *H. subfusispora* sometimes tear-shaped, in *H. multiguttulata* hemispherical and broadly attached) are difficult to distinguish from the often only slightly smaller LBs (a similar situation is noted in the group around *Orbilia eucalypti*). In *Hyalorbilia*, both SBs and LBs are medium to strongly refractive and grouped near each spore end, but they are sometimes also scattered over both spore halves. 1, 2, or up to 5 SBs occur in each spore half. In a few species (*H. pleioerythrostigma*, *H. oreadum*, *H. rotifera*, *H. texensis*) SBs are often or perhaps consistently absent. In a few collections of *H. subfusispora* and *H. erythrostigma* a very fine filum that connects the SBs to the terminal spore end could be observed. It is assumed that the SBs in *Hyalorbilia* are always connected by delicate fila to the apical or lateral spore wall, including species with more than two SBs per spore. Evidence for this is difficult to obtain with the TEM as filaments are easily missed in sections. Staining the SBs with CRB proved difficult because the stain penetrated the spore wall often very slowly, even after adding low-concentrated KOH. Distinction between SBs and LBs is rather easy based on the stability of the latter in KOH.

Ad (3). The paraphyses of *Hyalorbilia* are quite uniform in shape. They are never apically spathulate, lageniform or lanceolate, and they never protrude distinctly beyond the hymenial surface, i.e., the exudate always forms a rather even layer over them. Only in a few species are the apices strongly inflated (capitate-clavate). Usually the terminal cells are much longer (2–4×) than the lower cells, but in some small-spored taxa, such as *H. brevistipitata*, *H. erythrostigma*, *H. herbicola*, *H. pleioerythrostigma*, *H. rotifera*, or *H. resinae*, the cells tend to be of rather equal length, with the terminal cell up to twice as long as a maximum. The paraphyses emerge from partially inflated cells of the medullary excipulum. Dichotomous branches generally occur only in their lower part, but in species with short terminal cells branches may also occur in the upper part. Anastomoses were only occasionally seen in some species, either between the lower cells or especially between inflated cells from which the paraphyses emerge.

Ad (4a). With its characteristic prismatic cells at the flanks being oriented at a very low angle to the surface, the ectal excipulum of *Hyalorbilia* provides one of the most striking differences against the genus *Orbilia*. Nevertheless, this feature was only rarely reported in the literature, e.g., by Spooner (1987: 177, fig. 23 D) and Romero (1994, fig. 15 B) for *H. inflatula*. Particularly in those species with rather large apothecia, in which the excipular cells are usually strongly elongated at the flanks, this character can easily be observed, either in a median section (e.g., Pl. 126: 1g; Pl. 114: 1e; Pl. 106: 3f; Pl. 77: 1d, 10f) or in surface view in a squash mount (Pl. 116: 1g). Especially in minute but sometimes also in large apothecia the cells may be more isodiametric and then the parallel orientation to the surface is only indistinctly seen (see, e.g., Pl. 67: 2d, 11b, 13c). Rarely, a t. globulosa-angularis without a clear orientation is observed (e.g., Pl. 117: 3f, Pl. 67: 4c, Pl. 92: 1c, 2b). Near the base of the apothecium, however, the texture is often composed of indistinctly or more vertically oriented isodiametric to prismatic cells.

Ad (4b). In the medullary excipulum of *Orbilia* there are often ± horizontally oriented chains of distinctly inflated roundish cells among the narrow hyphae, while in *Hyalorbilia* such cell dimorphism was only indistinctly noted, e.g., in *H. erythrostigma*. In *Hyalorbilia* the two excipular layers are often difficult to distinguish, except that the medullary excipulum was gelatinized, or the cells of the ectal excipulum were comparatively large.

Ad (4c). The anchoring hyphae of *Hyalorbilia* are often long and ± straight by radiating more or less perpendicular to the excipular surface, comparatively wide and somewhat thick-walled. They strongly differ herein from the mostly narrow, more inconspicuous, undulating hyphae in *Orbilia*. Yet, some of those *Hyalorbilia* species with rather small apothecia possess narrow undulating hyphae very similar to *Orbilia*.

Ad (5). The gel between asci and paraphyses in *Hyalorbilia* is not easily seen, even when stained by various dyes. It becomes manifest when trying to separate the hymenial elements. Separation of living asci from the hymenium was usually impossible, with a few exceptions (e.g., Pl. 80: 9a). In KOH-mounts, separation was sometimes successful to a certain degree. Separation of the hymenial elements in *Orbilia* is generally easier, but it may similarly be hampered by an overlying continuous exudate attached to the paraphyses by some gel, and separation also often becomes more difficult with apothecial senescence. The intercellular space of medullary and ectal excipulum in

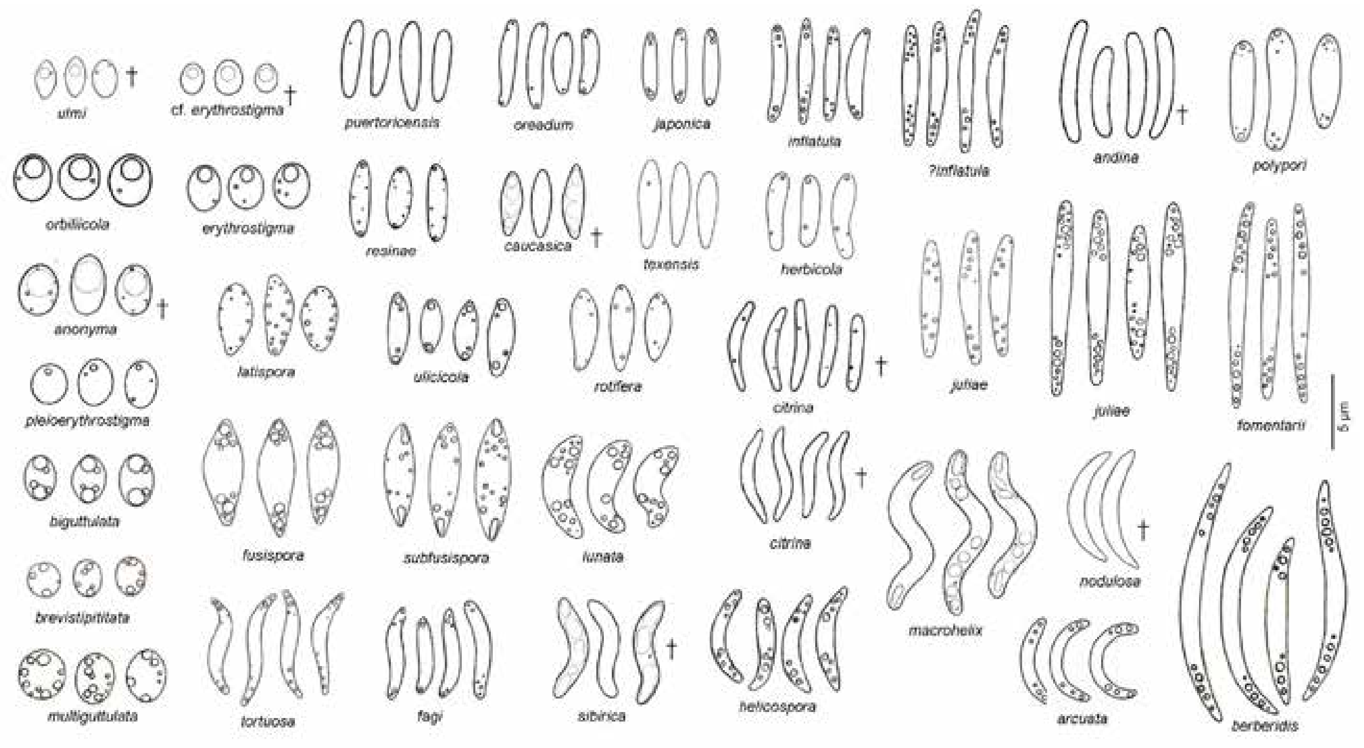

Plate 58. Ascospore diversity within the genus *Hyalorbilia*.

Hyalorbilia may be strongly gelatinized or nearly without gel, but in the former the gel is not always refractive and then not easy to see. In *Orbilia* such gelatinization is rarely seen.

Ad (6). The exudate in *Hyalorbilia* forms a coherent, inelastic layer which may sometimes get folded in squash mounts (Fig. 95: a–d) and probably also in the dry state. The cloddy warts obviously do not join when the apothecia shrink during drying, whereas in desiccation-tolerant species of *Orbilia* the large isolated clods of exudate get closer packed in the dry state to form a compact covering layer. The cloddy warts in *Hyalorbilia* might develop by splitting of an inelastic outer layer during growth of the very young apothecia.

Ad (7). Although quite frequently occurring in *Orbilia*, especially in desiccation-tolerant species, SCBs in *Hyalorbilia* were only occasionally seen. Crystalloid SCBs occur in *H. ulicicola*, and here usually in the basal excipular cells and in the anchoring hyphae, but never in the paraphyses, whereas in *Orbilia* they were never encountered in the anchoring hyphae. Globose SCBs commonly occur in *Orbilia* in the paraphyses and marginal ectal excipulum, but were never seen in the paraphyses of *Hyalorbilia*, and only very incosistently in the excipular cells of a few species (*H. erythrostigma*, *H. fagi*, *H. juliae*). Contrary to *Orbilia*, they tend in *Hyalorbilia* to be quite refractive and partially ring-shaped (Pl. 92: 1d). Rather small, ± globose, strongly refractive SCBs were rather frequently found in the cells of living conidia of *Hyalorbilia* (see below under Anamorph). Similar bodies occur in the genus *Lecophagus*, whereas conidia of *Orbilia* are generally without them.

Ad (8). Slightly to strongly refractive VBs are present in the living paraphyses and marginal cortical cells of almost every species of *Hyalorbilia*, irrespective of being desiccation-tolerant or not. In *Orbilia* VBs occur only in more or less desiccation-sensitive taxa, though only in some of these species.

Species delimitation, diversity of teleomorph. In contrast to the genus *Orbilia*, the morphological diversity of the teleomorph of *Hyalorbilia* is comparatively low. Species delimitation within *Hyalorbilia* is very complicated, because the morphological differences between closely related taxa are often only slight, and a more or less pronounced variation among the collections was noted in almost every species. Intermediate collections have actually been encountered between most of the here recognized taxa. This complex situation cannot be improved by applying a wider species concept, because species limits would thereby remain unsharp. We were also unable to recognize infrageneric groups within *Hyalorbilia* based on a combination of morphological traits of both teleomorph and anamorph.

The most reliable characteristics at the species level were found in the ascospores (size, shape, curvature), in combination with the number of SBs which they contain. Some species differ merely in spore curvature, others in spore length or width, and others only in spore guttulation (number and size of SBs). A severe complication with herbarium material is that SBs are invisible or only very faintly seen (Fig. 3). The strength of spore curvature in *Hyalorbilia* does not as markedly decrease in the dead state as observed in *Orbilia* section *Arthrobotrys* (see Pl. 104: 2a, 4a; Pl. 89: 1a; Pl. 100: 1a, 2a).

A majority of elements of the teleomorph are morphologically rather concordant within *Hyalorbilia* and, therefore, usually of little value for species delimitation (a similar conformity is noted in the anamorph, see below). This more or less concerns: ascus apex (shape and wall thickness), croziers, spore number, paraphysis characters (cell length, apical inflation, contents), exudate, excipular texture, anchoring hyphae, colour of apothecia. Also the presence of gel in the hymenium was found to be a rather constant feature across the genus. The gelatinization of the medullary and ectal excipulum, however, strongly varied among the species but often also within a species, being abundant preferably in the more tropical collections. A crenulate to denticulate margin made up of thick-walled cells is typical of *H. citrina*, but populations with smooth margins also appear to represent this species. Size and colour of apothecia as well as features of the margin provide hints to a species at best, and most of the species are impossible to identify by macroscopy alone. Strong difference in width of the marginal cortical cells was found to support separation of some closely related species, for instance, *H. fusispora* vs. *H. subfusispora*, *H. anonyma* vs. *H. erythrostigma*, or *H. ulicicola* vs. *H. caucasica*. In other taxa (e. g., *H. inflatula*, *H. fagi*) the marginal cells seem to be very variable, with frequent intergradations, and cell width was usually not correlated with other features. Preliminary results using molecular data, however, suggest that marginal cell width might permit distinction of at least two taxa within *H. inflatula* (Phyl. 5).

Characteristics of the living cytoplasm in *Hyalorbilia* have a similar importance as in *Orbilia.* Number and size of SBs in the spores serve as a valuable tool, e. g., in separating *H. multiguttulata* from *H. biguttulata* and *H. erythrostigma*. In contrast to *Orbilia*, SB shape is uniformly globose, rarely flattened where they are attached to the wall (*H. multiguttulata*), or ellipsoid to tear-shaped as in *H. subfusispora* in comparison with the similar *H. fusispora*. VBs in the paraphyses are present in almost every species of *Hyalorbilia*, and are, therefore, taxonomically unimportant at the species level.

Some of these spore features are coupled with ecological differences such as desiccation tolerance, or with those of the marginal excipulum, or with a different anamorph. However, spore and also ascus size may vary considerably. Likewise, the width of the marginal excipular cells may do so in some of the species. Hence, delimitation among closely related taxa based upon metric data is often problematic. For example, within *H. juliae* spore length varies from 7–9 up to 11–15 µm; yet, collections with an intermediate spore length were frequently seen, therefore, separation into two taxa was abandoned for the moment.

Nomenclature of teleomorph. A number of generic names, being today applied to non-orbiliaceous, mainly helotialean fungi, were used in the past for species here assigned to *Hyalorbilia*. The genus *Calloria* (*Calloriaceae*), was in use for, e. g., *Hyalorbilia ?fagi* by Saccardo (1882a, as *C. chrysocoma* var. *microspora*), for *H. inflatula* by Phillips (1887), and for *H. citrina* by Smith (1901). *Pithyella* (= *Helotiopsis*, *?Helotiaceae*), a genus comprising bryophilous taxa with globose, warted ascospores, was applied to *Hyalorbilia erythrostigma* and *H. anonyma* by Korf & Zhuang (1987), to the former species also by Boudier (1907), to the latter by Höhnel (1910: 623, 1926a: 68, as *Helotiopsis*, see also under *Calloria* (p. 205) and *Pithyella* (p. 209)). Species of *Hyalorbilia* were placed in further helotialean genera such as *Mollisiella*, *Pezizella* etc.

Among the orbiliaceous genera, the name *Hyalinia* was applied to *Hyalorbilia inflatula* and *H. ?fagi* by Boudier (1907, as *Hyalinia inflatula*), Rehm (in Straßer 1910, as *H. inflata* var. *lonicerae*), Kanouse (1939, as *H. breviasca*), and Grelet (1948b, as *H. rectispora* var. *majuscula*). A majority of the hitherto known species of *Hyalorbilia* have been considered as representing typical members of *Orbilia*, even by modern authors, although they lack the furcate ascus base, the truncate ascus apex, and the capitate paraphyses, previously estimated as key characteristics of *Orbilia*. In the absence of authentic material of the common ly known *H. inflatula*, the little-known but well typified *H. berberidis* was chosen in Baral & Marson (2001) as type species of the newly erected genus *Hyalorbilia.*

Anamorph. In six species a connection to an anamorph could be established in pure culture or when formed at the lid of the Petri dish (*H. brevistipitata*, *H. fagi*, *H. inflatula*, *H. latispora*, *H. polypori*, *H. tortuosa*), and in one by DNA extract from conidia (*H. orbiliicola*). In further 12 species conidia and sometimes also conidiophores were only observed on the natural substrate near apothecia (see Appendix 4). As in many sections of *Orbilia*, we use the current generic names of anamorphs in the sense of form genera when describing different conidial types within *Hyalorbilia*: unbranched conidia are referred to as brachyphoris- (straight) or vermispora-like (± curved), and branched conidia as trinacrium-like, curucispora-like, or dwayaangam-like, depending on the number of branches.

Unbranched septate conidia (phragmoconidia) were observed in most *Hyalorbilia* species with a known anamorph. Conidia of this type have earlier been accomodated in *Dactylella*. The term 'dactylella-like' is used here in a restricted sense, particularly for anamorphs of series *Neodactylella* (section *Arthrobotrys*) and *Hyalinia* (section *Aurantiorubrae*) with usually long, unbranched conidiophores. Similar anamorphs are found in *Orbilia* series *Orbilia* which, however, deviate from typical dactylella-like anamorphs in shorter conidiophores.

A morphologically different type of stauroconidia (T- to Y-shaped, trinacrium-like) characterizes two *Hyalorbilia* species with subglobose ascospores, *H. erythrostigma* and *H. orbiliicola*. Their anamorph strongly resembles those observed in various sections of *Orbilia*, but also in *Amphosoma*. Another type of stauroconidia (curucispora flabelliformis-like) occurs so far solely in *H. latispora*, whereas two other subglobose-spored species, *H. brevistipitata* and *H. multiguttulata*, form unbranched conidia. K-shaped, curucispora ponapensis-like conidia were several times seen on the natural substrate in association with apothecia of *H. subfusispora*. Dwayaangam-like conidia are typical for *H. quadridens*.

The anamorph-typified genera *Brachyphoris* and *Vermispora* or *Microdochiella* can only be recognized with certainty by molecular or cultural methods as belonging to *Hyalorbilia* s.l. As already mentioned above, several observations on living conidia of *Hyalorbilia* s.str. indicate that an organelle in the cytoplasm might serve as a characteristic of the genus: in the phragmoconidia of *H. citrina*, *H. fagi*, *H. inflatula*, *H. polypori,* and *H. tortuosa* (perhaps also in *H. arcuata*) we observed medium-sized, strongly refractive drops which resemble LBs but which irreversibly disappear in KOH or in dead material (Pl. 59: a, see also Fig. 89: f–g). With CRB they cannot be stained, even in a slightly alkalinized medium, hence they should be classified as SCBs (or WBs). These bodies also occur in the K-shaped conidia found associated with *H. subfusispora* (Pl. 118) and probably in the dwayaangam-like conidia of *H. quadridens*.

In the remaining groups of *Hyalorbilia* s.l. these bodies have so far not been seen: neither in the branched conidia of *H. orbiliicola* and *H. latispora*, nor in the unbranched conidia of the *Vermispora* clade. They have also never been seen in any of the many anamorphs of *Orbilia*, with rare exceptions (*O.* cf. *bembicodes* Pl. 1000). The bodies resemble those more or less cubical SCBs that occur in mycelial and excipular cells and conidia of *Lecophagus*, but whether they are homologous to them is uncertain. As in *Lecophagus*, these bodies have also been observed in the excipular cells of *Hyalorbilia*, though only exceptionally (see Pl. 92: 1d).

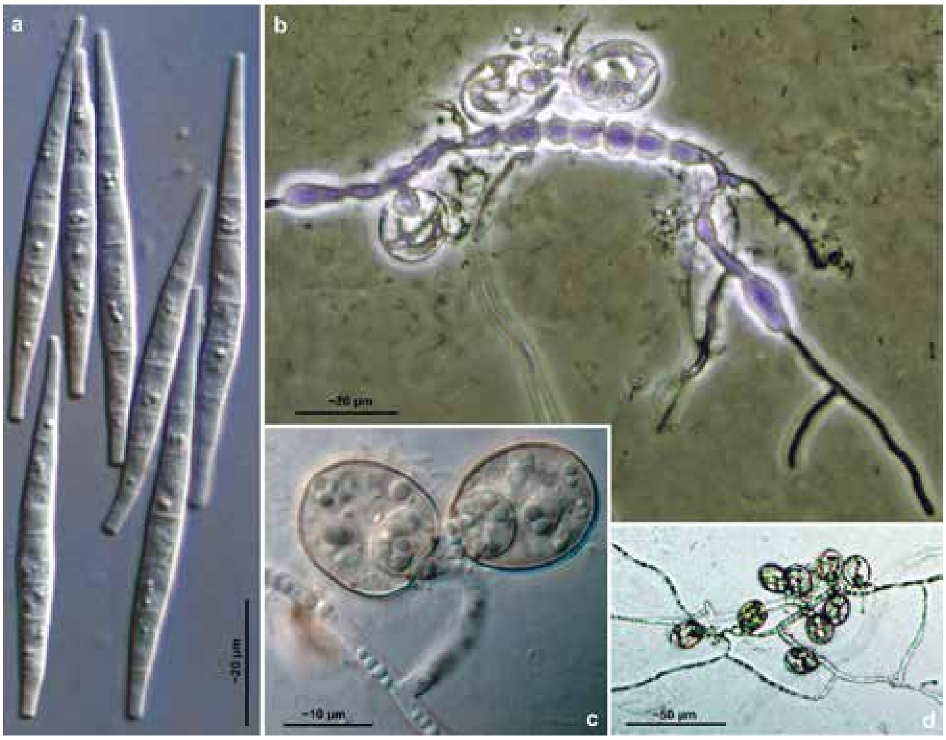

Plate 59. '*Dactylella*' *passalopaga* (anamorph of *H.* ?*inflatula*). – a. conidia containing globose SCBs; b, d. germinated conidium with captured testaceous rhizopods; c. two captured rhizopods. – phot. G. Barron (DIC), http://www.uoguelph.ca/~gbarron/2008/passalop.htm.

Despite these remarkable conidial characters, anamorphs of many *Hyalorbilia* spp. exhibit a rather poor morphological diversity, to the present knowledge. In fact, various closely or distantly related species possess very similar, often indistinguishable, elongate fusoid to fusiform, ± straight to slightly curved, multiseptate conidia. Taxa with this conidial type represent about a third of the genus and include (1) the anamorph-based taxa *H. lignatilis*, *H. oviparasitica*, '*D.*' *passalopaga*, and *H. tenuifusaria* in *Hyalorbilia* s.str., and *H. fusarina*, *H. fusarioides*, *H. leguminacea*, and *H. spermatophaga* in the *Vermispora* clade (see Pls 3 & 59) and (2) the teleomorph-based taxa *H. brevistipitata*, *H. caucasica*, *H. citrina*, *H. fagi*, *H. helicospora*, *H. inflatula*, *H. japonica*, *H. lunata*, *H. oreadum*, *H. resinae*, *H. rotifera*, and *H. ulicicola*. Whether differences in size, curvature or septation of the conidia, or in branching of the conidiophores exist, is unclear due to the low number of observed conidia and unknown conidiophores in some taxa and the few obtained cultures.

Predatory capabilities. Four species are known to prey on invertebrates but are only known from their anamorph (*H. oviparasitica* and *H. fusarina* invading nematode eggs, *H. tenuifusaria* and '*D.*' *passalopaga* capturing rhizopods). DNA sequences were available for the former three taxa, which fall into *Brachyphoris* and *Vermispora*, according to Chen et al. (2007a), but do not fit sequences of a teleomorph. For '*D.*' *passalopaga* a connection to a teleomorph (*H. inflatula*) is presumed here, based on very similar conidia (Pls 59, 77, 82).

In a few species with similar teleomorphs, differences in conidial shape support their delimitation. For instance, *H. erythrostigma* differs in Y-shaped conidia from *H. brevistipitata* and probably *H. multiguttulata* with unbranched phragmoconidia. *H. polypori* and *H. tortuosa* differ in cylindric-ellipsoid phragmoconidia from *H. fagi* and *H. inflatula* and probably *H. helicospora* with fusoid to fusiform phragmoconidia. *H. tortuosa* appears to be phylogenetically related to *H. berberidis* (see below), but anamorphs are unknown in *H. berberidis* as well as in the similar *H. fomentarii*, *H. juliae*, and *H. fusispora*. In several samples of *H. herbicola*, *H. rotifera*, *H. fusispora*, *H. juliae*, and *H. subfusispora*, narrow, filiform to fusoid phragmoconidia were encountered on the natural substrate (*28–77 × 1.5–3 µm, 3–6-septate). This conidial type was so far not obtained in pure culture, but it possibly corresponds to that in *H. fusarioides* (20–60 × 2–3 µm, 1–5-septate). We are somewhat doubtful about its connection to teleomorphs of *Hyalorbilia*, nevertheless we have figured them on the plates. In a few species conidia with more than two arms (curucispora- or dwayaangam-like) were observed, but their connection to the genus *Hyalorbilia* was so far demonstrated only for *H. latispora* (in pure culture and by molecular methods).

Nomenclature of anamorph. Because of the often very short conidiophores observed in *Hyalorbilia* (often shorter than the conidia) and particularly because of molecular results, Chen et al. (2007a, c) proposed the new genus *Brachyphoris* to accomodate the anamorphs of *Hyalorbilia* (see p. 217–219). Conidiophore length is not a very reliable characteristic of this group, however, because several *Hyalorbilia* species produce rather long though often strongly branched conidiophores with short to medium long side branches (*H. fagi*, *H. lignatilis*, *H. polypori*, *H. tortuosa*). On the other hand, the authors were unaware that in different sections of *Orbilia*, e.g., *Aurantiorubrae* and *Helicoon*, short conidiophores occur which produce unbranched conidia. Due to their strong morphological similarity these phragmoconidia are termed 'vermispora-like' here when more or less curved (C-shaped), or 'anguillospora-like' when very long and narrow. The limits to brachyphoris- and dactylella-like anamorphs with straight conidia is unsharp, however. One species assigned by Chen et al. to *Brachyphoris* without molecular data (*B. stenomeces*) resembles anguillospora-like anamorphs and might rather belong to *Orbilia* (perhaps in section *Helicoon*).

With the new nomenclatural rules (ICN Art. F.8.1), the later established phragmoconidial genera *Brachyphoris* and *Microdochiella* fall in synonymy with *Hyalorbilia*. Also the earlier established genera *Vermispora* with phragmosporous conidia and *Dwayaangam* and *Curucispora* with stauroconidia, though having priority, do not automatically displace *Hyalorbilia*. In order to avoid a large number of recombinations, Baral et al. (2017b) proposed to protect *Hyalorbilia* over all these names. However, synonymy with *Hyalorbilia* is only affirmed for *Brachyphoris* and *Microdochiella*, because molecular data of the type species of the other three genera were unavailable.

In fact there is a high probability that some of these genera are heterogeneous. For instance, Chen et al. (2007c) accepted five species in *Vermispora* by excluding *V. obclavata* by faintly pigmented conidiophores and firm-walled conidia. Synonymy with *Hyalorbilia* is affirmed here only for three species which we therefore combine as *H. fusarina*, *H. leguminacea*, and *H. spermatophaga*, whereas *V. grandispora* (type species), *V. obclavata*, and *V. cauveriana* are without molecular data. In our opinion, *V. cauveriana* could instead belong to *Orbilia* section *Arthrobotrys* because of very large conidia producing microconidia. Hernández-Restrepo et al. (2015) proposed the new genus *Microdochiella* for *M. fusarioides* which clustered sister to the three *Vermispora* species. However, scarcely any striking morphological and ecological differences to *Vermispora* exist, the only worth mentioning being narrower conidia with a drop of moisture at their mid-point, and presence of chlamydospores. Therefore, we here combine this species as *H. fusarioides*. For a more detailed historical review of *Curucispora* (p. 219), *Dwayaangam* (p. 232–234), *Microdochiella* (p. 239), and *Vermispora* (p. 246–247) see there.

Phylogeny. Molecular data from 21 validly described and accepted species of *Hyalorbilia* with a known teleomorph were available, and six further species with sequence data are without a known teleomorph (*H. fusarina*, *H. fusarioides* *H. leguminacea*, *H. oviparasitica*, *H. spermatophaga*, *H. tenuifusaria*). Many environmental strains belong to various unidentified species (in Phyl. 5, S6 H1–H33, V1–V16). The genus shows an extraordinarily high diversity in the ITS rDNA region. Nevertheless, it formed in previous phylogenetic analyses of ITS or LSU a more or less well-supported monophyletic group within the *Orbiliomycetes* (Liu et al. 2006a, Chen et al. 2007a, Smith & Jaffee 2009, Yang et al. 2012b). Smith & Jaffee named it '*Brachyphoris* clade' after its anamorph, and Yang et al. 'DO clade' after *Dactylella oviparasitica*, the object of their population dynamics study. Also in our combined analysis (Phyl. 2) it formed a weakly supported group.

The genus includes four supported clades with unresolved position: the 'core clade of *Hyalorbilia*' (= *Hyalorbilia* s.str., i. e., the majority of *Hyalorbilia* species), the *erythrostigma-orbiliicola* clade, *H. latispora*, and the *Vermispora* clade. Each of these clades received strong support even in single analyses of most regions (Phyls 5, 6, S5). The phylogenetic analyses by M. Weiß (in Baral et al. 2017b) and Magyar et al. (2017b) yielded a bootstrap value of 99–100 for *Hyalorbilia* s.l. *Hyalorbilia* s.str. and the *Vermispora* clade appear to be sharply separated by their molecular data, but also the *erythrostigma-orbiliicola* clade and *H. latispora* as well as some environmental taxa show a high distance to them and cannot be assigned to either clade: *H. latispora* is found in the *Vermispora* branch in M. Weiß' analysis and in Phyls 6 and S05 (ITS+LSU, LSU), but in the *Hyalorbilia* branch in Phyl. 5 (ITS), and likewise *H. erythrostigma* and *H. orbiliicola* clustered unresolved between the two groups (Phyls 5–6). One species with the typical teleomorph characteristics of *Hyalorbilia*, *H. rotifera*, clustered strongly supported in the *Vermispora* clade (Phyl. 6), and some species without molecular data might also belong there (*H. herbicola*, *H. resinae*). This placement prompted us to combine *Microdochiella fusarioides* and the three species of *Vermispora*, for which DNA data were available, with *Hyalorbilia*. Sequence data were not available for *Pseudorbilia* which appears to belong to the closest relatives of *Hyalorbilia*.

In Chen et al.'s (2007a) ITS analysis the three former *Vermispora* species formed a strongly supported but distant clade with *Orbilia* series *Neodactylella* (as *Dactylella*), whereas *Hyalorbilia* (as *Brachyphoris*) formed a basal sister clade. Further groups of *Orbiliomycetes* were not included in this analysis. Our studies confirm the high distance to the large genus *Orbilia*: analyses of either 5.8S, ITS, LSU, or SSU+ITS+LSU placed *Vermispora* always outside *Orbilia*, and in most analyses to *Hyalorbilia* in a strongly (Baral et al. 2017b) or weakly supported relationship (Phyls 1–2).

The phylogenetic position among the three large groups of *Orbiliomycetes* (*Hyalorbilia*, *Lecophagus-Amphosoma* clade, *Orbilia*) remained unresolved in maximum likelihood analyses. In those of SSU+ITS+LSU in Baral et al. (2017b, erroneously as 'SSU+5.8S+LSU') and ITS+LSU in Magyar et al. (2017b), *Hyalorbilia* formed a sister clade to *Orbilia*, and the *Lecophagus-Amphosoma* clade clustered sister to them. A different result was obtained in the present analyses of 5.8S+LSU D1–D6 or SSU+ITS+LSU (Phyls 1–2), in which *Orbilia* clustered sister to the *Lecophagus-Amphosoma* clade and *Mycoceros*, and *Hyalorbilia* sister to those. The support at the main branches was always low or absent under ML. Also Magyar et al.'s Bayesian/ML analysis yielded no or weak bootstrap support at these branches: 0.96/– at the first branch and 0.99/60 at the clade containing *Hyalorbilia* and *Orbilia*. The rather isolated position of *Hyalorbilia* is even obvious when analysing only 5.8S (not shown). Also within the genus, our NJ analysis of this region (Phyl. S3) shows the core clade of *Hyalorbilia* to differ sharply from the remaining groups which also are also separated into the *Vermispora* clade, *H. latispora*, the *erythrostigma-orbiliicola* clade, and H30–H31.

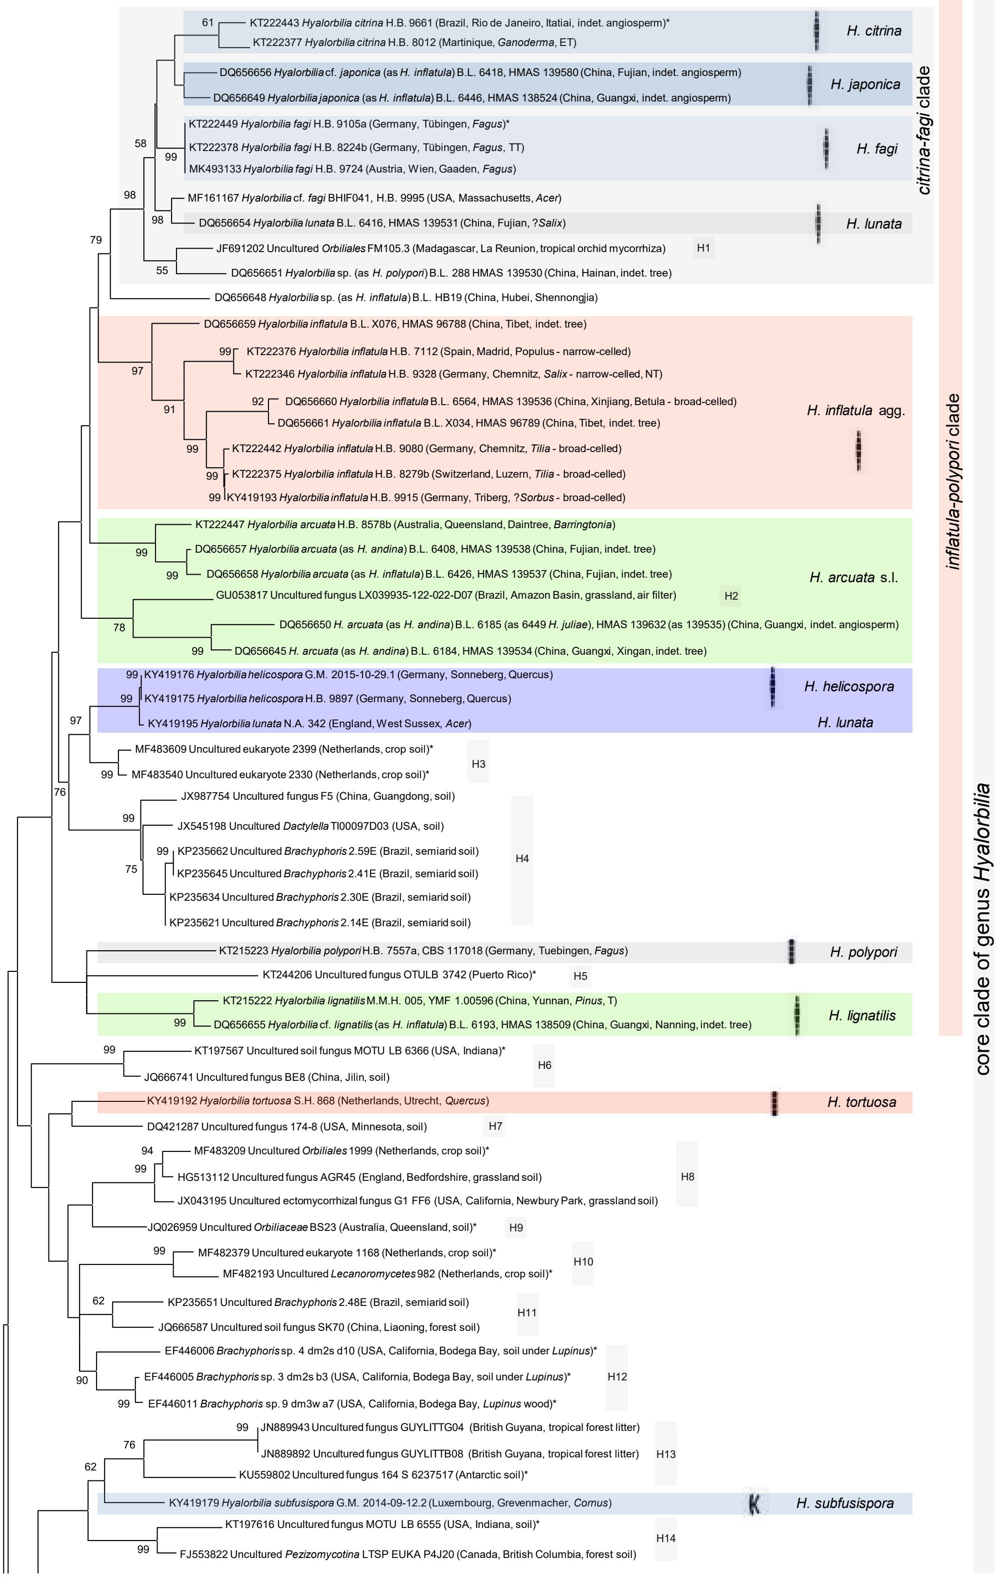
H. brevistipitata and *H. multiguttulata* clustered together with the anamorph-typified *H. oviparasitica* in the core clade of *Hyalorbilia* by forming a very distinct subclade which received strong support in analyses of ITS, ITS+LSU or LSU. *H. oviparasitica* and the undescribed *H.* aff. *multiguttulata*, which is only known from non-sporulating mycelium and DNA (including DoUCR50, in GenBank as *Dactylella oviparasitica*), infect nematode eggs and females. This group, here called *oviparasitica-multiguttulata* clade, differs from *H. erythrostigma* and *H. latispora* in fusoid phragmoconidia very similar to those of most remaining clades of *Hyalorbilia*.

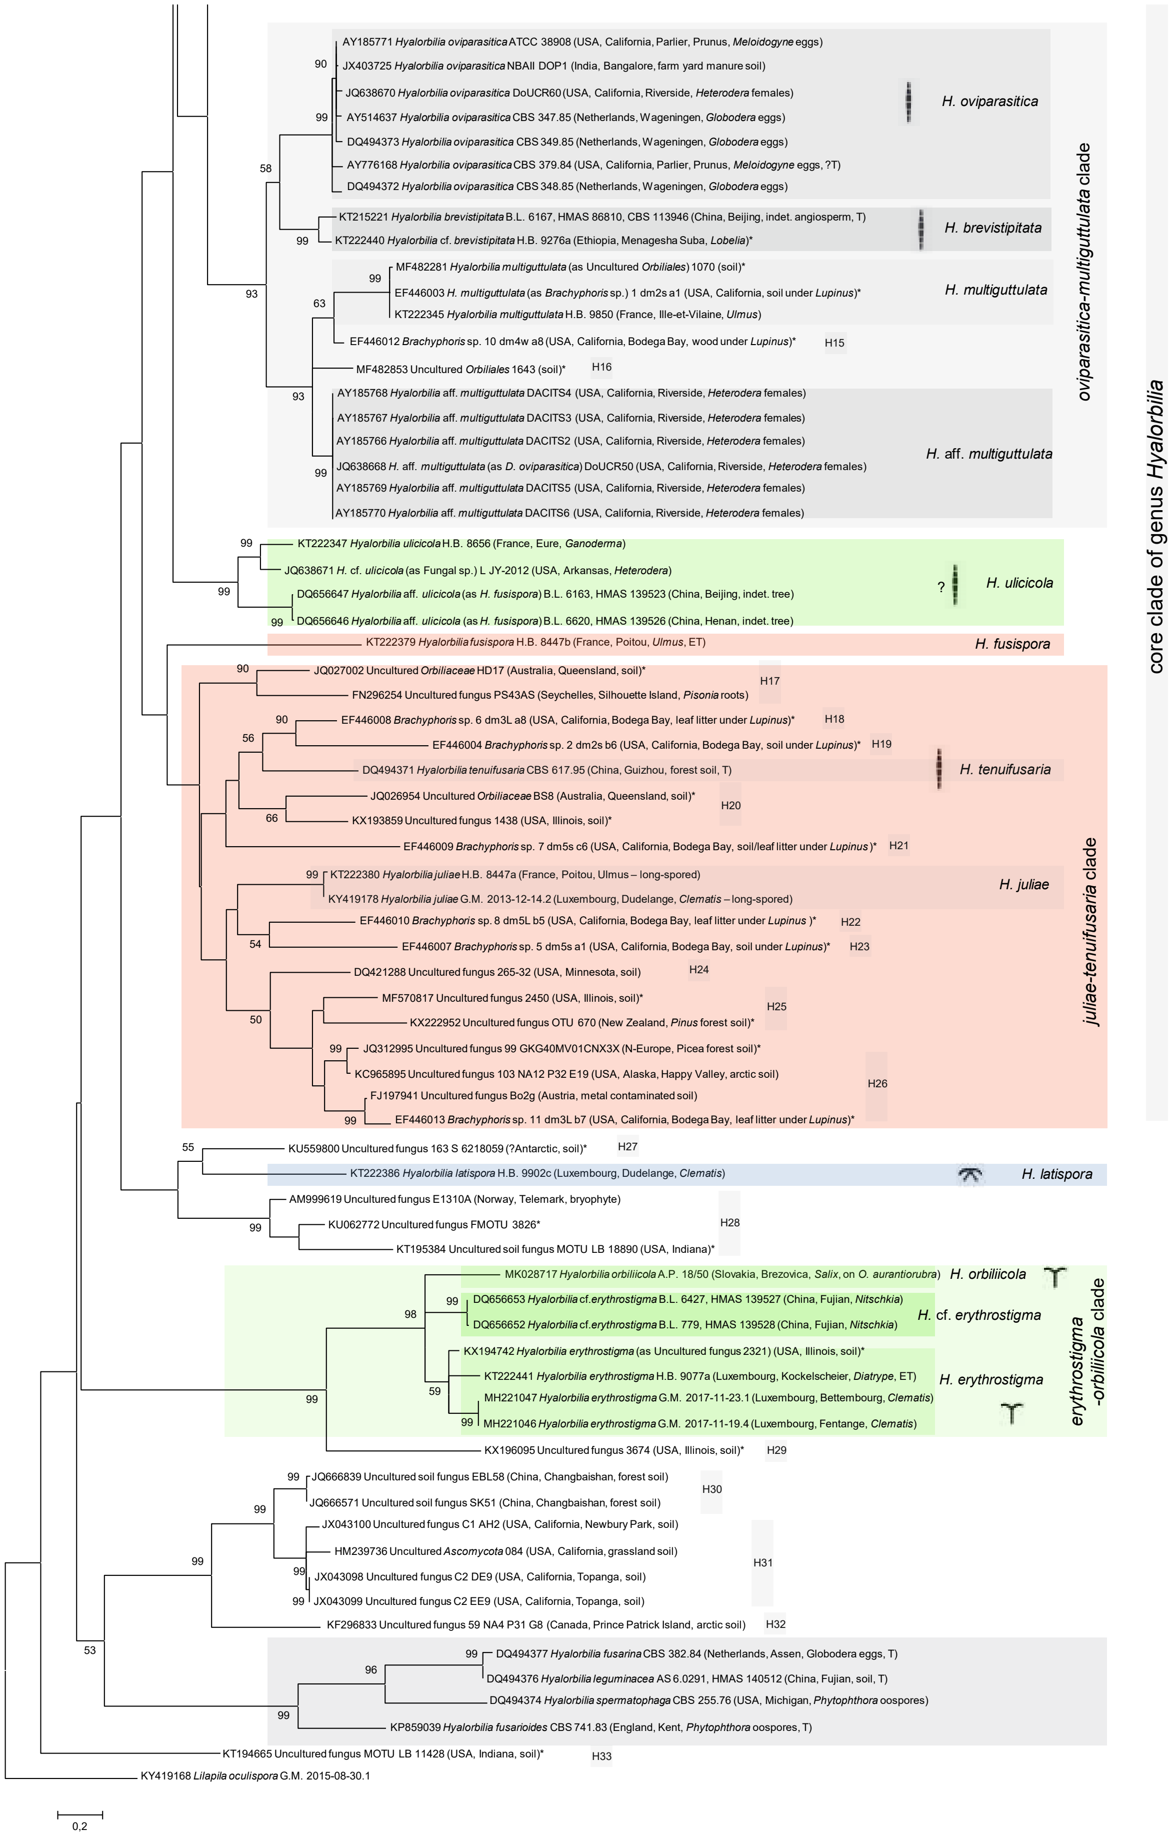
A large group of the *Hyalorbilia* core clade, characterized by elongate, mostly subcylindrical ascospores, is called *inflatula-polypori* clade here and includes *H. arcuata*, *H. citrina*, *H. fagi*, *H. helicospora*, *H. inflatula*, *H. japonica*, *H. lunata*, and *H. polypori*. The clade received rather strong support when analysing ITS+LSU and especially LSU (Phyls 6, S5), but no support when analysing ITS (Phyl. 5). These fungi have in common more or less large and predominantly desiccation-sensitive apothecia. Fusoid phragmoconidia are known in several of them, except for *H. polypori* which has cylindric-ellipsoid conidia. With the presumption that '*D.*' *passalopaga* is the anamorph of *H. inflatula* agg., the ability to capture rhizopods occurs in this clade.

H. subfusispora formed a clade with some environmental strains (Phyls 5, S5, H13–14, H36) and clustered with strong support sister to the *oviparasitica-multiguttulata* clade (Phyl. 6). *H. ulicicola* s.l. with short fusoid ascospores formed a strongly supported clade which clustered either with medium support sister to the *inflatula-polypori* clade (LSU, Phyl. S5), or unresolved (Phyl. 5, ITS) or weakly supported (Phyl. 6, ITS+LSU) with the *oviparasitica-multiguttulata* clade and *H. subfusispora*. An environmental isolate from Arkansas (USA), which like *H. oviparasitica* infects nematode eggs, belongs to *H. ulicicola* s.l. Narrowly fusoid conidia which represent the predominant conidial type in *Hyalorbilia* were repeatedly observed in association with *H. ulicicola*.

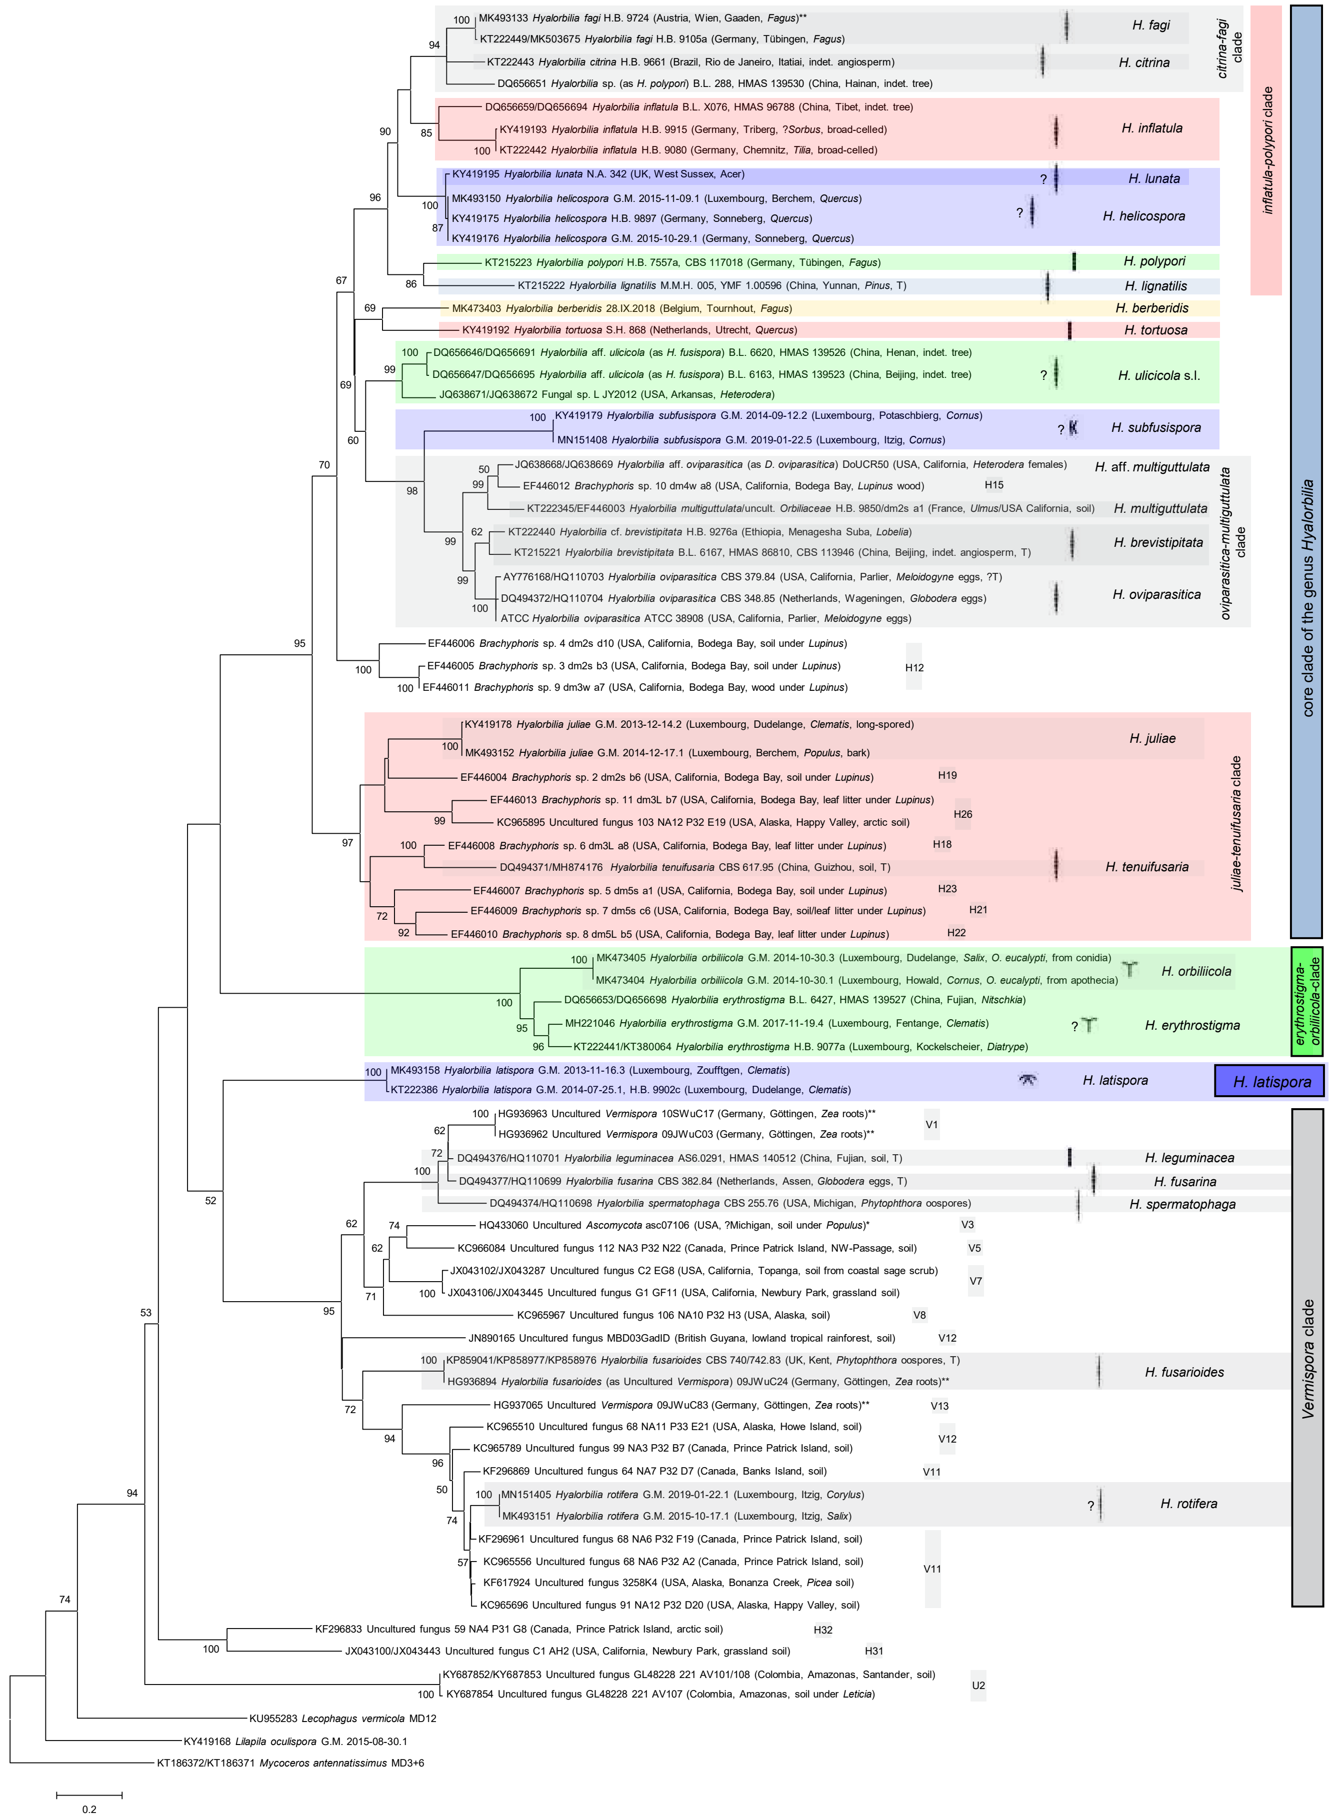
Some other species with elongate, fusoid to subcylindrical ascospores (*H. fusispora*, *H. juliae*, *H. berberidis*, *H. tortuosa*) clustered in different, mostly unsupported clades. In our combined analysis (Phyl. 6), only *H. juliae* formed with the anamorphic *H. tenuifusaria* a strongly supported clade (here called *juliae-tenuifusaria* clade), to which also some environmental isolates from soil and litter are associated (see also Phyl. 5, H18–H26). A soil isolate from Minnesota (H7) clustered unsupported with *H. tortuosa* (Phyl. 5). However, the recent sequence of *H. berberidis*, the type species of *Hyalorbilia*, formed with *H. tortuosa* a weakly supported clade in the combined analysis (Phyl. 6), although the support was strong in an earlier analysis, and in this clade falls also the soil isolate which lacks LSU.

Several species without molecular data are expected to fall in some of these clades, based on their similar morphology. For instance, *H. fomentarii* is probably closely related to *H. juliae*. *H. resinae* and *H. herbicola* might belong in relationship of *H. rotifera* in the *Vermispora* clade.





Phylogenetic analysis 5. Phylogram of genus *Hyalorbilia* inferred from ML analysis of ITS1-5.8S-ITS2 rDNA dataset (133 sequences, 991 positions, aligned with MUSCLE) using the GTR+G+I model in MEGA6 (100 replicates). Various environmental strains from GenBank are included, most of which representing unidentified species of *Hyalorbilia* (as H1–H32). The tree is rooted with *Lilapila oculispora*. For a more detailed *Vermispora* clade see S6. T = type, ET = epitype, TT = topotype; * = without ITS1 and often also partial 5.8S.



Phylogenetic analysis 6. Phylogram of genus *Hyalorbilia* inferred from combined ML analysis of ITS1-5.8S-ITS2+LSU (D1–D2) rDNA dataset (79 sequences, 1694 positions, aligned with MAFFT) using the GTR+G+I model in MEGA6 (500 replicates). The included sequence of *H. multiguttulata* is a chimere of KT222345 (H.B. 9850) and EF446003 (uncultured *Orbiliaceae* dm2s_a1). Various environmental strains from GenBank are included, most of which representing unidentified species of *Hyalorbilia* (as H15, H18–H19, H21–H23, H26, H32, V1, V3, V5, V7–8, V11–12). The tree is rooted with *Lilapila oculispora.* T = type, ET = epitype, * = without ITS1, ** = without LSU (D2).

Environmental sequences. Various more or less supported clades in our phylogenetic analyses include mainly environmental DNA isolates of unknown morphology retrieved from GenBank (clones H1–37, V1–V16), and in most cases no name could be attached to them. Sequences of our teleomorph-typified species clustered only sometimes with them, and only rarely they could be considered as conspecific.

Eleven uncultured DNA-isolates (H12, H15, H18–19, H21–23, H26) gained by Smith & Jaffee (2009, 'dm') from wood, litter, and soil in California (as 'uncultured *Orbiliaceae* clone') clustered in their '*Brachyphoris* clade', and only one isolate showed a high similarity to one of our new species: dm2s_a1 clustered with *H. multiguttulata* and an unlocalized strain (Phyl. 5) with a 0.3% distance in the 5.8S+ITS2. Another isolate (dm4w-a8) clustered in the same clade but with a 9% distance. Also for *H. berberidis* conspecific clones exist in GenBank. Among the isolates which clustered in the supported *Vermispora* clade (V1–V16), only one teleomorph (*H. rotifera*) clustered with them (V12), though with a 9.5–10.5% ITS distance.

Specific nucleotide positions. Various specific nucleotides of the rDNA characterize the genus *Hyalorbilia* or some subgroups of it (see Tabs 60–61). Their partial interlacing with other orbiliaceous genera suggests possible evolutionary pathways within the *Orbiliomycetes*.

In the SSU V8–V9 region about 12 nucleotides were found to be more or less diagnostic of the genus *Hyalorbilia*, based on available data from 15 species, including the two environmental taxa H14 and H37 (Tab. 60). A correlation with members of section *Arthrobotrys* forming adhesive traps is noted at 2 positions in an otherwise conservative region downstream of V8 (pos. 109 and 126: ATAG**G**GCATTGCAATTATTGC**C**CTT). Besides these groups, only two further taxa of *Orbiliomycetes* show this motif (U2, U3, Tab. 60). *H. latispora* is the only representative of the *Vermispora* clade for which SSU was available, and it concurs at these 2 positions with *Orbilia* p.p.maj. and the remaining orbiliaceous genera.

In the 5.8S region (Tab. 61 left part) 1 nucleotide (pos. 30) characterizes *Hyalorbilia* s.str. and the *erythrostigma-orbiliicola* clade by showing the motif GGTTC**C**CGCAT, compared to the current motif GGTTC**T**CGCAT in *H. latispora* and the *Vermispora* clade and many other *Orbiliomycetes*. However, this deviation (**C**) also occurs in a few subgroups within *Orbilia*, particularly section *Ovoideae* (see p. 1241) and all predacious members of section *Arthrobotrys* (see Tab. 76), whereas **T** also occurs in other classes of *Ascomycota*. At another nucleotide (pos. 11) the *Vermispora* clade (including clones V1–V13) and a few *Bryorbilia* spp. (clones B1, B2 p.p.) have G but almost any other *Orbiliomycetes* A (Tab. 61).

In Smith & Jaffee's (2009) Orb5.8s1F primer region (pos. 47–64, Tab. 18), *Hyalorbilia* s.str. concurs with *Orbilia*, but the *erythrostigma-orbiliicola* clade, *H. latispora*, and the *Vermispora* clade matches other orbiliaceous genera (*Amphosoma*, *Bryorbilia*, *Lecophagus*, *Lilapila*, and *Retiarius*). Primer Orb5.8s3F (pos. 137–157, Tab. 18) varies within *Hyalorbilia* with one frequent and several more rare variants. Most of these variants are unique, with a few exceptions: *H. tortuosa* concurs with *Orbilia* p.p.min., *H. fusarioides* with *Retiarius* and *Amphosoma* p.p., and species of the *Vermispora* clade (*Hyalorbilia*) with *Saccharomycetales* and *Boletales*. Also in stem-loop B8 of 5.8S (pos. 117–138, Tab. S4) *Hyalorbilia* is diverse and partially unique, some members concurring with *Mycoceros* and *Lilapila*, the *oviparasitica-multiguttulata* clade with some *Orbilia* spp., *H. latispora* with the *Vermispora* clade, and *H. rotifera* with some environmental clones of that clade (V7, V11–V12).

In the LSU (Tab. 61 right part) 5 nucleotides characterize the genus *Hyalorbilia* in the present sense (including *Vermispora* clade): pos. 112, 152/155, 266, and 311 are CA**G**AT, **C**TG**G**A or **C**TG**C**A (rarely **C**TG**A**A), A**C**GA, and T**C**C, whereas all other orbiliaceous genera consistently have CA**A**AT, **T**TG**A**A (rarely **T**TG**T**A), A**A**GA, and T**T**C, except for some sequences of series *Dactylellina* with A**C**GA at pos. 266. Pos. 123 is very diagnostic for the core clade of *Hyalorbilia* which has AATC**C** (including *H. latispora* and V3–V16) or sometimes AATC**G** (*erythrostigma-orbiliicola* clade) or AATC**A** (H21–23, H31–32), whereas the remaining *Vermispora* clade and other orbiliaceous genera consistently have AATC**T**. Similarly, pos. 534 is AA**A**GT or AA**C**GT in *Hyalorbilia* p.p.maj., but AA**T**GT in the *Vermispora* clade and most other orbiliaceous taxa.

Pos. 219 is **C**CCCG in *Hyalorbilia* p.p.maj. (including species previously assigned to *Vermispora* and *Microdochiella*), but **T**CCCG in the *erythrostigma-orbiliicola* clade, *H. latispora*, and most environmental clones of the *Vermispora* clade (including *H. rotifera*). At 2 positions (328 and 608) the *Vermispora* clade has **T**GC and **G**TG unlike all other *Orbiliomycetes* and most other ascomycetes which have **G**GC and **A**TG, respectively. At pos. 332 variant CG**G** characterizes *Hyalorbilia* s.str. and the *erythrostigma-orbiliicola* clade but also predacious members of *Orbilia* section *Arthrobotrys* (Tab. 76), *Mycoceros*, and some *Orbilia* spp. (series *Abutilones*, section *Ovoideae*, *O. dryadum*), whereas remaining orbiliaceous taxa have CG**A**

In Smith & Jaffee's (2009) Orb28s2R primer region (pos. 606–626, Tabs 19 & 61), *Hyalorbilia* s.str. is unique, while *H. erythrostigma* and *H. orbiliicola* concur with *Orbilia* p.p.maj., and *H. latispora* with the *Vermispora* clade. The latter group is unique because of a rare deviation at pos. 608 (G vs. A), but varies at pos. 616 (C vs. T). At pos. 616 the character C was otherwise only found in *Hyalorbilia* p.p.maj.

In the available LSU D3 domain, species previously assigned to *Vermispora*/*Microdochiella* share with the environmental clone V14 a unique motif (GTG**A**GAGCCCGCAAG) which deviates in *H. rotifera* and clones V11 and V15 by 3 gaps (GTG**A**GAGCCGC--AA-) and in *Amphosoma* and *Retiarius revayae* at the fourth position (pos. 722, GTG**G**GAGCCCGCAAG). Among other *Orbiliomycetes* pos. 722 is A only in *Hyalorbilia latispora* (GTG**A**GAT), *H. subfusispora* (GTG**A**GAG), *H. brevistipitata* and *H. oviparasitica* (GCG**A**GAG).

Ecology. Species of *Hyalorbilia* usually form their ascomata on decayed bark and wood, some also on herbaceous stems. Many of them exhibit a more or less pronounced tendency to grow on or close to other fungi, like resupinate basidiomycetes and pyrenomycetes, also apothecia of *Orbilia*, or gelatinous basidiomata. Usually the hosts are rather senescent and the *Hyalorbilia* appears to grow as a saprobiont on them. Yet, *H. erythrostigma* and particularly *H. orbiliicola* grow parasitic on fungi: they form apothecia and conidia on living fruitbodies, the latter exclusively on apothecia of *Orbilia* spp.

Trapping of rotifers was only once observed (*H. rotifera*) and firm evidence for this is lacking. *H. oviparasitica*, *H. tenuifusaria*, and *H. fusarina* are known to prey on nematode eggs and cysts, and arguments are presented above that also

Table 60. Informative nucleotides in the SSU (V8–V9) rDNA, about 12 of which being more or less specific for *Hyalorbilia* in comparison with other genera of *Orbiliomycetes*, based on available sequences of 11 species (*H. brevistipitata*, *H. citrina*, *H. erythrostigma*, *H. fagi*, *H. inflatula*, *H. lignatilis*, *H. lunata*, *H. orbiliicola*, *H. polypori*, *H. rotifera*, *H. tortuosa*) and two environmental taxa of the genus (clades H37–38). Note concordance between *Hyalorbilia* and five species of section *Orbilia* (*T. subuliphora*, *O. xanthostigma*, *O. leucostigma*, *O. liliputiana*, *O. eucalypti* clade D) at pos. 40 & 90, between *Hyalorbilia* and members of section *Arthrobotrys* with adhesive traps at pos. 109 & 126, and between *Hyalorbilia* p.p.maj. and the *Lecophagus-Amphosoma* clade at pos 141–142. Numbers of species are given in brackets (incomplete sequences after slash). Position numbers start with CCTTAGAT downstream of primer NS7. In *Amphosoma* (A6) only SSU pos. 190–362 was available and in *H. orbiliicola* only pos. 218–362.

H. ulicicola has such capabilities. ‘*Dactylella*’ *passalopaga* captures rhizopods (Pl. 59), and we strongly presume that a species of the *inflatula-polypori* clade is the teleomorph of this species. Two further species assigned to *Brachyphoris*, *B. helminthodes* and *B. stenomeces*, and *H. fusarioides* and *H. spermatophaga*, previously assigned to *Vermispora*, infect oospores, *B. helminthodes* also zygospores (see Tab. 43), but molecular data were not available to confirm their connection to the genus *Hyalorbilia*.

Members of *Hyalorbilia* were recorded from boreal to tropical, humid to subhumid, more rarely semihumid and exceptionally semiarid regions. Similar as in *Orbilia*, desiccation tolerance strongly differs between the taxa, with the tolerant species showing a tendency to produce smaller apothecia. However, the power of tolerance is less pronounced in *Hyalorbilia*, therefore, species diversity in semiarid regions is very low. The tolerance of mature asci usually did not exceed 1–4 weeks in our tests. Some species appear to be desiccation-sensitive, e. g., the asci of

Table 61. Specific nucleotides in the 5.8S rDNA (155 nt) and LSU D1–D2 (635 nt) of the *Hyalorbilia* clade or its subgroups, in comparison with other taxa of *Orbiliomycetes* (position numbers for 5.8S: 1 = **A**AAACTTT, 155 = GAGCGT**C**, for LSU starting with TGACCT by omitting predominant gaps in alignment of all groups of *Orbiliomycetes*. Pos. 138–141 and 152–155 are part of Orb5.8s3F primer (see Tab. 18). * = *V. spermatophaga*/*V. fusarina*/*V. leguminacea*. Rare or exceptional motifs are given in small font. Note more or less unique nucleotides of (1) the *Vermispora* clade (green) at pos. 11 and 85 of 5.8S and at pos. 328 and 608 of LSU, (2) *Hyalorbilia* p.p.maj. (orange) at pos. 140 of 5.8S, and (3) the e*rythrostigma-orbiliicola* clade (yellow) at pos. 83–84 (but concurring with H30–H32) and 155 (but concurring with H29) of 5.8S. Note also coincidence between *Hyalorbilia* p.p.maj. and *Orbilia* at pos. 64 and 98 of 5.8S.

Key to species of *Hyalorbilia* based mainly on teleomorph

1. Spores ovoid to subglobose or globose, *(1.8–)2.2–5(–5.7) × 1.3–3.7 µm, length/width ratio 1–1.5(–2); asci 8(–16)-spored; apothecia 0.05–0.9 mm diam. 2
1. Spores cylindrical to ellipsoid or fusiform, *(3.2–)3.5–17.5 × 0.6–2.8 µm, length/width ratio (1.5–)1.8–10(–15); asci 8-spored; apothecia 0.1–4 mm diam. 10

2. Asci 16-spored; spores subglobose, *2.6–3.8 × 2–2.8 µm, SBs apparently lacking; xeric bark of *Melaleuca*, subtropical semiarid western Australia .... ***H. pleioerythrostigma***, p. 430
2. Asci 8-spored 3

3. Living spores with 2 or more bipolar symmetrically arranged SBs; apothecia mainly on hygric substrate 4
3. Living spores with a single eccentric SB; apothecia mainly on xeric substrate 6
If without distinct SBs compare *Hyalorbilia hergiswiliana* (lead 22)

4. Spores broadly ellipsoid, *(3.3–)3.6–5(–5.7) × (2.2–)2.4–2.9 µm; 1(–2) SBs of 0.8–1.5 µm diam. near each spore end; angiosperm wood, subtropical humid eastern Asia .... ***H. biguttulata***, p. 412
4. Spores globose to broadly ellipsoid, *2–4.2 × 1.8–3.8 µm; 3–6 SBs of 0.3–0.8(–1.5) µm diam. peripherally dispersed in each spore half (multiguttulate) 5

5. Spores *(2.5–)3–3.8(–4.2) × 2.2–3.8 µm; asci †18.5–30 × 4–5.6 µm; bark & wood of angiosperms (including *Rubus*), temperate humid Europe, subtropical eastern Asia and western North America .... ***H. multiguttulata***, p. 414
5. Spores *2–2.8 × 1.7–2.5 µm; asci †15.5–25 × 3–4.5 µm; bark & wood of angiosperms, stems of bamboo, temperate to subtropical humid eastern Asia & Macaronesia .... ***H. brevistipitata***, p. 408

6. Asci †12–17 × 3–4 µm; spores ellipsoid-ovoid, *2.4–3.2 × 1.4–1.8 µm, SBs 0.6–0.8 µm diam.; apothecia 0.07–0.16 mm diam.; anamorph unknown; bark of *Ulmus* (on pyrenomycete), temperate humid atlantic northwestern Europe .... ***H. ulmi***, p. 436
Collections from Australia and Ethiopia with larger apothecia (0.15–0.65 mm), partly longer asci (†13–24.5 µm) but shorter spores (†1.7–2.4 µm) resemble *H. brevistipitata* but appear to contain one eccentric SB (p. 409–410)
6. Asci min. †18–21 µm long; spores *1.7–3.5 µm wide, SBs 0.8–1.5 µm diam.; apothecia 0.06–0.4 mm diam.; conidia Y-shaped, arms ± curved downwards 7

7. Conidia with 0–1-septate stipe and ± asymmetrical, non-septate arms; spores ± globose, *3–3.5 µm diam.; asci †29–35 µm long; parasitic on apothecia of *Orbilia* spp. (mostly only conidia present), subtropical subhumid to arid Australia .... ***H.* aff. *erythrostigma***, p. 419
7. Conidia with 1–4-septate stipe and ± symmetrical, 0–2-septate arms (unknown in *H. anonyma*); spores globose to broadly ellipsoid, *(1.7–)1.9–2.7(–3) µm wide 8

8. Asci †40–53 × 3.8–4.8 µm; spores †3–4 × 2.4–2.8 µm; paraphyses apically uninflated, terminal cells 13–28 × 1.2–2.3 µm; marginal cortical cells †1.5–3 µm wide; anamorph unknown; branch of *Melastoma* (on stromata of *Valsaria*), tropical humid South America .... ***H. anonyma***, p. 429
8. Asci †(18–)21–33(–38) × (3.2–)3.5–5(–6) µm; spores †(2–)2.2–2.8(–3.3) × (1.4–)1.7–2.4 µm; paraphyses apically often ± inflated, terminal cells 8.5–20 × 2–5.5 µm; marginal cortical cells †(2–)2.5–6(–7) µm wide; temperate to mesomediterranean humid to semihumid Europe, South America, Macaronesia, Asia, Australia 9

9. VBs ± globose, in paraphyses and marginal cortical cells 1.5–5 µm long; trinacrium-like conidia often present; parasitic on apothecia of *Orbilia* spp. .... ***H. orbiliicola***, p. 424
9. VBs ± elongated, in paraphyses and marginal cortical cells (2–)3–10(–13) µm long; trinacrium-like conidia rarely observed; ± parasitic on pyrenomycetes and gelatinous basidiomycetes, saprobic on bark & wood of angiosperms .... ***H. erythrostigma***, p. 417

10. Spores *9.5–17.5 µm long, with 3–5 or more SBs and some minute LBs near each end; apothecia hydrated 0.1–0.5(–0.9) mm diam. 11
10. Spores *3.5–10 µm long, with 1–2 or 3–5 SBs and some minute LBs near each end; apothecia hydrated 0.1–5 mm diam. 14

11. Spores slightly to strongly curved, rarely a few straight 12
11. Spores straight or only exceptionally slightly curved 13

12. Spores strongly helicoid, *9.5–12(–13) × 1.4–1.7 µm, intertwined within asci, ends only slightly tapered, SBs 0.7–1.1 µm diam.; hygric angiosperm wood, subtropical humid southeastern Asia .... ***H. macrohelicospora***, p. 376
12. Spores slightly to medium falcate, *(10–)11–14(–17.5) × (1.1–)1.2–1.6(–1.8) µm, not intertwined, ends distinctly tapered, SBs 0.3–0.8 µm diam.; hygric to mesic old polypores or angiosperm wood & bark, boreal to subtropical humid Europe, Macaronesia, eastern Asia .... ***H. berberidis***, p. 393

13. Spores *10–13(–15) × (1.1–)1.2–1.6(–1.9) µm (†1–1.5 µm wide); xeric bark & wood of angiosperms, also polypores, boreal to subtropical humid to semihumid Europe, Asia, Australia .... ***H. juliae***, p. 384
13. Spores *(11–)12–14.5(–15.5) × 1.1–1.2(–1.3) µm (†0.8–1.2 µm wide); hygric *Fomes fomentarius*, orotemperate humid Europe .... ***H. fomentarii***, p. 392

14. Spores *(1.2–)1.4–2.5(–3) µm wide 15
14. Spores *0.7–1.3(–1.5) µm wide 28

15. Spores slightly or strongly curved (falcate or helicoid), *(4.5–)5–7 × (1.5–)1.6–1.8(–2) µm, SBs 0.5–1(–1.3) µm diam.; apothecia 0.25–3 mm diam.; hygric bark & wood of angiosperms, temperate to subtropical humid to subhumid atlantic Europe, Macaronesia, eastern Asia .... ***H. lunata***, p. 381
15. Spores straight or only some spores slightly curved, rarely most spores slightly curved (then on xeric substrate) 16

16. Spores *(4.5–)5.5–8.5(–10) µm long 17
16. Spores *(3.5–)4.5–6.5 µm long 19

17. Spores cylindric-ellipsoid to subfusoid, *(1.3–)1.5–1.9(–2.3) µm wide, with 1(–2) globose SBs 0.2–0.5 µm diam. at each end; spores inside living asci usually in two superimposed bundles; apothecia 0.3–2 mm diam.; hygric gymno- & angiosperm wood, polypores, pyrenomycetes, boreal to temperate humid Europe . ... ***H. polypori***, p. 328
If spores somewhat narrower and more fusoid, with several SBs in each half, apothecia on xeric substrate: see *H. juliae* (p. 384).
17. Spores ellipsoid-fusoid to fusiform, *(1.7–)2–2.5(–3) µm wide, with 1–5 SBs 0.3–0.8(–1) µm diam. in each half; xeric bark & wood, atlantic to subcontinental, temperate to submediterranean humid to semihumid Europe 18

18. Apothecia 0.2–2 mm diam., yellowish-cream to ochraceous-orange; marginal cortical cells 3–5(–6) µm wide in surface view; terminal cells of paraphyses 18–33 µm long; all SBs globose; angiosperm bark (rarely wood)........ ***H. fusispora***, p. 397
18. Apothecia 0.08–0.5 mm diam., whitish to pale chlorinaceous; marginal cortical cells (5–)6–10 µm wide in surface view; terminal cells of paraphyses (10–)13–19(–25) µm long; SBs globose but polar ones often subglobose to tear-shaped; gymno- & angiosperm bark & wood, hemiboreal to mesosubmediterranean (semi- or sub)humid Europe, eastern & western North America.....***H. subfusispora***, p. 401

19. Marginal cortical cells thick-walled, forming a protruding collar; apothecia 0.7–2.8 mm diam.; spores †4–6.3 × 1.2–1.4 µm; hygric wood of angiosperms, tropical humid Middle America .... ***H. puertoricensis***, p. 334
19. Marginal cortical cells always ± thin-walled........ 20

20. Apothecia 0.2–2 mm diam., usually cream-chlorinaceous 21
20. Apothecia 0.08–0.2(–0.3) mm diam., usually whitish-greyish; always on xeric substrate........ 24

21. Apothecia mainly 0.2–0.6 mm diam.; spores without SBs, with or without a few minute LBs; on xeric substrate........ 22
21. Apothecia mainly 0.5–2 mm diam.; spores with 1–2 or more SBs and a few minute LBs near each end; on hygric substrate........ 23

22. Spores *5.2–6.5 × 1.3–1.5 µm, fusoid; ectal excipulum at lower flanks of horizontal t. prismatica, marginal cortical cells †4–5 µm wide; wood & bark of *Campsis*, subtropical humid North America .... ***H. texensis*** p. 333
22. Spores *3.2–4.4 × 1.6–2.1 µm, broadly ellipsoid-fusoid to subclavate; ectal excipulum at lower flanks of roundish, indistinctly vertically oriented cells, marginal cortical cells †2–3.5 µm wide; angiosperm wood, oro- to mesotemperate humid central Europe........ ***H. hergiswiliana***, p. 433

23. Marginal excipular cells in median section 6–13 µm wide; spores †4.2–5 × 1.3–1.5 µm; wood of *Platanus*, subtropical (semi)humid southeastern Europe .... ***H. caucasica***, p. 327
23. Marginal excipular cells in median section 3–6(–7) µm wide; spores mainly *4–6 × 1.4–1.7 µm; gymno- & angiosperm bark (& wood), polypores, warm-temperate to mediterranean (semi)humid atlantic Europe, eastern Asia, Australasia .... ***H. ulicicola***, p. 322

24. Spores *3.5–4.3 × 1.8–2 µm, broadly ellipsoid to subclavate .... see under 22 (*H. hergiswiliana*)
24. Spores *(3–)4–5.5(–6) µm long, cylindrical, ellipsoid, or fusoid........ 25

25. Paraphyses apically partly slightly to sometimes strongly inflated (up to *3–5 µm); spores mainly *4–5.3 × 1.3–1.6 µm, mostly straight and homopolar, narrowly ellipsoid, without or with one minute SB at each end; xeric to hygric bark or blackened resin of conifers, temperate humid Europe ....***H. resinae***, p. 437
25. Paraphyses apically usually not inflated (*2–3 µm); on angiosperms 26

26. Spores *1.3–1.5 µm wide; montane northeastern Africa .... see under 31 (*H.* aff. *herbicola*)
26. Spores mainly over *1.5 µm wide; (oro)temperate humid Europe........ 27

27. Spores *4–6 × (1.4–)1.6–1.8(–2) µm, homo- or sometimes heteropolar (subclavate), often without SBs; marginal cortical cells (3–)4–8(–9) µm wide; bark (rarely wood) of angiosperms .... ***H. rotifera***, p. 440
27. Spores *3–6 × (1.8–)2–2.3(–2.5) µm, ± homopolar, with ~3–5 SBs in each half; marginal cortical cells 3–6.5 µm wide; stems of *Senecio* & *Rubus*, bark & wood of *Clematis*, cupules of *Fagus* ....***H. latispora***, p. 431

28. Spores *(3–)4–5.5(–6.5) µm long (in situ, if curved then actual length partly exceeding 6 µm)........ 29
28. Spores predominantly over *5.5 µm long (in situ)........ 32

29. Spores †(4–)4.5–5.5(–6.3) × 1.2–1.4 µm, straight; marginal cortical cells thick-walled, forming a protruding collar; apothecia 0.7–2.8 mm diam. .... see under 19 (*H. puertoricensis*)
29. Spores predominantly < *1.2 µm wide (if > *1.2 µm then apothecia < 0.3 mm diam.), straight or slightly curved; margin usually not forming a protruding collar 30

30. Spores *(3.5–)4.5–6(–6.5) × 0.8–1.1(–1.2) µm; medullary excipulum often gelatinized; marginal cells thin- or thick-walled; apothecia 0.25–2.5 mm diam.; hygric angiosperm bark & wood, temperate to tropical humid eastern Asia, South Africa, Middle America (not sharply delimited from *H. citrina* and *H. oreadum*) .... ***H. japonica***, p. 354
A sample from central Europe on *Populus* wood deviates by partly helicoid spores (p. 367).
30. Spores *3.5–5.7 µm long; medullary excipulum non-gelatinized; marginal cells thin-walled........ 31

31. Spores *(3.5–)4–5.7 × (0.9–)1–1.1(–1.4) µm; apothecia 0.15–0.3 or 0.2–1(–2) mm diam.; excipular cells at lower flanks min. 9–25 × 5–15 µm; terminal cells of paraphyses 9–18.5 µm long, 2–4× longer than lower cells; spores *4-seriate in two superimposed bundles; xeric coniferous and angiosperm wood, temperate to montane humid Europe, ?Asia........ ***H. oreadum***, p. 335
Collections from the Antilles (H.B. 8036) and Azerbaijan (TAAM 68123, p. 355) mentioned under *H. japonica* are somewhat intermediate in having thick-walled excipular cells and slightly curved spores (†4.8–5.5 × 1–1.1 µm and †5.3–5.7 × 0.9 µm, respectively). Both have rather large apothecia.
31. Spores mainly *3.5–5 × 1.2–1.3 µm; apothecia 0.1–0.16 mm diam.; excipular cells at lower flanks 5–8 × 5–6 µm; terminal cells of paraphyses (4–)7–9(–10) µm long, 1.5–2× longer than lower cells; spores *2–4-seriate; hygric herbaceous stems (*Reynoutria*, *Phleum*), temperate humid Europe........ ***H. herbicola***, p. 438
A specimen from Ethiopia on angiosperm bark differs in slightly wider spores (*1.3–1.5 µm, p. 439).

32. Spores straight to partly slightly curved (sickle-shaped, never helicoid) 33
32. Spores consistently slightly to strongly curved (sickle-shaped to helicoid) 35

33. Spores with 1–2 minute SBs close to each end, mainly *5–7.5 × 0.9–1.2 µm, in living asci mostly in two superimposed bundles; apothecia mainly 0.4–2 mm diam., often cupulate to saucer-shaped, also flat from the beginning; conidia fusoid, (3–)4–8(–12)-septate; ± hygric (gymno- &) angiosperm wood & bark, also pyrenomycetes & polypores, boreal to subtropical (semi)humid, worldwide .... ***H. inflatula***, p. 339
33. Spores with usually 3–4(–6) SBs in each half, mainly *7.5–9.5 µm long, in living asci rarely in two superimposed bundles; xeric bark & wood, rarely hygric culms of *Poaceae* 34

34. Spores *6.5–9.7 × 0.9–1.1 µm; apothecia (0.4–)0.7–1.3 mm diam., saucer-shaped; wood of *Quercus*, temperate humid Europe (Luxembourg) .... ***H.* cf. *inflatula*** (H.B. 6819), p. 349
34. Spores *8–10 × 1.1–1.5 µm; apothecia 0.15–0.7(–0.9) mm diam., flat or only slightly concave; bark & wood of angio-, rarely gymnosperms, boreal to subtropical (semi)humid Europe .... ***H. juliae***, p. 384
A collection on hygric culms of *Phleum* from Poland (H.B. 9138b) is hardly different (apothecia 0.12–0.2 mm diam., p. 388).

35. Ectal excipulum at flanks often strongly gelatinized, margin 10–90 µm protruding, composed of globose thick-walled cells forming distinct lobes or teeth or a crenulate collar; spores *4.5–7 × 0.8–0.9 µm, distinctly helicoid (somewhat stair-like); apothecia (0.3–)0.6–3(–4.5) mm diam.; hygric angiosperm bark & wood, petioles, fruits, also polypores & pyrenomycetes, tropical to temperate humid Middle & South America, southern Africa, Asia, Australia (not sharply delimited from *H. japonica*) .... ***H. citrina***, p. 359
35. Excipular cells ± thin-walled (though cortical cells rarely with small glassy caps), never forming marginal teeth 36

36. Spores slightly to strongly sickle-shaped, only exceptionally slightly helicoid, */†5–8 × 0.9–1.3 µm; subtropical South America, Asia & Australasia 37
36. Spores partly or predominantly helicoid, temperate (to subtropical) 39

37. Spores slightly curved; asci †26–30 µm long; apothecia 1–5 mm diam., concave, margin curved upwards; stem of bamboo, angiosperm branches, subtropical humid South America & eastern Asia .... ***H. andina***, p. 337
The Asian collections differ in smaller (0.3–1 mm), flatter apothecia and shorter asci (†17–22.5 µm).
37. Spores medium to strongly curved; asci †18–26(–29) µm long; apothecia 0.14–1.8 mm diam., flat or only slightly concave; (sub)tropical humid eastern Asia, Australia 38

38. Marginal cortical cells without glassy caps; paraphysis apices uninflated, †2–2.5 µm wide; apothecia 0.4–1.8 mm diam.; gymno- & angiosperm bark & wood .... ***H. arcuata***, p. 377
38. Marginal cortical cells with small, knob-like glassy caps; paraphysis apices clavate, †2.5–4.2 µm wide; apothecia 0.14–0.24 mm diam.; angiosperm wood .... ***H. nodulosa***, p. 380

39. Spores †5.5–7.7 × 1.1–1.4 µm, rather strongly helicoid; asci †24–30 × 4–4.7 µm; apothecia 0.4–1 mm diam.; xeric wood of *Larix*, cold-continental humid central Asia .... ***H. sibirica***, p. 375
39. Spores max. †1–1.2 µm wide; asci †(13–)15–23(–26) × (3–)3.3–4.3(–4.7) µm 40

40. Apothecia 0.12–0.8(–1.4) mm diam.; spores *(5.5–)5–7.5(–8) × 1–1.3(–1.4) µm, with 2–4 SBs in each half; xeric angiosperm wood & bark, temperate humid Europe .... ***H. helicospora***, p. 372
40. Apothecia 0.2–0.4 up to 1–2.5(–4) mm diam.; spores with 1–2(–4) SBs in each half; hygric wood & bark 41

41. Spores *(4.3–)4.7–6.5(–7) × (0.9–)1–1.2 µm, slightly to medium helicoid, 1(–2) SBs at each end; conidia fusoid to fusiform, 3–5-septate; (gymno- &) angiosperm wood & bark, also polypores, pyrenomycetes, temperate humid Europe, eastern North America, eastern Asia .... ***H. fagi***, p. 368
41. Spores *(5–)6–7.5(–8) × (0.7–)0.8–1(–1.2) µm, medium to rather strongly helicoid, 1–2(–4) SBs at each end; conidia cylindric-ellipsoid with obtuse ends, 1–3(–4)-septate; angiosperm wood, bamboo, polypores, temperate to subtropical (sub)humid Europe, eastern North America, eastern Asia .... ***H. tortuosa***, p. 364

Key to species of *Hyalorbilia* based on anamorph

1. Conidia branched (staurosporous, trinacrium- to dwayaangam-like or K-shaped) 2
1. Conidia unbranched (phragmosporous, brachyphoris-like) 6

2. Conidia 2-armed (trinacrium-like), *20–35 × 15–24.5 µm, arms ± curved downwards 3
2. Conidia 3–4-armed 4

3. Conidia formed on pyrenomycetes, basidiomycetes, bark and wood, worldwide .... ***H. erythrostigma* s.l.**, p. 417
3. Conidia formed on apothecia of *Orbilia* spp., Europe, North America, Australia .... ***H. orbiliicola* s.l.**, p. 424

4. Conidia 4-armed (dwayaangam-like), *75–95 × 61–77 µm, arms diverging; parasitic on rhizopods, North America .... ***H. quadridens***, p. 407
If only *35 × 20 µm and arms more parallel see under *H. fusispora*.
4. Conidia 3-armed (K-shaped) 5

5. Conidia *27–45 × 11–22 µm, with straight arms; bark & wood, Europe & North America .... ***H. subfusispora***, p. 401
5. Conidia *11–13.7 × 9.5–12 µm long, with strongly curved arms; woody & herbaceous substrates, Europe .... ***H. latispora***, p. 431

6. Conidia filiform to fusoid, *2–3 µm wide 7
6. Conidia fusoid to fusiform, min. *(2.5–)3–4 µm wide 8

7. Conidia 30–60 × 2–3 µm, slightly falcate, 3-septate; parasitic on oospores, Europe .... ***H. fusarioides***, p. 443

7. Conidia *44–77 × 2.1–2.4 µm, slightly flexuous (S-shaped), 3–6-septate; bark, Europe .... ***H. rotifera***, p. 440
Similar type of conidia observed in *H. texensis* and *H. multiguttulata* (46–51 × 2.7–3 µm, 5–6-septate).

8. Conidia 160–180 × 10–22 µm, 6–9-septate; leaves of *Ficus*, India .... ‘***Vermispora’ cauveriana*** (see p. 247)
Possibly belonging to *Orbilia* section *Arthrobotrys* because the conidia produce microconidia.

8. Conidia < 100 × 6 µm 9

9. Conidia cylindric-ellipsoid, (1–)3(–6)-septate 10

9. Conidia fusoid to fusiform, 3–4 up to 5–8-septate 11

10. Conidia *26–45 × 8–10 µm; wood & polypores, Europe .... ***H. polypori***, p. 328

10. Conidia *15.5–35 × 4–7.3 µm; wood & polypores, Europe, eastern North America, eastern Asia .... ***H. tortuosa***, p. 364

11. Conidiophores 1.5–10(–28) µm long, non-septate, unbranched, unilocular or with nodulous scars when multilocular 12

11. Conidiophores (7–)15–50(–100) long, partly septate, branched or not, branches unilocular 13

12. Conidiophores unilocular or sometimes with one additional scar; conidia *31–65 × 3–5 µm, (4–)6–7(–9)-septate; parasitic on nematode cysts & eggs, western North America, Europe, southern Asia .... ***H. oviparasitica***, p. 247, 410

12. Conidiophores partly multilocular; conidia †23–52 × 3–4 µm, 3–5-septate; bark & wood, eastern Asia, Macaronesia .... ***H. brevistipitata***, p. 408

13. Conidia 73–120 µm long 14

13. Conidia 20–70(–83) µm long 15

14. Conidia 88–120 × 4–6 µm, 9–14-septate, apical end tail-like; parasitic on rhizopods, eastern Asia .... ***H. tenuifusaria***, p. 408

14. Conidia 73–96 × 4.5–5 µm, 5–8-septate, apical end not tail-like; hyperparasite of *Meliolaceae*, western Africa .... ***Vermispora grandispora*** (see p. 247)

15. Conidia ± straight, *(25–)40–70(–83) × (3–)4–8(–9) µm, (1–)3–8(–12)-septate; hygric bark & wood, parasitic on rhizopods .... ***Hyalorbilia* spp**.

15. Conidia slightly curved near the ends 16

16. Conidia 20–34 × 4–5 µm, cylindric-fusoid, 1–5-septate; parasitic on nematode eggs, eastern Asia .... ***H. leguminacea***, p. 442

16. Conidia 30–65 × 3.5–5 µm, fusoid-fusiform, (1–)3(–5)-septate 17

17. Conidia 30–50(–55) µm long, partly slightly widened at basal hilum; parasitic on nematode eggs, Europe .... ***H. fusarina***, p. 442

17. Conidia 35–65 µm long, not widened at basal hilum; parasitic on oospores, eastern North America .... ***H. spermatophaga***, p. 443
Compare also *H. lunata* (H.B. 7906a) with conidia *36–45 × 3.5–4 µm, ~4–5-septate (p. 382), and *H. brevistipitata* with conidia †23–52 × 3–4 µm, 3–5-septate (p. 410).

H. berberidis, *H. fomentarii*, *H. inflatula*, *H. lunata*, *H. polypori*, and *H. tortuosa* did not survive for a longer period than ½–2 days. Only in a few cases were mature asci still alive after 3 months (*H. subfusispora*), and immature asci after 11 months (*H. arcuata*). Excipular cells, ascospores, and conidia usually survived for a maximum of 1–5 months, in *H. arcuata*, *H. juliae* even 11–13 and in *H. pleioerythrostigma* 17 months. Because of a comparatively low tolerance, populations of *Hyalorbilia* species on xeric substrate often contain only dead asci when collected after a longer period of drought. The so far single population of a *Hyalorbilia* collected in a semiarid subtropical area, the Australian *H. pleioerythrostigma*, is extraordinary in several respects: it represents the only known species of the genus with 16-spored asci, its apothecia are at the lowermost range (0.15–0.25 mm diam.), and its excipular cells and ascospores showed the highest tolerance observed during storage in the herbarium, while this population has certainly been under dry condition in the field for an unknown period of time.

Hyalorbilia ulicicola Baral & Priou, **sp**. **nov**., MB 813466 — Pls 60–62, Map 5

Etymology: named after the predominant host plant, *Ulex europaeus*.

Typification: France, Morbihan, Île de Creïzic, on *Chaetosphaerella phaeostroma*, also on bark of *Ulex europaeus*, 11.III.2000, J.P. Priou, (ex H.B. 6612, M-0276421, holotype).

Misapplied names: Korf (1992: 508), as *O. inflatula*; Liu (2006: 33, 2007b), as *H. fusispora* (?= *H. ulicicola*); Guo et al. (2014b), as *H. fusispora* (?= *H. texensis* or *H. ulicicola*).

Latin diagnosis: Hyalorbiliae inflatulae similis sed ascosporae multo breviores et latiores, plerumque fusoideae.

Description: — **TELEOMORPH**: **Apothecia** fresh (0.3–)0.4–1.5 or 1.5–2.5(–3) mm diam., 0.14–0.2(–0.3) mm high (receptacle 0.08–0.13(–0.2) → 0.06–0.07 µm), pale or light chlorinaceous to cream-ochraceous, round, when large slightly to very strongly undulating or lobate, hardly to distinctly gelatinous, ± gregarious in small groups; disc ± concave, also flat to finally medium convex, margin thin, smooth, slightly raised; stipe ill-defined or obconical, 0.06–0.1 × 0.16–0.3 mm, superficial; turning light reddish-brown (to amber-orange) with age, dry concave, olivaceous-yellow to orange-brown, often with distinct white subiculum. **Asci** *(20–)25–36(–39) × 4.3–5.2(–5.5) µm {9}, †20–33 × 3.5–4.2 µm {3}, 8-spored, spores 2–3-seriate, pars sporifera *10.5–20 µm long (†16–21 µm); **apex** (†) hemispherical to slightly truncate; **base** with or without medium long, thick, ± flexuous stalk, arising from croziers {9} without perforation. **Ascospores** *(3–)4–5.5(–6) × (1.2–)1.4–1.7(–2) µm {22}, †3.8–4.8 × 1.3–1.6 µm {2}, ellipsoid to mostly fusoid or fusiform, sometimes slightly to distinctly heteropolar (fusoid- or fusiform-clavate), ends obtuse to subacute, straight, sometimes slightly inequilateral; exceptionally medium curved, 1–2 globose **SBs** (0.3–)0.4–0.5(–0.6) µm diam. {4} and 1–2 minute LBs at each end. **Paraphyses** apically uninflated or slightly (rarely medium) clavate-capitate, terminal cells *(14–)17–30(–37) × (2.5–)3–4.3(–4.8) µm {6}, †13.5–18.3 × 3–3.3 µm {1}, lower cells *5–8(–12) × 2–3.5 µm {5}, †5–9.5 × 2.5–3 µm {1}. **Medullary excipulum** 15–50 µm thick, of non- or slightly gelatinized textura globulosa-prismatica mixed with t. porrecta-intricata, cells up to *6–10 µm wide, medium to sharply delimited. **Ectal excipulum** non- or slightly gelatinized, at base of t. angularis 80–170 µm thick, from lower to mid flanks of horizontal t. prismatica 35–50 → 15–20

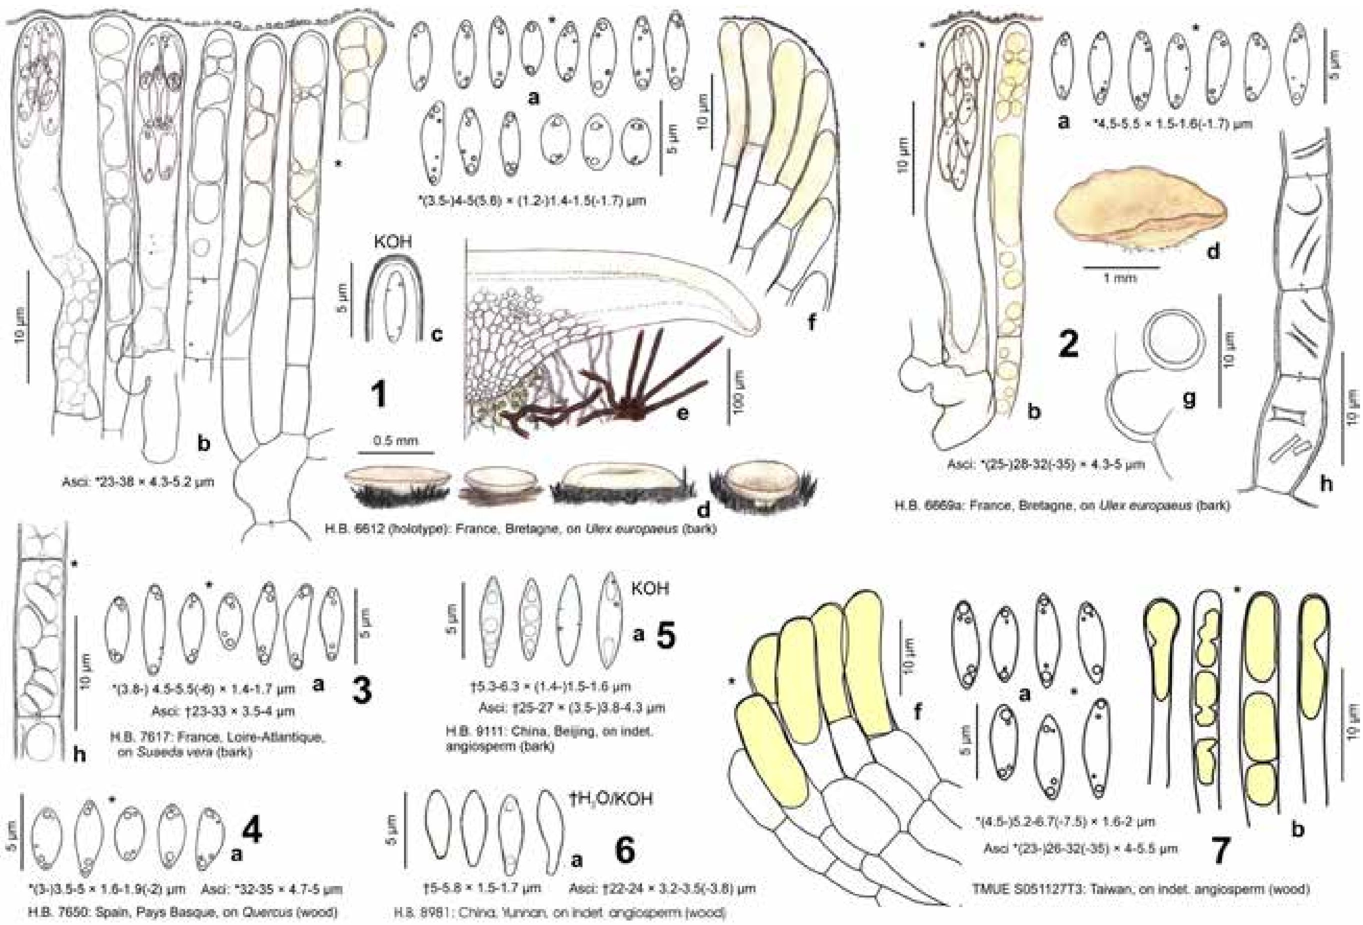

Plate 60. **1–4**: *Hyalorbilia ulicicola*; **5–7**: *H.* cf. *ulicicola*. – **a**. ascospores; **b**. asci (with croziers) and paraphyses; **c**. ascus apex; **d**. apothecia (fresh); **e**. apothecium in median section; **f**. id., marginal ectal excipulum; **g**. crystalloid SCBs in ectal excipulum; **h**. anchoring hyphae containing SCBs. – **7**: del. Y.C. Su.

µm thick, cells *(10–)20–40(–53) × (6–)10–17(–26) µm {5}, common walls *0.3–0.5 µm thick; cells towards margin in surface view *10–17 × 5–8 µm {1}; margin not or distinctly gelatinized, cortical cells cylindrical to slightly clavate, */†(7–)9–18(–24) × (2.5–)3–5(–7) µm {8}. **Anchoring hyphae** abundant, loose, long, radiating, *(3–)4–6(–8) µm wide, walls *(0.2–)0.3–1(–1.3) µm thick {9}, †(2–)3–5.5 µm, walls 0.2–0.6 µm thick {1}, individual cells *(6–)14–23 µm long. **SCBs** crystalloid, in basal cells of ectal excipulum and also in anchoring hyphae often present, low- to medium refractive, needle-, rod-, ring-, C-, S- or spool-shaped {11}, less often absent {3}. **VBs** in terminal cells of paraphyses very pale to light yellowish-chlorinaceous, very low to usually medium refractive, globose to elongate-angular; excipular cortical cells at mid flanks and margin sometimes filled with medium to large, globose, chlorinaceous, low- to medium refractive VBs; cells of medullary excipulum sometimes with 1 globose **LB** 1–3 µm diam. {1}, or with 1–6 medium refractive globose bodies (?VBs) moving inside vacuoles {1}. **Exudate** over paraphyses 0.3–0.6 µm thick, continuous, mostly strongly warted by small clod-shaped granules; over margin and flanks thin, minutely granular. — **ANAMORPH**: brachyphoris-like (presumed, from natural substrate {4}). **Conidiophores** not observed. **Conidia** unbranched, ± straight, narrowly fusoid, †29–37 × 2.3–4.3 µm, 4–7-septate {3}, or *75 × 4.5 µm, ~9–10-septate {1}.

Habitat: lying on ground, covered by moss, grass, or dead *Pteridium*, also 0.1–0.6 or rarely 2–3 m above the ground, ± corticated to decorticated, 6–80 mm thick branches, also thick logs, of *Alnus glutinosa* {1}, *Ceratonia siliqua* {1}, *Clematis vitalba* {1}, *Cytisus scoparius* {2}, *Eucalyptus camaldulensis* {2}, *Fagus sylvatica* {1}, *Fraxinus excelsior* {1}, *Malus domestica* {3}, *Pinus* sp. {1}, *Populus nigra* '*italica*' {1}, *Quercus* sp. {1}, *Robinia pseudoacacia* {2}, *Sambucus nigra* {2}, *Suaeda vera* {2}, *Tamarix africana* {2}, *T. anglica* {1}, *Ulex europaeus* {21}, medium to strongly decayed bark {23} (periderm, also bast), more rarely wood {14}; on pores (also upper side of pileus) of sometimes very old *Fuscoporia ferrea* {1}, *Phylloporia ribis* {1}, *Ganoderma applanatum* {1}, *G. australe* {1/2}, *Inonotus* sp. {1}, gills of *Cellulariella warnieri* {1}; on setae and old perithecia of *Chaetosphaerella phaeostroma* {2}, stromata of ?*Hypoxylon* {1}, green algae very abundant or sparse to absent. **Associated**: *Ascocorticium anomalum* {2}, *Athelia* ?*arachnoidea* {1}, *Calycina* sp. (?heterosporous) {1}, *Cosmospora episphaeria* {1}, ?*Diplodia* sp. {1}, *Duportella halimi* {1}, *Frullania dilatata* {1}, *Hyalorbilia erythrostigma* {1}, *H. fusispora* {1}, *H. juliae* {1}, *Karstenia rhopaloides* {1}, *Lasiosphaeria ovina* {1}, *Lophiostoma angustilabrum* {1}, *Mollisia* sp. {1}, *Neodasyscypha cerina* {1}, *Orbilia eucalypti* {1}, *O.* ?*xantho-*/*leucostigma* {1}, *Phaeangella* ?*ulicis* {1}, *Pyrenopeziza dextrinospora* {1}, *Ramicola obscura* {1}, *Tubeufia cerea* {1}. **Desiccation tolerance**: excipular cells survive for max. 1–2 days, some asci 1 week. **Altitude**: 1–475 m a.s.l. **Geology**: Cambrian siltstone & quartzitic wacke, Ordivician sandstone, Jurassic dolomite, Cretaceous sand-, marl- & limestone, Pleistocene sand; granite, migmatite, porphyry, gneiss, mica schist, ophite etc. **Phenology**: throughout the year (long-lived), collected especially in winter.

Phenology of *H. ulicicola*											
Jan	Feb	Mar	Apr	May	June	July	Aug	Sept	Oct	Nov	Dec
3	10	3	4	1	2	4	2	4	4	10	4

Taxonomic remarks. *Hyalorbilia ulicicola* is characterized by comparatively small, ellipsoid to fusoid or fusiform ascospores, and rather large, ± desiccation-sensitive apothecia. *H. caucasica* is very closely related (see below). *H. fusispora* and *H. subfusispora* differ in longer and wider spores, and in desiccation-tolerant apothecia, the latter also in usually

Plate 61. **1–10**: *Hyalorbilia ulicicola*. – **1a**. *Ulex* shrubland, **9a**. *Eucalyptus* log in an open *Pinus halepensis* forest; **2a–b**, **3a–b**, **4a**, **5**, **6a–b**, **8b**. fresh apothecia; **6d**, **7b**. apothecia in median section; **4d**, **7a**. id., marginal region; **1b**. id., near base; **1c**. id., region of lower flanks; **1d–e**, **4b**. ectal excipular cells near base, with SCBs; **4e**. exudate on hymenium; **6c**. anchoring hyphae; **2c**. paraphyses with VBs; **9b**. mature asci; **2d**, **4c**, **6e**, **8a**. ascospores; **10**. conidia from substrate. – Living state. – **1a**, **2a–b**, **5**: phot. much smaller apothecia and wider marginal cortical cells. *H. puertoricensis* differs in subcylindrical spores and thick-walled excipular cells, *H. inflatula* in distinctly longer and narrower spores, and *H. texensis* in somewhat longer and narrower spores which apparently do not contain SBs, and in desiccation-tolerant apothecia.

Variation. The spores vary between 3 and 6 µm in length, but this variation can be observed within a single apothecium. The width of the marginal cortical cells varies among the collections between usually 2.5–4 to 3–6 or rarely (on *Populus*) 5–7 µm. The observation of crystalloid SCBs in the anchoring hyphae and excipular cells is so far unique within the genus *Hyalorbilia*, but these cell inclusions were absent or often only very faintly visible in some of the collections. The apothecia vary in size, often attaining 1–2.5 mm but sometimes only 0.4–1 mm.

Not included collections. Under the name *H. fusispora*, Liu (2006: 33, fig. 6; 2007b) reported 13 collections from various provinces of China (Beijing, Henan, Hubei, Jiangsu, Jiangxi, Liaoning, Xinjiang, altitude 400–1000 m), and Guo et al. (2014b) eight collections (from Anhui, Jiangsu, Jiangxi, Zhejiang, Yunnan), but the small size of the spores given there (4.2–6.5 × 1.3–2 µm) clearly excludes *H. fusispora*. The fusoid spore shape and polar SBs resemble instead *H. ulicicola*. One of Liu's collections was reexamined (Beijing, Pl. 60: 5): the spores are slightly longer than in European *H. ulicicola*, and the apothecia measured rehydrated only 0.25–0.35 mm diam. To a different collection (from Henan) belongs his photo plate (Pl. 62: 4), with spores †5–5.2 × 1.5–1.7 µm (*~5.5 × 1.7 µm) and apothecia of 0.35–0.8 mm diam., according to scale. Slightly longer spores occurred also in a specimen from Taiwan studied by Y.C. Su and M.L. Wu (pers. comm., Pls 60: 7; 62: 5), with apothecia 0.4–0.7 mm diam. Another examined Chinese collection (H.Y. Su, pers. comm., Yunnan, Pls 60: 6; 62: 3) has partially heteropolar spores, rather narrow asci, and small apothecia (rehydrated 0.13–0.33 mm diam.). Apothecia reported by Guo et al. (2014b) measured 0.3–1.5 mm, and the similarity in spore shape prompted us to place his samples closer to *H. texensis* (see Pl. 69: 2).

As in European *H. ulicicola*, the living spores in these Asian collections contained 1–2 globose SBs 0.4–0.6 µm diam. at each end. The comparatively narrow marginal cortical cells (3–7 µm wide) seem to exclude *H. caucasica*. The apparently desiccation-sensitive apothecia grew on bark and wood of twigs and branches of angiosperms. Because of available molecular data (see below) we refrain from including these Asian specimens in the description of *H. ulicicola*.

A sample from New Zealand is shown in Pl. 62: 2. In its spore size of †(3.3–)3.5–4.8 × (1–)1.2–1.4 µm it falls in the scope of European *H. ulicicola*, though the spores and also the asci [†(15–)19–25 × 3–3.3 µm] are slightly too narrow. The apothecia measure rehydrated 0.4–1.3 mm, and the marginal cortical cells are 3–5(–6) µm wide and gelatinized. It grew as a mixture with the macroscopically hardly distinguishable *Orbilia cunninghamii*.

Two specimens from Azores identified by Korf (1992) as *Orbilia inflatula* were reexamined by L. Quijada (Quijada et al. 2014a) and resemble the preceding one. That from São Miguel (CUP-MM 2487, Pl. 62: 1) has rather small asci (†19.5–25 × 3.7–4.3 µm) and spores (†3.7–4.3 × 1–1.2 µm). Although its spores are distinctly fusoid, they are too narrow to be included in *H. ulicicola*, besides the apothecia have a distinctly crenulate margin. For the specimen from Flores (CUP-MM 2126) see under *H. texensis* (p. 334).

Anamorph. Conidia were detected near apothecia in four collections of *H. ulicicola*, though only a single conidium in each of them. Those found in three collections from Bretagne (Pl. 61: 10) resemble in shape and size species having smaller conidia, such as *H. brevistipitata*, *H. lignatilis*, or *H. oviparasitica*. In a collection from Valencia (IVV: 25.IX.2010) a much larger conidium was found that resembles those seen in *H. caucasica*.

Phylogeny. An ITS sequence was obtained from apothecia of a French collection of *H. ulicicola* (on *Ganoderma*, H.B. 8656), while two ITS and four LSU sequences were gained by B. Liu from apothecia of four Chinese specimens of *H.* aff. *ulicicola* (as *H. fusispora*). In the ITS region the European sample deviates from the two Chinese ones by 12 %, which suggests that different species are involved, although in the 5.8S region they are identical. A sequence of an unidentified fungus (strain L or ARF-L) comprising ITS and LSU, isolated from eggs of the nematode *Heterodera glycines* in soybean fields in Arkansas (USA) by Yang et al. (2012b), shows a 9 % ITS distance to H.B. 8656 and 12 % to *H.* aff. *ulicicola*. In Liu et al.'s (2006a) and our analyses of ITS, LSU, or ITS+LSU (Phyls 5–6, S5) all these samples form a strongly supported monophyletic clade.

In the LSU (D1–D2), the four Chinese samples show a distance of 0.6–1.5 % to each other. Between HMAS 139526 from Henan and HMAS 139523 from Beijing the distance is 1.5 %, although in the ITS region it is only 0.8 % (5 nt and 2 gaps). However, the two Chinese LSU sequences differ almost only near the 3'-end of D2. Also here the clade of *H. ulicicola* s.l. contains the sample from Arkansas, which shows a distance of 1.5–2.5 % to the Chinese samples.

H. ulicicola s.l. clustered in our combined analysis with weak support sister to *H. subfusispora* and the *oviparasitica-multiguttulata* clade (Phyl. 6)). In our analysis of LSU, however, it formed with moderate support a sister clade to the *inflatula-polypori* clade (Phyl. S5) and in that of ITS it clustered unresolved (Phyl. 5). To European *H. subfusispora* the three ITS sequences of *H. ulicicola* s.l. show a very high distance of ~20 %, while in the 5.8S region they deviate by only 2 nt in the Orb5.8s3F primer region.

Ecology. *Hyalorbilia ulicicola* was found on rotten bark (rarely wood) of hygric branches of angio-, rarely gymnosperm shrubs and trees, predominantly of *Ulex*, also on polypores or pyrenomycetes. It shows a striking restriction to the (south)atlantic area of western and southwestern Europe with a supra- to thermotemperate or mesosubmediterranean humid climate at planar to colline altitude. The vegetation includes *Ulex* shrubs, sometimes with *Rubus*, salt marshes, and forests of *Pinus maritima* or *Quercus*/*Castanea* with tall *Ulex*. In two coastal collections from southern Europe, the climate is mesosubmediterranean semihumid (Montenegro) or thermomediterranean semihumid (almost semiarid, Valencia), and in the not included collection from Azores it is thermotemperate semihumid oceanic (almost humid).

The not included collections from China were from temperate to tropical, humid, monsoon-influenced (winter-dry), sometimes montane forests, and that from New Zealand from a subtropical humid, oceanic climate with damp winters. Based on the genetic similarity with an isolate from northwestern Arkansas, *H. ulicicola* s.l. also occurs in warm temperate humid south of Northern America. The Arkansas fungus was found to infect eggs of the nematode genera *Cactodera*, *Heterodera* and *Meloidogyne* but not *Globodera* (Kim & Riggs 1991). We may assume that also European and Asian *H. ulicicola* s.l. is able to infect nematode eggs.

Map 5: Known distribution of *H. ulicicola* in Europe.

Specimens included. **FRANCE**: **Haute-Normandie**, **Eure**, 16 km SSW of Rouen, 1 km NW of Martot, Forêt de Martot, on *Ganoderma australe*, 6 m, 10.XI.2007, A. Delannoy, vid. J.P. Priou (*Ganoderma* collected X.2006, apothecia developed in garden at Rouen and La Gacilly a year later, J.P.P. 27120, 27130, H.B. 8656, sq.: KT222347). – **Île-de-France**, **Seine-St.-Denis**, 16 km NE of Paris, 2 km NE of Aulnay-sous-Bois, Parc de Sausset, 60 m, branch of *Fagus sylvatica*, on bark, 25.X.2006, G. Eyssartier (H.B. 8357). – **Bretagne**, **Finistère**, 1.7 km NNW of Crozon, SW of Landaoudec, 25 m, branch of *Ulex europaeus*, on wood, 16.II.2002, J.P. Hyalorbilia caucasica Baral & E. Weber, **sp. nov.**, MB 813467 — Pls 63–64

Etymology: named according to the geographical origin, the Kolkheti National Park in th wider Caucasus region (towards Pontic Mts.).

Typification: Georgia, Poti, Kolkheti National Park, branch of *Platanus orientalis*, 7.VIII.1977, V. Puusepp (TAAM 109530, holotype).

Latin diagnosis: Hyalorbiliae ulicicolae *valde similis sed cellulae excipuli marginalis latiores*, *conidia multo longiora et latiora.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated (0.2–)0.5–1.5(–2) mm diam., 0.16–0.22 mm high (receptacle 0.09–0.1 → 0.05–0.06 mm), pale chlorinaceous-ochraceous, slightly translucent, round, gregarious; disc (slightly concave to) flat, margin not raised, smooth; broadly sessile, superficial; dry light dirty ochre(-brown), ± cupulate. **Asci** †(20–)22–27(–30) × 3.8–4.2 µm, 8-spored, spores ± biseriate; **apex** (†) hemispherical to slightly subconical; **base** unstalked, with croziers. **Ascospores** †4.2–5 × 1.3–1.4(–1.5) µm, fusoid (to fusiform), homopolar, both ends obtuse to subacute, straight to very slightly inequilateral; **SBs** unknown († always with 4 large vacuole-like non-refractive structures). **Paraphyses** apically slightly capitate, terminal cells †(18–)22–25 × 2.7–3.5 µm, lower cells †4–7 × 1.8–2 µm. **Medullary excipulum** 10–20 µm thick, small-celled, slightly gelatinized, medium sharply delimited. **Ectal excipulum** of slightly gelatinized (common walls 0.5–1 µm thick), horizontally oriented textura prismatica at flanks, 70–100 µm thick near base, cells †21–40 × 10–20(–30) µm; 15 µm thick near margin, marginal cortical cells †8–19 × 6–13 µm, thin-walled (0.2 µm). **Anchoring hyphae** abundant near base, very long, straight, radiating, †3.3–5.5(–6.3) µm wide, walls 0.2–0.5(–0.8) µm thick. **Exudate** over paraphyses and margin 0.1–0.2 µm thick, with scattered to dense warts. **— ANAMORPH**: brachyphoris-like (presumed, from natural substrate). **Conidiophores** not observed. **Conidia** unbranched, fusiform, straight, †63–67 × 4–4.8 µm, 7–8-septate.

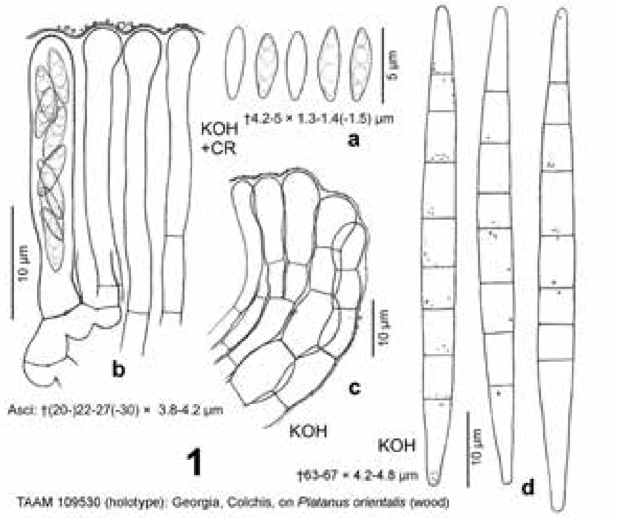

Plate 63. **1**: *Hyalorbilia caucasica*. – **a**. ascospores; **b**. ascus (with croziers) and paraphyses; **c**. marginal ectal excipulum (median section); **d**. conidia from substrate.

Habitat: on fallen, decorticated, 30 mm thick branch of *Platanus orientalis*, on 0.1 mm deep medium decayed wood, ± blackened, no algae, sometimes on old *Lasiosphaeria*. **Associated**: *Chaetosphaeria myriocarpa*, *Lasiosphaeria hirsuta*. **Desiccation tolerance**: unknown (probably intolerant). **Altitude**: ~5 m a.s.l. **Geology**: Cretaceous and Eocene sediment. **Phenology**: VIII.

Taxonomic remarks. *Hyalorbilia caucasica* strongly resembles the ozeanic *H. ulicicola* in size and shape of the ascospores. The single collection is tentatively separated here at the species level by its rather strongly inflated marginal cortical cells and the presumed anamorph having distinctly larger conidia with more septa (however, a single conidium detected in a collection from Valencia closely resembles those of *H. caucasica*). *H. rotifera* differs from *H. caucasica* in wider ascospores and much smaller apothecia.

Ecology. *Hyalorbilia caucasica* was found on medium rotten wood of a hygric branch of *Platanus orientalis* in the warm-temperate humid (somewhat summer-dry) Kolkheti riparian forest, a marshy delta of the Rioni river east of the Black Sea at the Eurasian, Turco-Caucasian border between Caucasus and Pontic Mts.

Specimens included. **GEORGIA**: **Samegrelo-Zemo Svaneti**, Kolkheti (as Colchis), ?15 km E of Poti, 5 m, branch of *Platanus orientalis*, on wood, 7.VIII.1977, V. Puusepp (TAAM 109530, **holotype**; H.B. 7966 ø, anam. substr.).

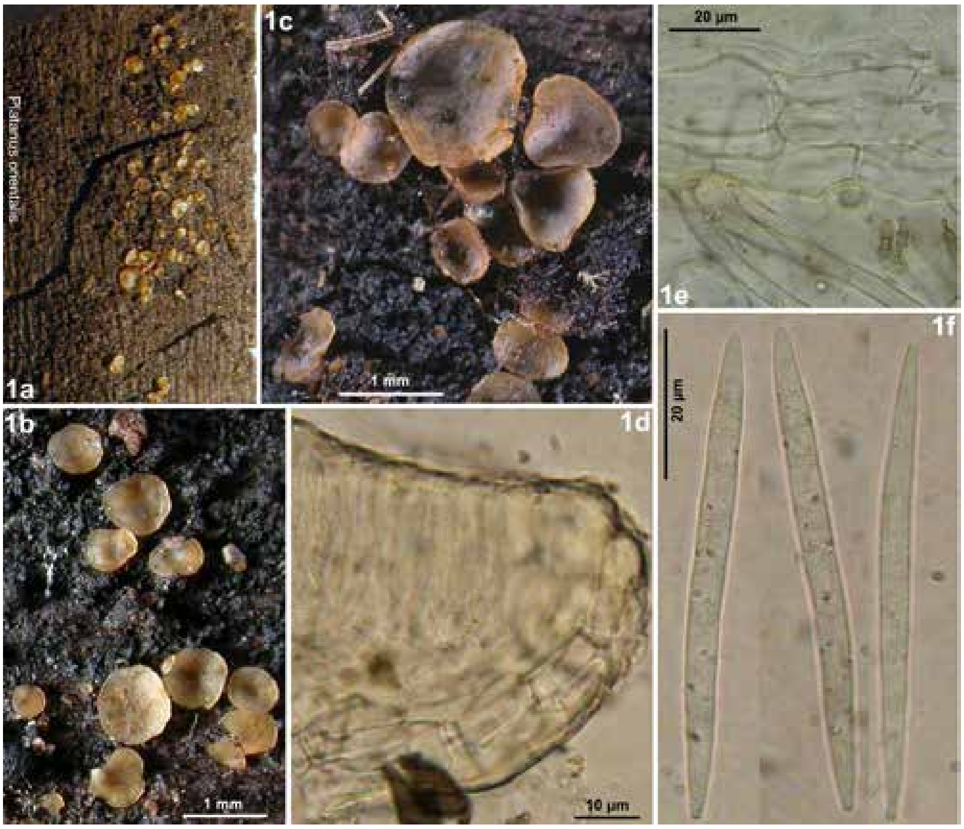

Plate 64. **1**: *Hyalorbilia caucasica*. – **1a**. decorticated wood; **1a–c**. rehydrated apothecia; **1d**. median section of marginal region; **1e**. id., ectal excipulum at lower flanks with anchoring hyphae; **1f**. conidia from substrate. – Dead state (in KOH). — **1a–f**. TAAM 109530 (holotype): Georgia, on *Platanus*.

Hyalorbilia polypori (Velen.) Baral & E. Weber, in Quijada et al., Nova Hedwigia 100: 10 (2014) — Pls 65–67, Map 6

≡ *Orbilia polypori* Velen., Monogr. Discom. Bohem.: 99, pl. 11 fig. 41 (1934)
= *Orbilia cryptocarpa* Svrček, Česká Mykol. 40: 215, pl. 4 fig. 3 (1986)
?= *Orbilia abietina* Velen., Opera Bot. Čech. 4: 103 (1947)

Etymology: *polypori*, *abietina*: named after the substrate (*Ganoderma*, *Abies*); *cryptocarpa*: growing hidden on inner surface of bark.

Typification: Czechia, Central Bohemia, Jevany, *Ganoderma lucidum*, 15.IX.1924, J. Velenovský (PRM 149743, holotype of ***Orbilia polypori***). — Czechia, Dobřichovice, log of *Quercus*, 4.VII.1985, M. Svrček (PRM 842957, holotype of ***O. cryptocarpa***). — Czechia, Mnichovice, log of *Abies alba*, 20.VIII.1941, J. Velenovský (PRM 152436, holotype of ***O. abietina***).

Misinterpretation: Liu (2006, B.L. 288, HMAS 139530), = *Hyalorbilia* sp. (*H.* aff. *citrina*).

Description: — **TELEOMORPH**: **Apothecia** fresh or rehydrated (0.2–)0.3–1.2(–2) mm diam., (0.08–)0.11–0.25(–0.27) mm high (receptacle 0.06–0.14 → 0.04–0.07 mm), pale yellowish-chlorinaceous-cream, rarely light yellow, slightly to medium translucent, round, margin only very slightly undulating when large, very slightly to sometimes rather strongly gelatinous, scattered to subgregarious, also gregarious in small groups; disc slightly (to medium) concave or often flat, sometimes umbilicate, margin thin, not or only very slightly protruding, smooth or slightly rough; sessile on an obconical base or with a distinct stipe 0.08–0.12 × 0.12–0.4 mm, superficial; dry pale to light yellow-ochraceous. **Asci** *(25–)27–38(–43) × ((4.5–))(5–)5.3–6.3(–6.8) µm {9}, †(20–)22–34(–39) × ((3.5–))(4–)4.5–5.5(–6) µm {11} [Macaronesia: *(23–)25–33(–39) × (4–)4.5–5.5(–6.2) µm {3+}, †(18–)22.5–26.5(–29) × (3.2–)3.5–4 µm {2+}], 8-spored, spores *4-seriate, always or mostly in two superimposed bundles, also ± 3-seriate, rarely some heteropolar spores clearly inversely oriented, pars sporifera *(11–)12–15.5(–17) µm long; **apex** (†) hemispherical (to slightly truncate); **base** only slightly narrowed, arising from croziers {11}, sometimes with small perforation. **Ascospores** *(5–)5.5–8.5(–10)((–11)) × (1.3–)1.5–1.9(–2.3) µm {14}, †(4.5–)5–7.7(–8.5) × ((1.1–))(1.2–)1.3–1.8(–2.2) µm {10} [Macaronesia: *(5–)6–6.5(–7.5) × (1.3–)1.4–1.7(–2.1) µm {4+}, †4.9–6.7 × 0.9–1.4 µm {2+}], (sub)cylindric to slightly fusoid or sometimes fusoid-clavate, exceptionally ellipsoid to fusiform, both ends rounded to obtuse, straight or only slightly curved or inequilateral; **SBs** *0.2–0.5 µm diam. {5}, globose, 1–2 at each end; with a few minute LBs. **Paraphyses** apically uninflated to slightly (rarely medium to strongly) clavate-capitate, terminal cells *(15–)19–28(–30) × (2.5–)3–4(–5) µm {3}, †15–22(–26) × (2–)2.5–3.5(–4.8) µm wide {3}, lower cells *(3–)4–9(–10) × 2–3(–3.7) µm {4}, †3–9(–10) × 1.8–2.7(–3.5) µm {4}. **Medullary excipulum** 10–40 µm thick, of small-celled, medium dense textura globulosa-angularis with hyphoid elements, medium sharply delimited, very slightly to strongly gelatinized. **Ectal excipulum** at base of t. prismatica-globulosa-angularis, (†) slightly to medium gelatinized (common walls 0.3–1 µm thick, at edges up to 2–3 µm), (25–)70–170(–200) µm thick near base, vertically or obliquely oriented, cells */†18–40(–70) × (12–)17–30(–37) µm {8}; 40–60 → 20–25 µm thick at flanks, of horizontal t. globulosa-angularis to short-celled t. prismatica, cells */†(8–)10–25(–30) × (5–)8–15(–20) µm {6}, 10–20 µm thick near margin, marginal cortical cells */†(6–)10–21(–26) × (3–)5–12(–15)((–20)) µm {9}. **Anchoring hyphae** ± abundant at base, */†(2–)2.5–4.5(–7) µm wide, walls 0.2–0.4(–0.7) µm thick {8}, vertically radiating. **VBs** in living terminal cells of paraphyses low to medium refractive, (very) pale chlorinaceous, at a length of 10–23 µm from tip. **Exudate** over paraphyses and ectal excipulum smooth or usually finely to roughly granular, 0.2–0.4 µm thick. **— ANAMORPH**: brachyphoris-like (from ascospore isolate {1} and natural substrate {4}). **Conidiophores** mostly branched (often several side branches in opposite arrangement), hyaline, up to 95(–200) µm long, side branches *40–100 × 3–3.5(–4.5) µm, not or scarcely attenuated above, conidiogenous cells monoblastic. **Conidia** cylindrical to narrowly ellipsoidal, the upper end rounded or obtuse, the lower end with abrupt basal protrusion, *26–45 × 8–10 µm {4}, (0–)3(–6)-septate, †26–34 × 7.8–9 µm {1}, cells containing strongly refractive, globose **SCBs** (0.5–)1–2 µm diam. {1}, often aggregated in groups, instantly disappearing in KOH, not stained in CRB+KOH, and small peripheral LBs (KOH-resistant); large glycogen regions visible in IKI. **Trapping organs** were not formed when nematodes (*Acrobeloides maximus*) were added.

Habitat: decorticated, 22–200 mm thick branches and logs (also stumps and roots), lying on moist ground, of *Abies nordmanniana* {1}, *Acer pseudoplatanus* {1}, *Alnus alnobetula* {1}, *A. incana* {1}, *Betula pubescens* {1}, ?*Corylus avellana* {1}, *Erica arborea* {1}, *Fagus orientalis* {1}, *F. sylvatica* {5/1}, *Laurus novocanariensis* {2}, *Myrica faya* {1}, *Ocotea foetens* {2}, *Picconia excelsa* {1}, *Picea abies* {2}, *Pinus sylvestris* {1}, *Populus* sp. {1}, *Prunus lusitanica* subsp. *hixa* {2}, *Pseudotsuga menziesii* {1}, *Quercus* sp. {1}, *Salix* sp. {1}, indet. gymnosperm {2}, usually on underside, on 0.3 mm deep up to very deeply medium to strongly decayed wood {27}, rarely bark {1}, often blackened; sometimes on senescent stromata of *Eutypa maura* {1}, also on pores of old *Fomes fomentarius* {1}, *Ganoderma lucidum* {1}, *Ischnoderma benzoinum* {1}, *Phellinus* sp. {1}, no or only a few green algae seen. **Associated**: *Ascocoryne inflata* {1}, *Botryobasidium aureum* {1}, *Brachysporium obovatum* {1}, *Calycina citrina* {1}, *Chaetosphaeria* sp. {1}, *C. myriocarpa* {1}, *Diatrype flavovirens* {1}, *Eutypa maura* {1}, *Hyalorbilia berberidis* {1}, *H. inflatula* {1},

Hyaloscypha leucostigma {1}, *Jackrogersella multiformis* {1}, *Mollisia ?oblonga* {1}, *Natantiella ligneola* {1}, *Orbilia dryadum* {2}, *O. flavovacuolata* {1}, *O. leucostigma* {2}, *O. ?xantho-/leucostigma* {1}, *Psilocistella quercina* {2}, *Scutellinia* sp. {1}, *Trichia decipiens* {1}, *Trichosphaeriaceae* {1}. **Desiccation tolerance**: only ascospores survived for 15 h in the dry state. **Altitude**: 67–715 m a.s.l. (Scandinavia & Baltic), 300–1620 m (central Europe), 775–1700 m (southern Europe & Caucasus), 665–1136 m (Macaronesia). **Geology**: Cambrian and Devonian sedimentary rock, Ordovician shale, silt- & sandstone, Keuper (Stubensandstein, Knollenmergel), Upper Jurassic limestone, Cretaceous mudstone, Tertiary molasse, peat; granite, granodiorite, quartz diorite, amphibolite, tephritic and phonolitic mafic or basaltic flows, phyllosilicate & gneiss, mica schist. **Phenology**: (II–)VI–X(–XI).

Phenology of *H. polypori*											
Jan	Feb	Mar	Apr	May	June	July	Aug	Sept	Oct	Nov	Dec
0	2	0	2	0	2	5	10	6	6	2	0

Taxonomic remarks. *Hyalorbilia polypori* differs from *H. inflatula* in much wider ascospores, also in a tendency to wider and somewhat longer asci. Usually, the two species are sharply delimited, but in the holotype collection of *O. abietina* spore width was found to be intermediate. The ectal excipulum of *H. polypori* is at the flanks mostly composed of rather short and wide, almost isodiametric cells, whereas in *H. inflatula* they are more elongate and prismatic. Only in a few specimens of *H. polypori* (H.B. 7965, 8245) the excipular cells tended to be more elongated in some apothecia. Macroscopically *H. polypori* differs from *H. inflatula* in apothecia being never distinctly cupulate, but *H. inflatula* also occurs in a form with flat apothecia. *H. andina* appears to be closely related to *H. polypori*, but differs in narrower, more curved spores, larger apothecia with inrolled margins (rehydrated) and an ectal excipulum of more elongated prismatic cells (similar as in *H. inflatula*). For the differences to *H. juliae* see p. 386.

Variation in *H. polypori* was mainly observed concerning spore size, though often within a collection or apothecium. Considerably long and narrow spores occurred in the sample from Huesca [*(7–)8–9(–11) × 1.2–1.5 µm]. Collections from Macaronesia studied by L. Quijada (Quijada et al. 2014a) and in the present study (Pl. 67: 6) differ in somewhat shorter spores (mainly *6–6.5 µm) and narrower asci (mainly *4.5–5.5 µm), therefore, their values are given separately in the description. Yet, such short spores occurred also in some European samples. The medullary excipulum was most often found to be not or only slightly gelatinized, though a strong gelatinization was noted in the holotype of *H. polypori*.

Type studies: Already when examined by Velenovský (1934), the holotype of ***O. polypori*** consisted of apparently only one apothecium (1 mm diam. in the protologue, rehydrated 0.8 mm in the present study). Svrček (1954: 19) found the asci (30 × 3–4 µm) and spores (5–7 × 0.8–1 µm) to fit *O. inflatula* and, therefore, placed it in synonymy. Velenovský's description (asci 25 × 5 µm, spores 4–5 µm long, narrowly acicular) also fits quite well Svrček's data, but his drawing on the uncalibrated manuscript sheet shows distinctly wider spores. Together with Svrček's data, a spore size of ~5.5–7 × 1–1.1 µm can be assumed. However, in the present study of the very same apothecium the asci and spores were found to be much wider (Pl. 65: 1). This strong divergence can hardly be explained by different preparation media, or by flattened spores in dead material: a slightly flattened spore showed a width of 2.2 µm, but when seeing it in profile view during floating its width was still 1.8 µm. In Velenovský's manuscript sheet (Pl. 66: a) the spores are also sketchily drawn inside an ascus, and here their width much better corresponds to the present data.

Svrček (1986a) segregated ***O. cryptocarpa*** from *O. inflatula* on the basis of strong differences in spore width [*O. cryptocarpa*: *5–8.5(–9) × 1.3–1.8 µm]. That his description was made from living apothecia can be seen from his drawing which shows a turgescent mature ascus with a compact spore fascicle, and from the regular presence of a small droplet at each spore end (Pl. 66: b), a feature that also Svrček stressed ('always biguttulate'). This drop undoubtedly represents the spore body because in the present reexamination of the holotype no such drop could be seen at the spore ends when mounted in KOH (Pl. 65: 9). The spores slightly deviate from those of typical *H. polypori* in a sometimes more fusoid to fusiform and slightly heteropolar shape, with some spores inversely oriented within the asci, though they look quite homopolar in Svrček's drawing. The paraphyses, which Svrček did not see, are more capitate than in the other collections here assigned to *H. polypori*. Svrček reported the species to grow on the inner surface of bark of a large fallen trunk of *Picea abies*. However, the label on the holotype written by him says '*Quercus*', and the microanatomy of the bark clearly excludes a coniferous substrate. Svrček reported numerous algal cells referred to *Stichococcus bacillaris* as occurring among the excipular cells. Only a few algal cells were seen in the examined type specimen, and the apothecia were found to grow among and sometimes on abundant perithecia of a *Chaetosphaeria*.

A few doubts remain on the correct placement of *O. cryptocarpa* since all the other collections here referred to *H. polypori* were not on bark, and since a number of features of *O. cryptocarpa* somewhat resemble those of the type of *H. juliae* which frequently grows on bark. However, in the present concept of *H. juliae* the living spores usually contain several SBs in each spore half, whereas the SBs in *O. cryptocarpa* as drawn by Svrček match very well those in recent collections of *H. polypori*. The anchoring hyphae are in *O. cryptocarpa* with 3–6(–7) µm rather wide for typical *H. polypori* and even more so for *H. juliae*. The excipular cells at the lower flanks fit with mainly †11–30 × 12–19 µm better typical *H. polypori* (*/†10–25 × 8–15 µm) than the type of *H. juliae* (†10–14 × 6–9

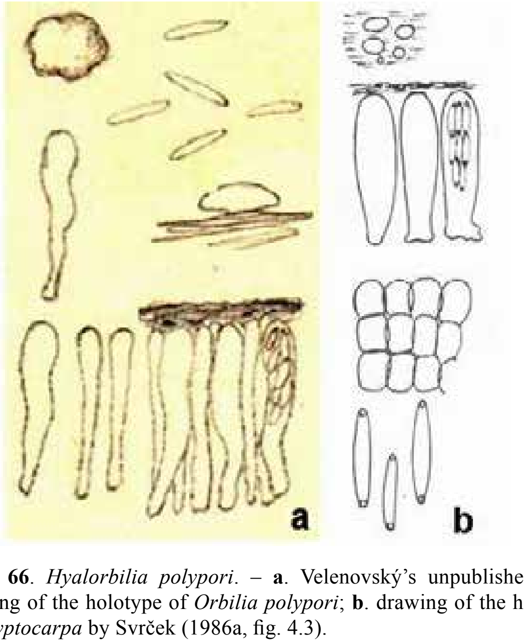

Plate 66. *Hyalorbilia polypori*. – **a**. Velenovský's unpublished original drawing of the holotype of *Orbilia polypori*; **b**. drawing of the holotype of *O. cryptocarpa* by Svrček (1986a, fig. 4.3).

µm). Finally, the size of the rehydrated apothecia (Pl. 67: 4a) fits with (0.25–)0.5–1(–1.3) mm much better *H. polypori*, as does the growth on a fallen trunk. The SBs drawn by Svrček is also reminiscent of *H. subfusispora*, but in that species the spores are wider and, as in *H. juliae*, the distinctly smaller apothecia grow on xeric substrate.

Not included collections. The holotype of ***O. abietina*** (PRM 152436) consists of a piece of rotten decorticated coniferous wood from a thick log, with ~20 well-preserved apothecia. This taxon was likewise placed in synonymy with *O. inflatula* by Svrček (1954: 8) because of narrow spores (6–7 × 1 µm). Actually, the spores were found in the present study to measure only 3.3–5 × 0.9–1.1 µm when mounted in water, but in KOH they swelled to 5–7.5(–8.5) × (1.1–)1.2–1.3(–1.6) µm. Spore width is at the lower limit of *H. polypori*, therefore, this taxon is somewhat intermediate to *H. inflatula*. However, the anchoring hyphae measured only 2–4 µm in width which is a bit too narrow for *H. inflatula*, The excipular cells at the flanks, though prismatic and quite variable (10–50 × 8–20 µm), tend to be rather short and thick, and the spores are a bit too wide. Therefore, we did not include this collection in either description. The apothecia of *O. abietina* were distinctly larger (rehydrated 0.3–0.7 mm) than indicated by Svrček (0.1–0.3 mm, ?dry), but much smaller than stated by Velenovský (1–3 mm). A *Cladonia* grew on the *Abies* log 1–2 cm away from the apothecia on an apparently rather xeric wood area. Probably the area of the *Hyalorbilia* was more protected against drying since Velenovský wrote 'ad lignum humidum'. Velenovský reported dark brown setae (100–150 × 2–3 µm) near the apothecia which were not detected here.

Liu (2006: 45, pl. 10) reported under the invalidly combined name *Hyalorbilia polypori* two Chinese collections, one from temperate Jilin (on wood of *Liquidambar*, IVV: HMAS 96786) and one from tropical Hainan (on unidentified wood, B.L. 288, unillustrated). Spore (†5.2–7 × 1.2–1.5 µm) and ascus size (†21.7–28 × 3.2–4 µm) of the combined diagnosis well correspond to the included Macaronesian samples. Judging from the photo plate of the Jilin sample, spore shape is a bit too fusoid-clavate, and some living spores inside the asci contain one comparatively large SB at each end, which would be untypical for *H. polypori*. The scale bar of the two shown dead spores of HMAS 96786 (fig. E) is erroneous (B. Liu pers. comm.) as it would result in a size of 9.5–10 × 1.9–2.1 µm. The identity of the two records remains uncertain, but a relationship to a specimen from Azores (CUP-MM 2126) mentioned under *H. texensis*, or perhaps to the type of *Orbilia cryptocarpa*, cannot be excluded with certainty. Only the Hainan specimen was sequenced by B. Liu (see below).

Anamorph. The brachyphoris-like anamorph of *H. polypori* resembles *Dactylella tenuis* and *D. coccinella* in conidial shape and to some extent also in size. Yet, these two taxa differ in unbranched conidiophores, *D. coccinella* also in smaller conidia. In *D. zhongdianensis* the conidia are likewise slightly smaller, but the conidiophores are branched similar as in *H. polypori*. However, *D. coccinella* is genetically not a *Brachyphoris* but related to *Orbilia dryadum*, according to Yang & Liu (2005, as *O. alnea*) (see under *O. dryadum*, p. 1390). Also *D. zhongdianensis* clustered in the phylogenetic analysis of Chen et al. (2007a) in *Dactylella* s.str., distant from *Brachyphoris* (see also p. 1472). *H. tortuosa* has a very similar anamorph which differs from that of *H. polypori* in smaller, especially narrower conidia. In the type of *O. abietina* a single conidium (†41 × 3.6 µm, 7-septate) was observed on the substrate, which would fit, e. g., *H. inflatula* but not *H. polypori*.

Phylogeny. A sequence gained from apothecia of *H. polypori* (Germany, H.B. 7557a) comprises SSU (with S1506 intron), ITS, and LSU. When analysing ITS or ITS+LSU, *H. polypori* clustered unsupported or with medium support in a clade with *H. lignatilis*, respectively (Phyls 5–6), as a part of the *inflatula-polypori* clade. When analysing LSU, it clustered with medium support with a strain from Thailand (as *H.* cf. *inflatula*) (Phyl. S5), with a distance of 2.6 % in the D1–D2 domain. However, in previous analyses without the latter strain it clustered in a supported clade with *H. lignatilis*, with a distance of 2.4 % in the D1–D2 (in contrast to ~23 % in the ITS).

A sequence of one of the not included Chinese collections of *H.* '*polypori*' (as *Hyalorbilia* sp., Hainan, B.L. 288, ITS+LSU) clustered strongly supported with *H. citrina* (H.B. 9661) when analysing ITS+LSU, with an LSU distance of 2.5 %, whereas European *H. polypori* deviates from the Hainan collection by 4.5 %. In the ITS region, the Hainan collection showed a distance of 14–15 % to *H. citrina* (H.B. 8012) and *H. japonica* (HMAS 138524), and ~20 % to European *H. polypori*.

Ecology. *Hyalorbilia polypori* was found on rotten wood (very rarely bark) of hygric branches and logs of various gymno- and mainly angiosperm trees and shrubs lying on the moist ground, sometimes on polypores and pyrenomycetes. Similar as *H. inflatula*, *H. polypori* grows predominantly on their underside. *H. polypori* was found in humid, atlantic to continental Europe, at colline to subalpine altitude from hemi- to oroboreal and supra- to orotemperate and orosubmediterranean. Vegetation types include shady deciduous or mixed forests such as *Querco-Fagetea* (*?Stellario holosteae-Fagetum*, *Abieto-Fagetum*), subalpine birch forest, e.g., in ravines close to rivulets. In Macaronesia *H. polypori* was recorded in mesosub- to thermomediterranean (subhumid to) humid laurel forests (*Lauro novocanariensis-Perseetum indicae*) at four sites in the northeast of Tenerife (Anaga) and two in the north of Madeira.

Specimens included. **SWEDEN**: **Västerbotten**, 4.5 km SW of Saxnäs, Satsfjället, Pojken, 715 m, branch of *Betula pubescens*, on wood, 24.VII.2010, T. Læssøe (H.B. 9361). — **FINLAND**: **North Karelia**, 26 km SSW of Lieksa, 1.5 km SE of Koli, ENE of Forest Research Institute, ~180 m, on *Fomes fomentarius* on *Alnus incana*, 11.VIII.1995, K. Hyalorbilia texensis Baral & G. Marson, **sp**. **nov**., MB 813468 — Pls 68–69

Etymology: From the geographical origin, Texas (USA).
Typification: USA, Texas, Houston, branch of *Campsis* (?)*radicans*, 20.VI.1996, G. Marson (ex H.B. 5552b, M-0276419, holotype).
Misapplied name: Guo et al. (2014b), as *H. fusispora* (?= *H. texensis*).
Latin diagnosis: Hyalorbiliae polypori *similis sed ascosporae minores*. *Habitat ad corticem putridum siccum*, *etiam lignum*, *ramorum fruticis* Campsidis (?) radicantis *in zona subtropica humida Americae septentrionalis.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.2–0.6(–0.8) mm diam., 0.11–0.14 mm high (receptacle 0.07–0.1 → 0.06 mm), light cream-yellowish to orange-brownish, scarcely translucent, round, medium to strongly gelatinous, very scattered; disc slightly concave to flat with raised smooth margin; with ± distinct stipe 0.05–0.06 × 0.12–0.15 mm, superficial; dry dirty red-brown. **Asci** *28–34 × 5.6–6 µm, †25–30 × 4–4.4 µm, 8-spored, spores *2–3-seriate; **apex** (†) hemispherical to subconico-subtruncate; **base** unstalked, with croziers. **Ascospores** *5.2–6.5 × 1.3–1.5 µm, †(4–)4.5–6(–6.5) × 1.2–1.3(–1.4) µm, fusoid, sometimes fusoid(-clavate), ends rounded to obtuse, rarely one end subacute, straight to very slightly inequilateral; **SBs** (*) apparently absent. **Paraphyses** apically uninflated to slightly capitate(-clavate), terminal cells †13–17 × (2–)2.5–3.3 µm, lower cells †5–7 × 1.8–2.2 µm. **Medullary excipulum** 20–40 µm thick, of dense, non-gelatinized textura prismatica-angularis, indistinctly delimited. **Ectal excipulum** of thin-walled to slightly gelatinized t. angularis(-prismatica), 30–60 µm thick near base, cells †17–23 × 6–10 µm; at flanks of 20 µm thick horizontally oriented t. prismatica, near margin 10 µm thick, marginal cortical cells †9–12 × 4–5 µm. **Anchoring hyphae** abundant, †(2–)2.5–4(–5) µm wide (near insertion 5–6 µm), walls 0.2–0.3(–0.5)((–1)) µm thick, vertically radiating. **Exudate** over paraphyses and excipulum 0.2 µm thick, densely finely granular-warted. — **ANAMORPH**: brachyphoris-like (presumed, from natural substrate). **Conidiophores** not observed. A single **conidium** found, †46 × 2.7 µm, narrowly fusoid, slightly curved at apex, ?5-septate.

Habitat: decorticated to partially corticated, attached, 10–20 mm thick stems of *Campsis* (?)*radicans*, on 1 mm deep strongly decayed wood and mainly bark (periderm & bast), slightly greyed, covered by green algae. **Associated**: *Orbilia cejpii*, *O. hesperidea*. **Desiccation tolerance**: fully tolerant for at least 1–2 weeks. **Altitude**: 35 m a.s.l. **Geology**: Pleistocene clay and mud. **Phenology**: VI.

Taxonomic remarks. *Hyalorbilia texensis* is tentatively separated from *H. polypori*, *H. fusispora*, and *H. subfusispora* based on the living spores being smaller and eguttulate, from *H. polypori* also by desiccation-tolerant apothecia. *H. caucasica* differs in wider marginal cortical cells and shorter spores, and *H. ulicicola* in slightly shorter and wider spores with several distinct SBs, and in desiccation-sensitive apothecia. *H. juliae*

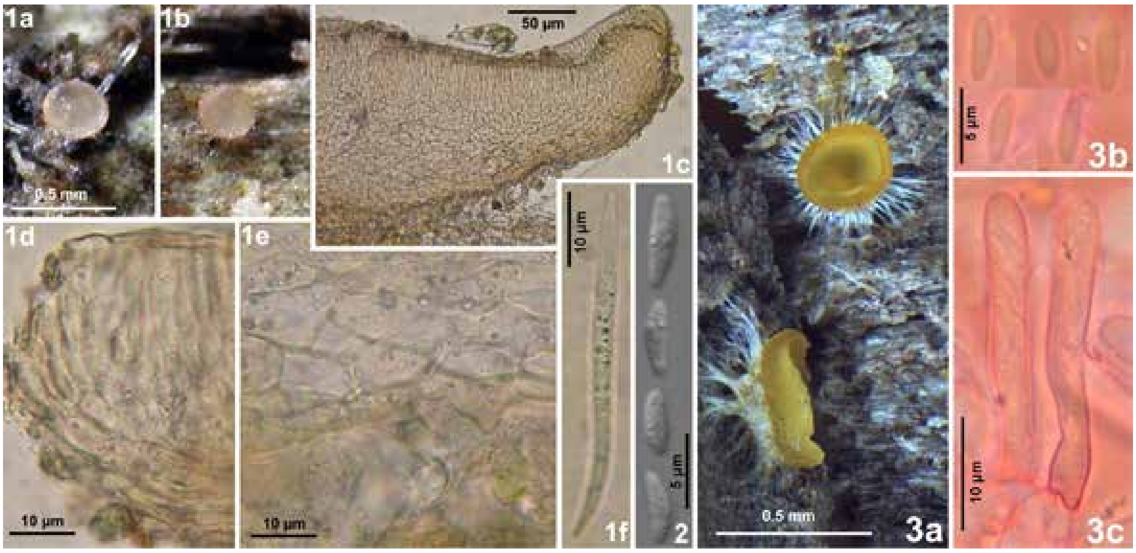

Plate 69. **1**. *Hyalorbilia texensis*; **2–3**. *H.* cf. *texensis*. – **1a–b**, **3a**. rehydrated apothecia; **1c**. apothecium in median section; **1d**. id., marginal ectal excipulum; **1e**. id., ectal excipulum at lower flanks; **3c**. asci; **2**, **3b**. ascospores; **1f**. conidium from substrate. – Dead state: **2** (in H_2O), **1c–f** (in KOH), **3b–c** in KOH+CR. – **2**: from Guo et al. (2014b, DIC), **3a–c**. from Quijada et al. (2014a). — **1a–f**. H.B. 5552b (holotype): USA, Texas, on *Campsis*; **2**. J.W.G. ym-j-179: China, Yunnan, on indet. tree; **3a–c**. CUP-MM 2126: Azores, Flores, on indet angiosperm.

differs in much longer spores. A similar sparse collection from Texas (285 km to the west, altitude 380 m higher) on *Vitis* (IVV: H.B. 5554c) differs in distinctly wider spores (*5–7.5 × 1.8–2 µm) with small to medium-sized drops and is tentatively included in *H. subfusispora*.

Not included collections. Eight Chinese collections reported by Guo et al. (2014b) under the name *H. fusispora* are mainly known in the dead state. Judging from spore size and shape (Pl. 69: 2, †4.2–6.3 × 1.3–1.8 µm) this could well belong to *H. texensis*. However, the asci are given much shorter (16.6–26.2 × 2.8–5.9 µm) and the apothecia which grew on hygric branches of indet. angiosperms or indet. trees attained a much larger size (0.3–1.5 mm). Guo et al. did not indicate which collection is figured on his fig. 3, but when he earlier sent this plate to us he referred it to ym-j-179 (J.W. Guo pers. comm.). Caution is advised with the published plate which is vertically 10 % shorter compared to the original plate. Measurements taken by us from the original plate confirmed those in the description: †4.3–6 × 1.3–1.5 µm, †18.7–20.3 × 3.4–3.7 µm, and 0.7–1.3 mm, respectively. The description includes also living spores containing 2 elongate terminal and several globose peripheral SBs, therefore, it is also mentioned under *H. ulicicola*.

A specimen from Azores (CUP-MM 2126) identified by Korf (1992) as *Orbilia inflatula* was reexamined by L. Quijada (Quijada et al. 2014a; Pl. 69: 3). The size of asci (†23.5–30 × 3.8–4 µm) and spores [†4–5(–5.8) × 1.3–1.6(–1.9) µm] fit quite well the North American *H. texensis*, but the specimen resembles also the smaller-spored collections of *H. polypori* from Tenerife reported by Quijada et al. (l.c.). Korf erroneously believed that the conspicuous subiculum was characteristic solely of *H. inflatula*.

Anamorph. The single fusoid conidium found near the apothecia is slightly narrower (†46 × 2.7 µm) than typical conidia of *Hyalorbilia* spp.

Ecology. *Hyalorbilia texensis* grew on rotten wood and bark of a xeric branch of *Campsis* (?)*radicans* cultivated in the northern suburb of Houston in the subtropical humid south of USA. The not included collections from Azores and China are from evergreen forests with a thermotemperate or subtropical humid climate, respectively.

Specimens included. **USA**: **Texas**, 32 km N of Houston, Motel 6, 35 m, branch of *Campsis* (?)*radicans*, on wood & bark, 20.VI.1996, G. Marson (ex H.B. 5552b M-0276419, **holotype**, anam. substr.).

Not included. **MACARONESIA**: **Azores**, **Flores**, ?SW of Cedros, Ribeira do Cascalho, Alagoa, ?200 m, indet. angiosperm, on wood, 13.IV.1978, R.P. Korf, L.M. Kohn & N. Korf, vid. L. Quijada (CUP-MM 2126, as *O. inflatula*, doc. vid.). — **CHINA**: **Yunnan**, **Yuxi**, Yimen, 54 km NW of Yuxi, 3 km NW of Fangtunxiang, Dalongkou, Longquan, 1750 m, branch of indet. tree, 23.VIII.2006, J.W. Guo (J.W.G. ym-j-179, YMFT, doc. vid.).

Hyalorbilia puertoricensis Baral, **sp. nov.**, MB 813469 — Pls 70–71

Etymology: named after the geographical origin, Puerto Rico (Middle America).
Typification: Puerto Rico, El Yunque, log of indet. angiosperm, 23.I.1996, D.H. Pfister, F.A. Harrington, M. Liftik, S. Hundorf & D.J. Lodge (ex D.H.P. PR 111, FH, holotype).

Latin diagnosis: Hyalorbiliae citrinae *similis sed ascosporae rectae*, *latiores*, *excipulum ectale textura prismatica crassitunicata*, *ad marginem textura angularis*, *valde gelatinosum.*

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.7–2.8 mm diam., 0.09–0.15 mm high (receptacle 0.08–0.11 → 0.05–0.06 mm), light chlorinaceous-yellow, translucent, round, slightly gelatinous, scattered to gregarious; disc medium concave to flat, margin ± thick, 20–40 µm rising above disc, even or often with fine lobes 5–20 × 40–70 µm; broadly attached to substrate, superficial; dry cupulate to flat with inrolled margin, light cream-yellowish to bright chlorinaceous-yellow. **Asci** †18–26 × 3.3–4.5 µm {2}, 8-spored, spores ~3-seriate; **apex** (†) hemispherical; **base** with very short, thick stalk arising from croziers {2}. **Ascospores** †(4–)4.5–5.5(–6.3) × 1.2–1.4 µm {2}, subcylindric, rarely slightly (fusoid-)clavate, ends rounded to obtuse, straight; **SBs** not seen in dead state; with 1–3 minute LBs. **Paraphyses** apically uninflated, terminal cells †18–25 × 1.4–2 µm {2}, lower cells †4.5–6.5 × 1.5–2.3 µm. **Medullary excipulum** 15–20 µm thick, of slightly to strongly gelatinized, dense textura prismatica-angularis, sharply delimited. **Ectal excipulum** from base to mid flanks of thick-walled, horizontal t. prismatica, 40–110 µm thick near base, cells †15–50 × 10–24 µm {1}, common walls 0.5–2 µm thick, frequently containing large **LBs** 2–10 µm diam.; 20 µm thick at mid flanks and margin, upper 100–140 µm of margin composed of a gelatinized t. globulosa-angularis (common walls 0.4–1.2 µm thick), marginal cortical cells †5–13.5 × 4–6 µm {1}, 5–9 µm wide in surface view, upper margin terminated by a 1–3 µm thick gel layer. **Anchoring hyphae** abundant, †(3–)4–6 µm wide {2} (near insertion 5.5–7.5 µm), walls (0.3–)0.5–1 µm thick {2}. **Exudate**

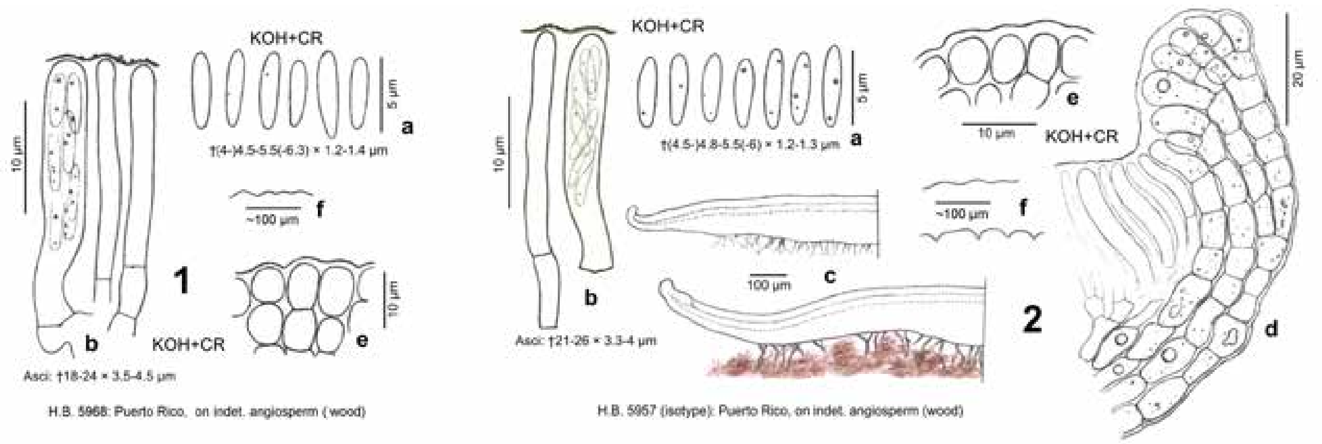

Plate 70. **1–2**: *Hyalorbilia puertoricensis*. – **a**. ascospores; **b**. asci (**1b**: showing crozier) and paraphyses; **c**. apothecia in median section; **d**. id., ectal excipulum at margin and mid flanks; **e**. margin in top view; **f**. id., undulating outline of apothecia.

over paraphyses 0.2 µm thick, continuous, smooth to finely rough; over margin and flanks externally smooth or with very indistinct warts. — **ANAMORPH**: unknown.

Habitat: probably lying on ground, decorticated logs of unidentified angiosperm trees {2}, on entirely or only 1 mm deep medium to strongly decayed wood {2}, on dark detritus or boring dust, no algae. **Associated**: *Orbilia nemaspora* {1}. **Desiccation tolerance**: unknown (probably sensitive). **Altitude**: 20–450 m a.s.l. **Phenology**: I (tropical belt).

Taxonomic remarks. *Hyalorbilia puertoricensis* seems to be closely related to *H. citrina* in having yellowish apothecia and a strongly gelatinized ectal excipulum that forms a projecting, sometimes finely undulating or lobate margin of thick-walled, ± isodiametric cells. The straight, much wider ascospores sharply segregate it from *H. citrina* and *H. japonica*. *H. inflatula*, *H. andina* and *H. oreadum* differ in a less or non-gelatinized ectal excipulum and a tendency to longer and narrower spores.

Variation. The two collections are microscopically very similar. They vary mainly in the excipular margin which is less gelatinized in the paratype (Pl. 70: 1e, 2d–e), the gel layer at upper margin 1–1.5 vs. 2–2.5 µm thick. In some apothecia of the holotype the margin forms distinct incisions while in the remaining apothecia it is only minutely wavy (Pl. 70: 1f, 2f).

Ecology. *Hyalorbilia puertoricensis* was collected on ± rotten wood of unidentified angiosperm trees and is only known from tropical humid rainforests in Puerto Rico (Caribbean belt of Middle America). The ecological data and large apothecia suggest that *H. puertoricensis* is a desiccation-sensitive species comparable to *H. citrina*.

Specimens included. **PUERTO RICO**: Sierra de Luquillo, El Yunque, ?7 km S of Rio Grande, Guzman Obajo Camino Los Tapia, ~450 m, log of indet. angiosperm, on wood, 23.I.1996, D.H. Pfister, F.A. Harrington, M. Liftik, S. Hundorf & D.J. Lodge (D.H.P. PR 111, FH, **holotype**, H.B. 5957 **isotype**). — N of El Yunque, 2.5 km SSW of Luquillo, near Rio Sabana, hill above chicken farm, 20 m, log of indet. angiosperm, on wood, 17.I.1996, D.H. Pfister, F.A. Harrington, D.J. Lodge & S. Hundorf (D.H.P. PR 31, FH, H.B. 5968 ø).

Hyalorbilia oreadum (Velen.) Baral, J.W. Guo & K.Q. Zhang, Mycosystema 33: 749 (2014) — Pls 72–74

≡ *Orbilia oreadum* Velen., Monogr. Discom. Bohem.: 100, pl. 11 fig. 26 (1934)

Etymology: derived from the climatic zone (montane).

Typification: Slovakia, Tatranská Lomnica, branch of *Pinus*, VIII.1926, A. Pilát (PRM 151736, holotype).

Description: — **TELEOMORPH**: **Apothecia** rehydrated 0.15–0.27 {T} or (0.2–)0.4–1(–2) mm diam. {1}, 0.1–0.125 mm high (receptacle 0.05–0.09 → 0.03–0.05 mm), whitish to pale yellowish-chlorinaceous, ± translucent, round but ± strongly lobate when large,

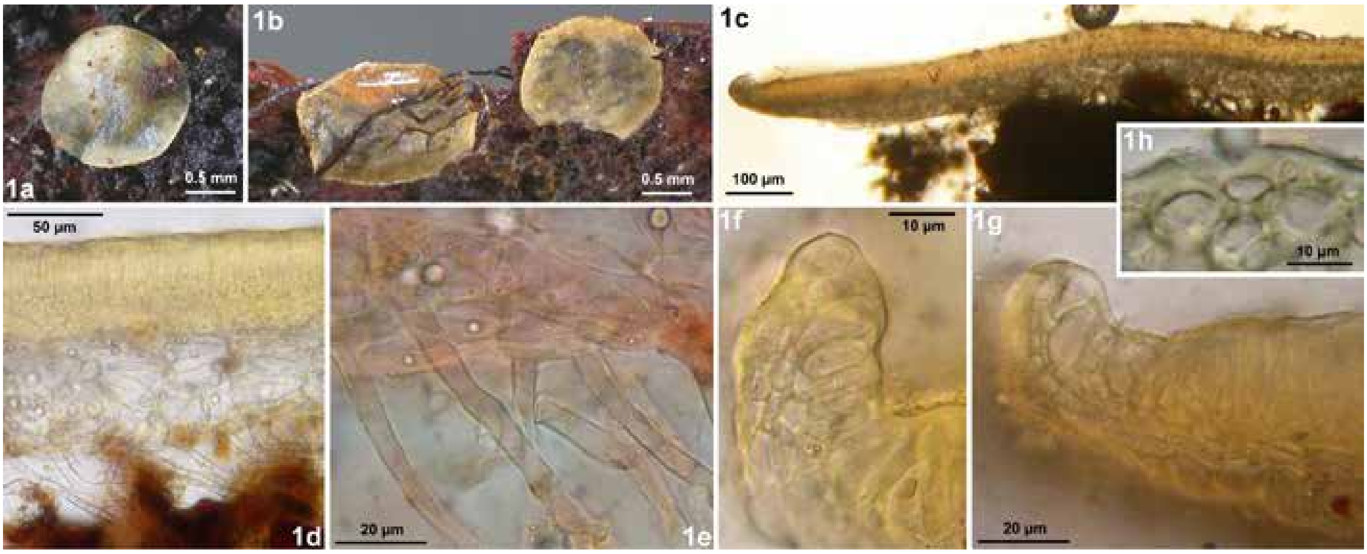

Plate 71. **1**: *Hyalorbilia puertoricensis*. – **1a–b**. rehydrated apothecia; **1c**. apothecium in median section; **1d**. id., central part of apothecium; **1f–g**. id., marginal ectal excipulum; **1h**. top view of marginal cells; **1e**. anchoring hyphae. – Dead state (in KOH, **1e** in KOH+CR). — **1a–h**. H.B. 5957 (isotype): Puerto Rico, on indet. angiosperm.

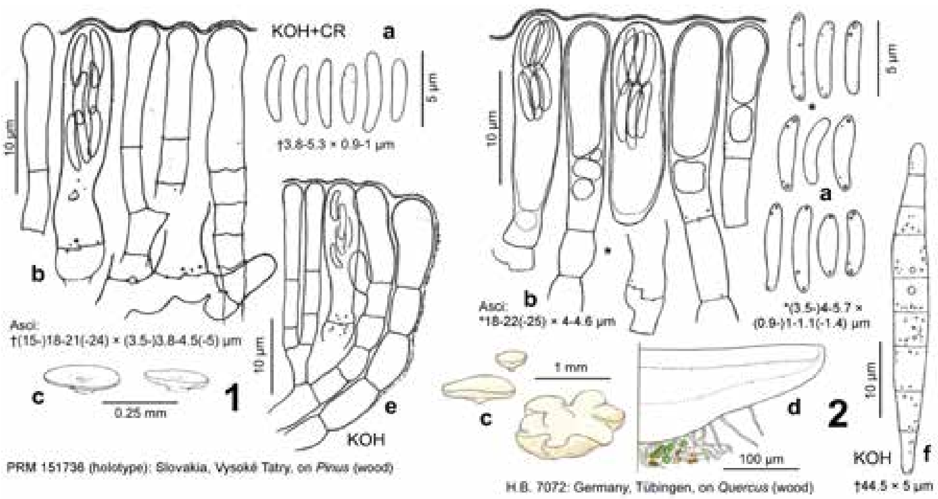

Plate 72. **1–2**: *Hyalorbilia oreadum*. – **a**. ascospores; **b**. asci (with croziers) and paraphyses; **c**. rehydrated apothecia; **d**. apothecium in median section; **e**. id., ectal excipulum at margin and mid flanks; **f**. conidium from substrate.

slightly gelatinous, ± gregarious over smaller or larger areas; disc (medium concave to) flat (to medium convex), margin thin, smooth; sessile or often with an abrupt stipe 0.02–0.08 × 0.06–0.15 µm, superficial. **Asci** *18–22(–25) × 4–4.6 µm {1}, †15–20 × 3–3.5 {1} or †(15–)18–21(–24) × (3.5–)3.8–4.5(–5) {T} µm, 8-spored, spores *4-seriate (in two superimposed bundles), pars sporifera *9.5–11 µm long; **apex** (†) ± hemispherical; **base** ± unstalked or with short, thick stalk, with croziers {2}, sometimes with small perforation. **Ascospores** *(3.5–)4–5.7 × (0.9–)1–1.1(–1.4) µm {1}, †3.8–5.3 × 0.9–1 µm {T}, subcylindrical or sometimes slightly fusoid or fusoid-clavate, both ends rounded to obtuse, straight to slightly, rarely medium curved; **SBs** *(0.1–)0.2 µm diam. {1}, globose, 1 at each end, sometimes absent. **Paraphyses** apically uninflated to slightly (rarely medium) clavate-capitate, terminal cells *12–18.5 × 3.5–6 µm {1}, †9–15 × 2–3.3(–4) µm {T}, lower cells *4–7 × 3–3.5 µm {1}, †2.5–6 × 1.8–3 µm {T}, sometimes branched near base. **Medullary excipulum** 10–15 {T} or 40 {1} µm thick, of dense, non-gelatinized textura globulosa-angularis-prismatica, medium sharply delimited. **Ectal excipulum** in stipe of vertically oriented t. globulosa-angularis-prismatica 50–80 µm thick, at flanks 25–30 µm, of horizontal t. prismatica(-angularis), cells thin- to firm-walled (common wall †0.2–0.4 µm thick), *17–25 × 10–16 or up to 30–80 × 14–30 µm {1}, †9–10 × 5–7 or 14–20 × 8–10 µm {T}, 8–10 µm thick at margin, marginal cortical cells †10–12.5 × 3–6 µm {2}, clavate, ± firm-walled, somewhat immersed in gel. **Anchoring hyphae** medium abundant, */†2–4 µm wide, near insertion */†3.8–5.5 µm wide, walls 0.2–0.3(–0.4) µm thick {2}, radiating. **VBs** in paraphyses medium refractive, subhyaline. **Exudate** over paraphyses and marginal excipulum 0.2–0.3 µm thick, continuous, smooth or very finely rough. **— ANAMORPH**: brachyphoris-like (presumed, from natural substrate {1}). **Conidiophores** not observed. A single **conidium** fusiform, straight, †44.5 × 5 µm, 8-septate.

Habitat: collected 4 m above the ground {1}, corticated or decorticated, 25–40 mm thick branches of *Quercus* sp. {1}, *Pinus* sp. {T}, on 0.3–1 mm deep or entirely strongly decayed wood {2}, not or slightly greyed, with or without algae. **Associated**: *Rhizodiscina lignyota* {1}, ?*Lasiosphaeriaceae* {1}. **Desiccation tolerance**: only spores survived for 5 days in the herbarium. **Altitude**: 345–1800 m a.s.l. **Geology**: Slovakia: Pleistocene fluviatile sandy clay; Germany: Keuper (Stubensandstein). **Phenology**: VIII, XI.

Taxonomic remarks. Besides the holotype (on *Pinus*), only one further collection (on *Quercus*) was included in the description of *Hyalorbilia oreadum*. *H. inflatula* closely resembles *H. oreadum*, e.g., in the rather straight, narrowly cylindrical ascospores that are arranged in the living asci in two superimposed bundles, but differs in distinctly longer spores. *H. japonica* has about the same spore length as *H. oreadum* but differs in slightly narrower spores, more thick-walled anchoring hyphae, and a different geographical and climatic distribution. However, some collections appear to be intermediate (see under *H. japonica*, p. 355). *H. puertoricensis* and *H. resinae* both resemble *H. oreadum* in the spores. The former differs in thick-walled marginal excipular cells and wider spores, the latter in apically more inflated paraphyses, wider spores and asci, and very minute apothecia. Since all these taxa have rarely been recorded, their taxonomic limits need to be explored from further collections. *H. herbicola* resembles *H. oreadum* in the spores, but differs in various respects (see p. 438).

Variation. The *Quercus* collection from southern Germany differs from the holotype in larger apothecia, also in somewhat longer and wider terminal cells of paraphyses, and in smaller asci, but this might fall in the scope of variation of the species. Great variation is noted in the size of the ectal excipular cells at the flanks between the two samples, but this variation is also observed within each population in correlation with apothecial size.

Type studies. The holotype of *H. oreadum* contains about a hundred, rehydrated flat to medium convex, fully mature apothecia, which Velenovský (1934) reported as 0.1–0.2 mm, gregarious, pale yellow. The author described and depicted the ascospores as filiform, strongly curved (± semicircular), 3–4 µm long. On his manuscript sheet the spores are drawn distinctly wider than in the published drawing (see Pl. 73). Svrček (1954: 17) revised the holotype and found only slightly curved or sometimes even almost straight spores 3–5.5 × 0.8 µm. Due to the strong discrepancy in spore curvature he doubted that Velenovský's drawing was correct. In the present study 5 apothecia of the holotype were examined, and the spores, though seen only inside the asci, fully concur with Svrček's observation (Pl. 72: 1).

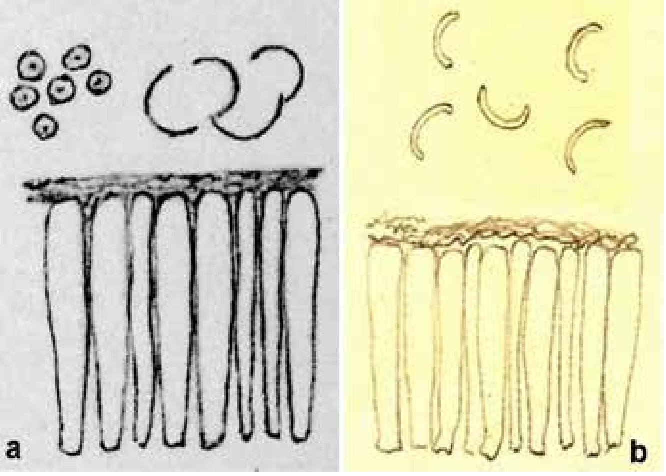

Plate 73. *Hyalorbilia oreadum*. – **a**. from Velenovský's published plate (1934: pl. 11 fig. 26); **b**. from his original drawing.

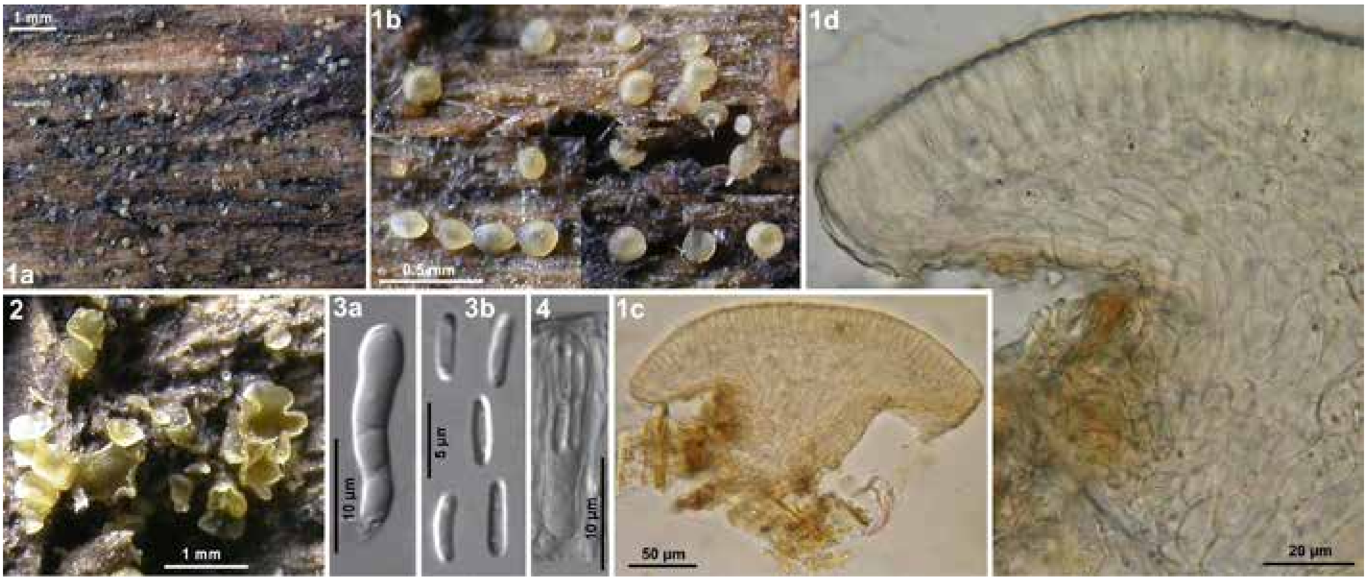

Plate 74. **1–2**: *Hyalorbilia oreadum*; **3–4**: *H.* cf. *oreadum*. – **1a–b**, **2**. rehydrated apothecia (**1**: after 79 years, **2**: after 3 years); **1c–d**. apothecia in median section (in KOH); **3a**. paraphysis; **3b**. ascospores; **4**. mature ascus. – Dead state: **1–2**, living state: **3–4**. – **3–4**: phot. J.W. Guo (DIC; **3**: from Guo at al. 2014a). — **1a–d**. H.B. 6188 (holotype): Slovakia, Vysoké Tatry, on *Pinus*; **2**. H.B. 7072a: Germany, Tübingen, on *Quercus*; **3a–b**. Guo et al. (2014a): China (data not specified), on indet. tree; **4**. J.W.G. zcw-j-2: China, Sichuan, on indet. tree.

Despite the rather homogeneous appearance of the dense population in the holotype, a mixture of two species cannot be excluded with certainty. Considering such a possibility, the name *H. oreadum* is to be considered as tentatively applied here. The more or less semicircular spores seen by Velenovský could belong to the Asian *H. arcuata*, or perhaps to *H. berberidis* in the case that his spore measurements are erroneous. Since Velenovský did not draw the spores within the asci he might also have described stray spores.

Not included collections. Five Chinese collections assigned to *H. oreadum* in Guo et al. (2014a) show apothecia 0.3–1 mm diam., asci †18.5–21.6 × 3.4–4.2 µm, and spores *(4.7–)5.0–6.1 × (0.8–)0.9–1.1(–1.3) µm (a range of 4.2–5 × 1.1–1.2 µm is obtained when evaluated from their scale of fig. 2). The droplets in the spores are very minute so that it is difficult to decide whether the polar ones are SBs or LBs. The ectal excipular cells at the flanks were rather small (†4.2–6.4 × 3.1–5 µm), but they attain 9 µm length on their fig. 2B. Guo et al. (2014a) did not indicate from which collection their data were gained and to which the photo plate refers (another unpublished plate refers to zcw-j-2, see IVV). We refrained from including these samples in the description, although we agree that the available data suggest conspecificity with European *H. oreadum*. However, we see problems in separating *H. oreadum* from *H. japonica*, for instance to their *H. japonica* gz-5 (see p. 354). Also a collection from which the anamorph of *Orbilia xiushanensis* (YMF 1.03033), a member of series *Orbilia*, was erroneously thought to originate (Zhang et al. pers. comm.), could belong here (IVV: 15.VIII.2008, see also p. 1425).

Guo et al.'s (2014a) article was published by four authors, though without involvement of its second author (H.O.B.).

Anamorph. The single conidium found on the natural substrate in our collection of *H. oreadum* (Pl. 72: 2f) matches those observed in *H. inflatula*.

Ecology. *Hyalorbilia oreadum* appears to be a rare species. The two known collections from cold-temperate humid, subcontinental Europe are otherwise ecologically quite different: the type was on rotten wood of a ?hygric branch of *Pinus* in a montane forest of the High Tatras, the other on wood of a xeric branch of *Quercus* in a colline, thermophilous broad-leaved forest with *Robinia*. The *Pinus* branch was possibly collected from the ground, as can be seen from the appearance of the wood. The slightly greyed and algae-covered *Quercus* branch was hanging 4 m above the ground, and the apothecia grew only in the area of a small and deep cavity probably caused by picking of a bird. Despite growing on a dry branch, the large apothecia surprisingly did not survive repeated desiccation. Not included collections from southern China were on hygric branches of unidentified trees, in evergreen broad-leaved or mixed orotemperate to subtropical humid (winter-dry) forests.

Specimens included. **GERMANY**: **Baden-Württemberg**, Schönbuch, 5 km ENE of Tübingen, 1 km SE of Pfrondorf, SE of Rauhalde, 345 m, branch of *Quercus*, on wood, 18.XI.2001, H.O. Baral (H.B. 7072a, anam. substr.). — **SLOVAKIA**: **Prešov**, Vysoké Tatry, above Tatranská Lomnica, 1800 m, branch of *Pinus*, on wood, VIII.1926, A. Pilát (PRM 151736, **holotype**, H.B. 6188 ø).

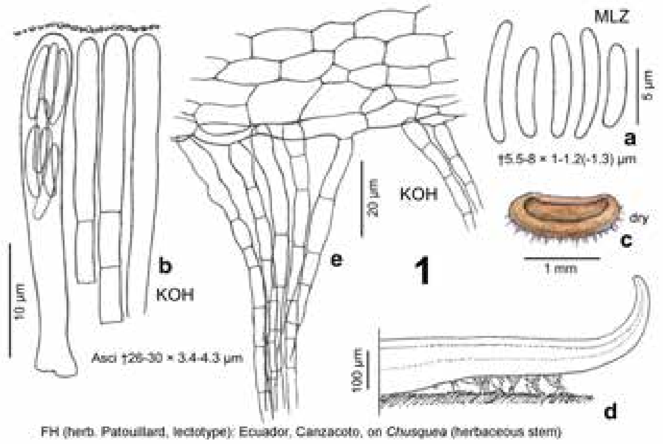
Not included. **CHINA**: **Sichuan**, **Ngawa** (Aba), Jiuzhaigou, 2000–2500 m, branch of indet. tree, 8.X.2006, J.W. Guo (J.W.G. zcw-j-2, YMFT, doc. vid.). – **Yunnan**, **Kunming**, Songming, branch of indet. tree, 6-IX.2006, J.W. Guo (J.W.G. azy-j-1, YMFT). – **Dali**, Yongping, Baotai Shan, branch of indet. tree, 14.VI.2006, J.W. Guo (J.W.G. yp-j-2, YMFT). – **Yuxi**, Yimen, Dalong Shan, branch of indet. tree, 23.VIII.2006, J.W. Guo (J.W.G. ym-j-166, YMFT). – Xinping, ?18 km S of Xinping, Mopanshan, ?1800 m, branch of indet. tree, V.2009, J.W. Guo (J.W.G. mp2-34, YMFT). – Tonghai, 35 km SE of Yuxi, ~2 km S of Tonghai, Xiushan Forest Park, ~1900 m, twigs of indet. angiosperm, 15.VIII.2008, Z.F. Yu & S.F. Li (YMFT 1.03033, but the culture YMF 1.03033 is *Orbilia xiushanensis*). (Guo et al. 2014a did not specify which collection was illustrated in their fig. 2.).

Hyalorbilia andina (Pat.) Baral, J.W. Guo & K.Q. Zhang, in Guo et al., Mycosystema 33: 747 (2014) — Pls 75–76

≡ *Orbilia andina* Pat., in Patouillard & Lagerheim, Bull. Soc. Mycol. Fr. 11: 218 (1895)

Etymology: named after the geographical origin, the Andes (South America).
Typification: Ecuador, San Jorge, stem of *Chusquea*, VII.1892, G. Lagerheim (FH, lectotype, designated here, MBT202370).
Misinterpretation of *H. andina*: Liu (2006: 26), = *H. arcuata*.

Description: — **TELEOMORPH**: **Apothecia** dry 1–3.8 mm diam. (up to 5 mm in protologue), rehydrated 0.15 mm high (receptacle 0.09–0.1 → 0.04 mm), [protologue: amber-coloured, translucent,



FH (herb. Patouillard, lectotype): Ecuador, Canzacoto, on *Chusquea* (herbaceous stem)

Plate 75. **1**: *Hyalorbilia andina*. – **1a**. ascospores; **1b**. asci and paraphyses; **1c**. apothecium (dry); **1d**. apothecium in median section; **1e**. id., ectal excipulum at lower flanks, with anchoring hyphae.

moderately gelatinous], round; disc flat but concave near strongly upwards curved, smooth margin, ± sessile, superficial; dry honey-yellow-ochraceous, margin strongly inrolled, with white subiculum. **Asci** †26–30 × 3.4–4.3 µm, 8-spored, spores 4-seriate; **apex** (†) hemispherical; **base** with or without ± thick stalk, with croziers. **Ascospores** †5.5–8 × 1–1.3 µm, cylindrical, sometimes very slightly narrower towards base, ends rounded, consistently slightly curved; **SBs** not seen in dead state. **Paraphyses** apically uninflated, terminal cells †15–18 × 2–2.5 µm, lower cells ~5–5.5 × 1.6–1.8 µm. **Medullary excipulum** ~50–60 µm thick, not examined. **Ectal excipulum** at base of thin-walled textura angularis 60–70 µm thick, at flanks of horizontal t. prismatica, cells †10–23 × 6–15 µm; at mid flanks and margin of thin-walled t. porrecta ~10 µm thick. **Anchoring hyphae** very abundant, †3.5–5 µm wide, walls 0.3 µm thick, forming long radiating strands. **Exudate** over paraphyses 0.2–0.4 µm thick, granular-cloddy. **— ANAMORPH**: unknown.

Habitat: on dead, medium decayed, 15 mm thick herbaceous stem of *Chusquea* sp. **Associated**: none observed. **Desiccation tolerance**: unknown. **Altitude**: ?1940 m a.s.l. **Phenology**: VII (tropical belt).

Taxonomic remarks. *Hyalorbilia andina* is tentatively accepted as distinct from *H. inflatula* because of its broader ascospores which are consistently slightly curved. With an inrolled margin of hyphoid elements (textura porrecta), *H. andina* resembles those populations of *H. inflatula* with narrow marginal cortical cells. Some collections of *H. inflatula* resemble *O. andina* in their cylindrical instead of narrowly fusoid spores, e. g., the examined syntype of *Orbilia sinuosa*, but these tend to have somewhat shorter and narrower, also less distinctly curved spores. A species mainly known from Europe, *H. polypori*, differs from *H. andina* in smaller apothecia with a hardly raised margin, and in wider, straight spores. The spores in the holotype of *O. abietina*, tentatively referred here to synonymy with *H. polypori*, resemble those of *H. andina*, but the small (0.3–0.7 mm) and flat, stipitate apothecia fit more *H. polypori*.

Type studies. In the protologue Patouillard (1895) assigned at least two collections to *Orbilia andina*, one on *Chusquea* which bears Patouillard's original sketch and on which the present redescription is based, and another on an apparently unidentified host from the same locality which was not received. In the same paper, Patouillard also described *O. andina* var. *lateritia* which is referred to synonymy with *H. citrina* in the present study.

Patouillard's data on the label of the *Chusquea* collection slightly deviate from the protologue: asci 23–30 × 6 µm (23–33 × 6–7 µm in the protologue), excipular cells 20–26 × 13 µm (20–30 × 13–15 µm), anchoring hyphae 6 µm wide (60–150 × 6–8 µm). The sketch on the *Chusquea* label figures acicular, slightly curved spores of rather equal length (no size indicated), whereas the protologue says 'straight or slightly curved, 5–13 × 1 µm'.

When erecting the new genus *Orbiliaster*, Dennis (1954: 294, fig. 6 H) briefly treated *O. andina* and pointed out that the 'hairs' mentioned in the protologue do not emerge from the margin but are, in fact, anchoring hyphae growing out from the lower part of the excipulum. Dennis mentioned several collections (probably all from K) which were referred by Patouillard to *O. andina* (one on a 'log'), and for which different spore measurements were noted by Patouillard (5–7 × 1 and 13 × 1 µm). This high variation and the different substrates suggest that the included specimens were not conspecific. We here designate the *Chusquea* specimen in FH as **lectotype** of *H. andina*.

Dennis (1954) appears to have figured the *Chusquea* collection, for which he found narrow, slightly allantoid spores (no size given, see Fig. 159H). Later, Dennis (1970: 352) referred *O. andina* (the *Chusquea* collection) to synonymy with *Orbilia auricolor* (s.auct., = *H. inflatula*). The data given there for asci (22–23 × 4–5 µm) and spores (5–6 × 0.5 µm) deviate from the here presented values (Pl. 75) especially in a much shorter ascus length and in much too narrow spores.

Misinterpretation. Six Chinese specimens named *H. andina* by Liu (2006) have rather strongly curved spores which fit *H. arcuata* (for more details see p. 377).

Not included collections. Three Chinese collections (Yunnan, hygric branches of unidentified trees) were referred by Guo et al. (2014a) to *H. andina* (Pl. 76). They resemble the type in their slightly allantoid spores *5.7–7.3 × 1–1.2(–1.4) µm, but the asci were said to be much shorter (†17–22.5 × 2.9–4.3 µm) and the translucent white apothecia only 0.3–1 mm diam. when fresh, almost flat, without a raised margin in median section. Together with ecological deviations, conspecificity of these records with the type remains uncertain. The ascospores contained in the living state 1–3 globose SBs of 0.3–0.7 µm diam. near each end. Guo et al. stressed the almost isodiametrical cells of the ectal excipulum in the Chinese specimens, and their similarity to *H. inflatula* and *H. erythrostigma*. These findings are in contrast to the present study which presents prismatic cells for *H. inflatula* as well as the type of *H. andina*.

It must be mentioned that Guo et al.'s article was written and published without involvement of its second author (H.O.B.). Because of this, the article does not mention and discuss the here presented reexamination of the type of *H. andina*.

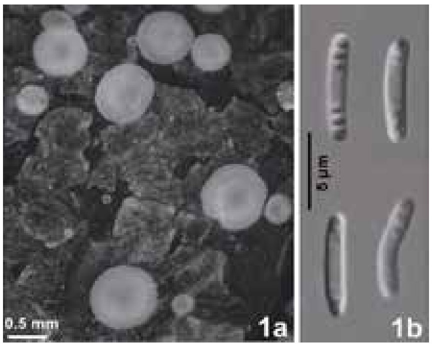


Plate 76. **1**: *Hyalorbilia* cf. *andina*. – **1a**. fresh apothecia; **1b**. ascospores (3 in living state). **— 1a–b**: China, on indet. tree (phot. Guo et al. 2014a).

Ecology. The lectotype of *Hyalorbilia andina* grew on herbaceous stems of *Chusquea* (*Bambusoideae*) under a subtropical humid highland climate in the northwest of South America. The not included Chinese collections were on hygric (angiosperm) branches of unidentified trees in subtropical humid southern China.

Specimens included. **ECUADOR**: **Pichincha**, Quito, ?30 km SW of San Jorge, Canzacoto, ?1940 m, stem of *Chusquea*, VII.1892, G. Lagerheim (FH, **lectotype**, H.B. 5748 ø).

Not included. **CHINA**: **Yunnan**, **Dali**, Yongping, ~25 km SSW of Yongping, Baotai Shan, ~1600 m, branch of indet. tree, 14.VI.2006, J.W. Guo (J.W.G. jgs-j-5, YMFT). – **Wenshan**, locality not stated, branch of indet. tree, 30.VI.2006, J.W. Guo (J.W.G. ws-j-5, YMFT). – **Jiangsu**, **Nanjing**, Zijinshan, ?200 m, branch of indet. angiosperm, IX.2009, J.W. Guo (J.W.G. zjs-3, zjs-32, YMFT). (Not specified by Guo et al. 2014a: fig. 1 which collection was illustrated.)

Description: — **TELEOMORPH**: **Apothecia** fresh (0.2–)0.4–2(–4)((–5)) mm diam., 0.1–0.21(–0.4) mm high (receptacle 0.07–0.16 mm thick, at margin 0.04–0.06 mm), pale (yellowish-)chlorinaceous(-cream) to sometimes light yellow-chlorinaceous, rarely whitish or carneous when young, translucent, round or sometimes ± undulating to lobate when large, slightly gelatinous, scattered or often subgregarious, rarely densely aggregated; disc at first strongly concave, deeply to shallowly cupulate, then cyathiform to saucer-shaped and often with ± distinct concentric rings, also ± flat from the beginning, outermost margin not or up to 20 µm rising above disc, smooth; broadly sessile or with an indistinct to distinct, obconical stipe 0.05–0.3 × 0.1–0.7 mm, superficial; dry light to bright honey-yellow-chlorinaceous to ochre-amber or orange-brown, margin of larger apothecia incurved and covering the disc, often with a conspicuous white subiculum at apothecial base (invisible in hydrated state), senescent dirty reddish-brownish. **Asci** *((13–))(16–)20–27 {22} or 25–32(–38) {38} or (27–)32–38(–42)((–48)) {6} × (3.8–)4–5.3(–6) µm {~56}, †(17–)19–28(–30) × (2.8–)3.2–4.5(–5) µm {28}, 8-spored, spores *(3–)4(–5)-seriate, mostly in two superimposed bundles, pars sporifera *(11–)13–16(–17)((–20)) µm long; **apex** (†) hemispherical to slightly (rarely medium) truncate; **base** with or without very short, thick stalk arising from croziers {32} without or rarely with small round perforation. **Ascospores** *((4.5–))(5–)5.5–7.5(–8.5)((–9)) × (0.8–)0.9–1.2(–1.3)((–1.4)) µm {91}, †((4.2–))(5–)5.5–7(–8)((–9)) × (0.7–)0.8–1.1(–1.2) µm {~58}, narrowly (sub)cylindrical to fusoid, rarely very slightly heteropolar, ends rounded to obtuse, straight to very slightly curved, only exceptionally slightly helicoid; 1–2(–3) globose **SBs** ~0.3–0.4 µm diam. and 1–3 minute LBs at each end. **Paraphyses** apically uninflated or slightly clavate-capitate(-spathulate), terminal cells *15–30 × 2.5–4.5 µm {7}, †15–21(–28) {3} × (1.5–)1.8–3(–3.5) µm wide {6}, lower cells *5–11 × 2–3.5(–4) µm {3}, †4–8(–10) × 1.5–2 {3}; unbranched. **Medullary excipulum** ~20–110 µm thick in centre, of medium to very dense textura globulosa-prismatica(-intricata), (*) non–gelatinized, (†) slightly or partly medium to strongly gelatinized, towards margin 15–30 µm thick, of more horizontal t. prismatica-porrecta or t. intricata, only here medium to very sharply delimited. **Ectal excipulum** near base 50–160 µm thick, of (indistinctly) vertically oriented t. (prismatica-)angularis, cells *(10–)15–50(–60) × 10–27(–32) µm {6}, †27–43 × 10-19 {1}, not or slightly to medium gelatinized, common walls */†(0.2–)0.5–1(–1.5) µm thick, rarely †0.8–2(–3) µm {3}; from lower flanks up to margin of horizontal t. prismatica, 20–45(–

60) µm thick at flanks, cells */†10–30 × (5–)6–13 µm {6}, thin- to firm-walled, 10–20 µm thick at margin, marginal cortical cells in median section or surface view */†(7–)9–16(–22) {25} × ((2–))(3–)4–6(–7) {17} or (5–)6–12(–16) µm {16}, cylindrical to clavate or obovoid, ± thin-walled (0.2–0.5 µm), immersed in thin gel (wall 0.5–1.3 µm thick including gel). **Anchoring hyphae** sparse to usually abundant, radiating, ± straight, */†(2–)3–5(–6.5) µm wide {39}, near attachment up to 5–7 µm, walls 0.2–0.5(–0.8) {35} or (0.2–)0.5–1(–1.3) {8} µm thick, individual cells 8–22 µm long. **VBs** in terminal and often also lower cells of paraphyses (very) pale chlorinaceous (multiguttulate), medium-refractive, later low-refractive and fusing to angular or very elongate bodies. **Exudate** over paraphyses (0.2–)0.3–0.5(–1) µm thick, continuous, smooth or mostly strongly warted, very pale yellowish-chlorinaceous; over margin and flanks 0.3–1 µm thick, finely warted or sometimes smooth, hyaline to very pale chlorinaceous, very rarely brownish. — **ANAMORPH**: brachyphoris-like (from ascocarp in Petri dish {1} and from natural substrate {24}). **Conidiophores** *~12–23 × 2.5–3.7 µm, 2 µm at the tip, unbranched or sometimes branched, conidiogenous cell often sympodial (with a lateral scar). **Conidia** fusoid to fusiform, straight, *(33–)40–70(–83) × (3.5–)4–8(–9) µm {13}, †37–72 × 4–7 µm {7}, (3–)4–8(–12)-septate, living conidia with many minute, often peripheral guttules (LBs, KOH-resistant), usually also with some larger refractive globose **SCBs** (0.5–1.7 µm diam) {8} which disappear in KOH.

Habitat: lying on ± moist ground, rarely 0.5–2.5 m above the ground, corticated, more rarely decorticated, 14–40 mm thick branches, also logs or stumps, of *Abies alba* {2}, *A. nordmanniana* {1}, *Acacia* sp. {1}, *Acer* sp. {3/1}, *A. campestre* {1}, *A. pseudoplatanus* {2}, *Alnus* sp. {3}, *A. alnobetula* {1}, *A. glutinosa* {5}, *A. incana* {1}, *Betula* sp. {9/1}, *B. pubescens* subsp. *tortuosa* {2}, *Carpinus betulus* {2}, *Castanea sativa* {2}, *Cornus sanguinea* {1}, *Corylus avellana* {6}, *Cytisus scoparius* {1}, *Euonymus europaeus* {1}, *Fagus sylvatica* {27}, *F. sylvatica* var. *moesiaca* {1}, *Fagus orientalis* {1}, *Frangula alnus* {1}, *Fraxinus* sp. {1}, *F. excelsior* {15}, *Ilex aquifolium* {1}, *Juglans regia* {1}, *Malus domestica* {1}, *Ocotea foetens* {1}, *Picea abies* {1}, *Pinus* sp. {1}, *P. sylvestris* {2}, *Populus* sp. {4}, *P. alba* {1}, *P. ?canadensis* {1}, *P. tremula* {1}, *Prunus avium* {1}, *P. serotina* {1}, *P. spinosa* {3}, *Pyrus communis* {1}, *Quercus* sp. {14}, *Q. cerris* {1}, *Q. ilex* {3}, *Q. robur* {2}, *Rosa* sp. {1}, *Salix* sp. {4/5}, *S. ?atrocinerea* {1}, *Sorbus aria* {2}, *S. aucuparia* {1/3}, *Tilia* sp. {6}, *T. cordata* {1}, *T. platyphyllos* {3}, *Ulex europaeus* {5}, *U. minor* {2}, indet. angiosperms {17/2}, on 0.5–3 mm deep medium to strongly decayed bark {95} (bast and periderm) or wood {100}, on upper, lateral or mainly underside of logs, also on inner surface of bark, substrate partly dark brown to blackish, no green algae; on petiole of *Arecales* {1}; sometimes on ± old stromata of *Daldinia* sp. {1}, *Diatrype stigma* {2/3}, *Diatrypella favacea* {1}, *Eutypa ?lata* {1}, *Hypoxylon fragiforme* {4/1}, *Jackrogersella multiformis* {1}, *Menispora glauca* {1}, *Rosellinia* sp. {1}, or on basidiomata of indet. perennial basidiomycete {1}, *Cerioporus mollis* {1}, *Cyathus striatus* {1}, *Fomes fomentarius* {3}, *Ganoderma applanatum* {3}, *Schizopora paradoxa* {1}, *Trametes hirsuta* {1}, *T. versicolor* {1}. **Associated** *Ascocoryne cylichnium* {1}, *A. solitaria* {1}, *Astrosphaeriella* sp. {1}, *Brachysporium obovatum* {2}, *Cacumisporium capitulatum* {1}, *Calycellina* sp. {1}, *Calycina citrina* {1}, *Capronia* sp. {1}, *C. pilosella* {1}, *Claussenomyces atrovirens* {1}, *Cosmospora ?episphaeria* {1}, *Cryptadelphia brevior* {1}, *Dematioscypha delicata* {1}, *D. olivacea* {1}, *Endoxyla cirrhosa* {1}, *Flagelloscypha minutissima* {1}, *Glyphium elatum* {1}, *Hamatocanthoscypha laricionis* {1}, *Hymenoscyphus phiala* {1}, *Hyalorbilia berberidis* {2}, *H. fusispora* {1}, *H. juliae* {2}, *H. polypori* (1), *Hyaloscypha leucostigma* {1}, *H. quercicola* {1}, *Lachnum impudicum* {1}, *L. subvirgineum* {1}, *L. virgineum* {1}, *Menispora glauca* {1}, *Mollisia* sp. {2}, *M. cinerea* {1}, *M. ?oblonga* {1}, *M. prunicola* {1}, *Nectria* sp. {1}, *Orbilia auricolor* {1}, *O. crenatomarginata* {1}, *O. eucalypti* {4}, *O. naumburgensis* {4}, *O. subclavuliformis* {1}, *O. subsphaerospora* {1}, *O. ?tremulae* {1}, *O. xanthostigma* {1}, *Protounguicularia transiens* {1}, *Polydesmia pruinosa* {1}, *Resupinatus applicatus* {1}, *Rhizodiscina lignyota* {1}, *Scutellinia crinita* {1}, *Troposporella fumosa* {1}, *Tubeufia cerea* {2}, *Tulasnella cystidiophora* {1}. **Desiccation tolerance**: hymenial elements survive for 1 day or not even 2 hours in dry state, cells of medullary and ectal excipulum still viable after 4–7 days (narrow marginal cells), in specimens growing on still-attached branches even after 4 months; conidia sometimes viable after 4 months {H.B. 7623}. **Altitude**: 2–1620 m a.s.l. (Europe), 400–850 m (northeastern China), 1300–3500 m (western China), 180–1500 m (southern China), 5–270 m (eastern Australia). **Geology**: Ordovician, Devonian & Carboniferous sand-, silt- & mudstone, Permian (Rotliegend), Buntsandstein, Muschelkalk, Keuper (sand & marlstone), Jurassic & Cretaceous shale, sand-, lime- & marlstone, dolomite, Tertiary molasse, Pleistocene sand & gravel, loess, peat; granite, trachyte, basalt, dolerite, biotite-amphibolite, serpentinite, gneiss, mica schist. **Phenology**: throughout the year (especially from spring to autumn).

Phenology of *H. inflatula* (± temperate to boreal northern hemisphere)											
Jan	Feb	Mar	Apr	May	June	July	Aug	Sept	Oct	Nov	Dec
4	5	11	27	30	33	26	19	19	12	12	0

Taxonomic remarks. *Hyalorbilia inflatula* is characterized by comparatively large, often cupulate but also flat, pale chlorinaceous or yellowish apothecia, more or less straight, rather small and narrow, cylindrical to narrowly fusoid ascospores, and a mostly hygric habitat. In the living mature asci the spores mostly form two characteristic parallel, superimposed bundles of four conglutinated spores.

H. andina can tentatively be separated by its wider, slightly curved spores. The more subtropical *H. japonica* differs in shorter asci and spores. The temperate *H. fagi* and *H. tortuosa* and the tropical *H. citrina* differ in ± helicoid spores, the latter also in narrower spores and thick-walled marginal cortical cells. Intermediate forms were now and then observed between most of these taxa, however.

Variation. Extraordinary variation among the many collections here referred to H. *inflatula* was particularly noted in width of marginal excipular cells, length of asci and spores, and apothecial shape. As an extreme example, the largest asci were observed in a specimen with narrow marginal cells on *Fomes* from Bad Reichenhall [H.B. 7758: *36–40(–42)((–48)) × 4.6–5.3 µm], and the smallest asci in one with broad marginal cells on *Sorbus* from Chemnitz [H.B. 8221: *(13–)16–21 × (3.8–)4.2–4.7(–5) µm]. In correlation with this huge difference in ascus volume, also the spores showed a very different size: *(5–)7.5–8.7 × 1.2–1.3(–1.4) µm and *(3.7–)4.5–5.5(–6) × 1(–1.1) µm, respectively. It is, therefore, well possible that the present concept of *H. inflatula* includes an aggregate of different taxa, a view which is confirmed by molecular data (see below). Yet, a separation based on morphological traits of either teleomorph or anamorph proved so far quite impracticable, since clear limits and correlations of the observed features could not be found.

In another collection on *Alnus* from Chemnitz (H.B. 8882a/b), two different variants of *H. inflatula* s.l. grew intermingled. One (a) shows wide marginal cells (mainly *7–11 µm) a smooth hymenial exudate, and rather small asci and spores (Pls 77: 9; 78: 2a–d; 80: 1), the other (b) narrow marginal cells (mainly *3–5 µm), a warted hymenial exudate, and slightly larger asci and larger, especially wider spores (Pls 77: 6: 78: 2a–c, e; 81: 12). The two variants are even macroscopically different: in (a) the apothecia are almost flat, watery-white, and 0.3–1 mm diam., while in (b) they are cupulate, pale chlorinaceous, and only 0.3–0.5 mm diam., but with a thicker flesh. In contrast to the above extreme example, ascus and spore size strongly

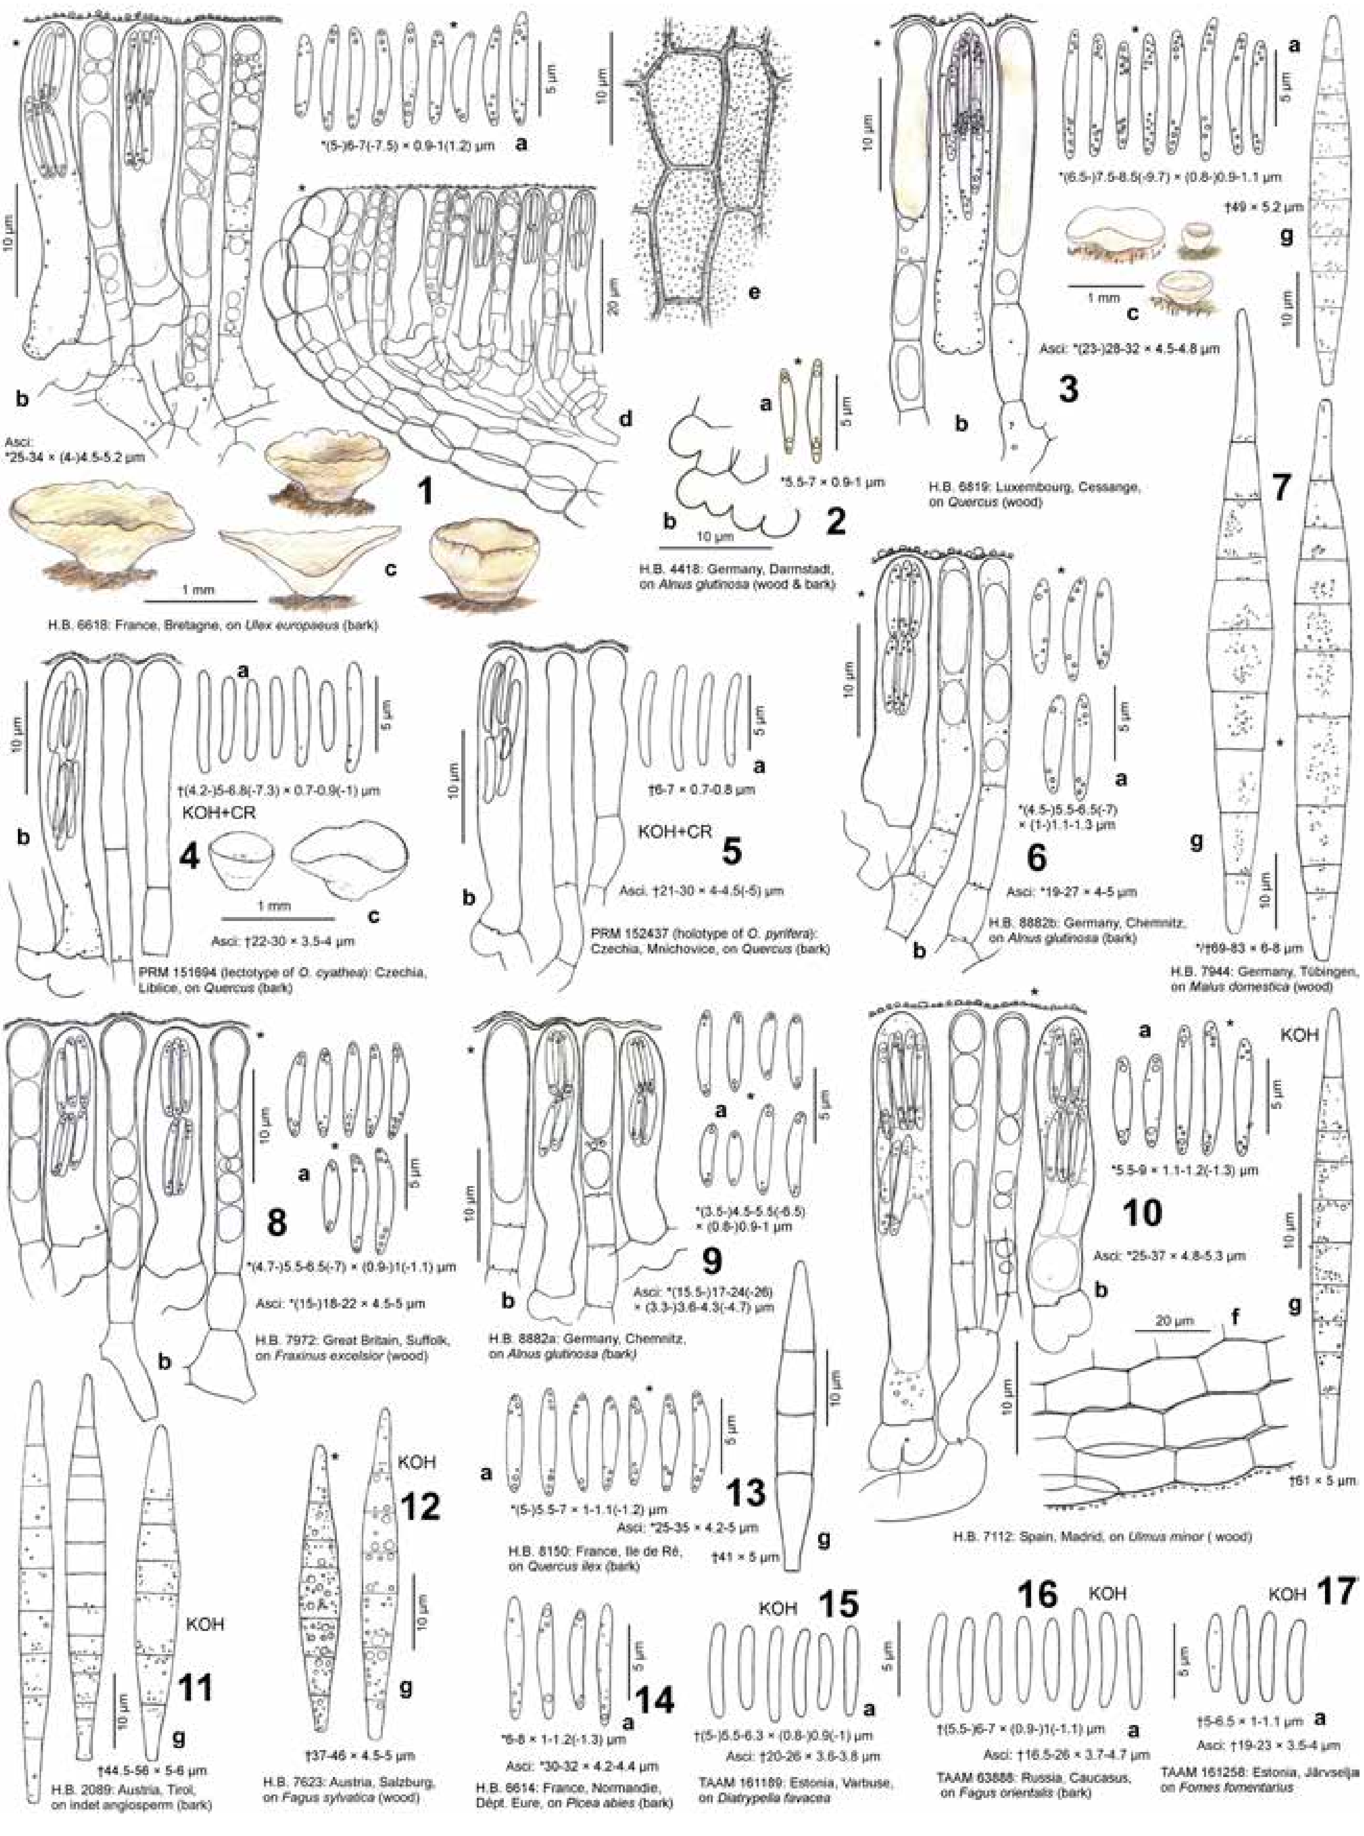

Plate 77. **1–2**, **4–17**: *Hyalorbilia inflatula*; **3**: *H.* cf. *inflatula*. – **a**. ascospores; **b**. asci and paraphyses (ascus bases with croziers); **c**. fresh or rehydrated apothecia; **d**. ectal excipulum with hymenium (margin and mid flanks, median section); **e**. id., at flanks, surface view; **f**. id., at lower flanks, in median section; **g**. conidia (**12**: large drops were partly LBs which resisted in KOH).

overlap here, except for spore width. Another population with broad marginal cells of *6–8 µm (on *Ulex* from Bretagne) has a warted hymenium, comparatively large asci, and spores intermediate between the two (Pl. 77: 1). Indeed, such broad spores as in H.B. 8882b were only rarely seen within *H. inflatula* s.l., for instance, in a sample on *Ulmus* from Madrid which has also narrow marginal cells (†3–5.5 µm, Pl. 77: 10).

The wide spores in H.B. 8882b are similar as in the type of *Orbilia abietina* (Pl. 78: 5), a collection with medium wide marginal cells [†(4–)5–7(–9) µm] and a warted hymenium. This sample is considered as possibly conspecific with *H. polypori*, but could instead, belong to the scope of the here proposed neotype of *H. inflatula* (Pl. 78: 1), which belongs to the variant with rather narrow marginal cells and cupulate apothecia.

Ellis & Ellis (1985: 11) separated between *O. cyathea* with distinctly cyathiform apothecia and *O. auricolor* (s.auct.) with non-cyathiform apothecia. This separation seems to have partly been based on material identified by Clark (1980b: 44) who distinguished between the two taxa in a collection list without diagnoses, and it seems to correspond to some rate with the present observation within *H. inflatula* s.l. of narrow marginal cortical cells in ± cupulate apothecia vs. broad cells in more flattened apothecia. However, broad marginal cells occur sometimes also in populations with cupulate apothecia, e. g., in a specimen from Bretagne and in the type of *O. cyathea* (Pl. 77: 1, 4). Adult apothecia of the cupulate form usually show rather typical concentric hymenial zones of slightly differing transparency when viewed from above, caused by a changing thickness of the receptacle. However, such concentric zones may also occur in *Orbilia leucostigma*, which may easily be confounded under the dissecting microscope with the present species (see Pl. 877: 2).

Cupulate apothecia with narrow marginal cells might display a certain desiccation tolerance, but such possible correlation requires further study.

Misapplications, **Nomenclature and type studies**. Great confusion occurred over the centuries regarding the epithets *inflatula* and *auricolor* (see Spooner, 1987: 164, 180), but also *epipora*. Whilst the epithet *inflatula* has rather consistently been applied in the here used wide concept, the epithets *auricolor* and *epipora* were misinterpreted for a long time as earlier synonyms of the former. *Peziza auricolor* was erected in 1865 almost without microscopic details (apart from 'narrow spores'), and it was only in 1987 when its rather long, distinctly curved, basally tapered spores were correctly described for the first time from the holotype (see p. 1527). When *Peziza epipora* was described in 1869, its description comprised already a mixture of two distinct species: *O. epipora* in the here lectotypified sense, and *H. inflatula*. A further name, *O. leucostigma* var. *xanthostigma*, was once applied by Feltgen (1901) without description to a sample here reidentified as *H. inflatula*.

In the 19th century the epithet *inflatula* has been used in the present sense, e. g., by Karsten (1869: 175, 1871: 100), Phillips (1887: 335), Saccardo (1889: 627), and Massee (1895: 149, figs 48–51). Descriptions of these authors include translucent, thin, flat, 1–1.5 mm large whitish apothecia with a tinge of yellowish-green when moist, but dirty-yellow and contracting angular to globose when dry, subsessile asci, and apparently straight (or slightly curved), short and narrow spores. Karsten wrote that the apothecia have quite a few whitish 'cilia' (anchoring hyphae) at their often stipe-like base, and also in Massee's description the apothecial base is 'furnished with a white down'. Karsten did not mention the paraphyses, and also Saccardo and Massee wrote not to have seen any. Massee even asserted their factual absence, and thought that would be characteristic of the species.

Particularly the microscopical data deviate somewhat in the descriptions provided by the older authors. Ascus and spore size as given by Karsten and Saccardo are rather concordant: 22–25 × 3 µm and 4–7 × ~0.5 µm vs. 18–24 × 2–3 µm and 5–8 × 0.5–0.7 or 0.5–1 µm, respectively. The spores are reported as acicular-filiform by Karsten, but cylindrical and slightly curved by Saccardo. It was Saccardo who emphasized the asci to be 'subsessile'. His illustration of a sample from Selva del Montello (Saccardo 1883: pl. 1290) shows slightly to medium allantoid spores and could instead refer to *H. fagi*. Phillips merely copied the description of Karsten. Massee described the spores as filiform, 6–10 × 0.5 µm, but his drawing shows much wider spores reminiscent of *H. polypori*.

Even more modern authors gave a rather incorrect spore width for *O. inflatula* or *O. auricolor* s.auct. Romero (1994: 113, fig. A–D) measured 5–6 × 0.5 µm, but judging from her scale the spores are 5–6 × 0.8–1 µm. Bride & Caillet (1975) gave the spores as 4–6 × 0.1 µm, probably in error for 1.0 µm. Svrček (1954: 8; 6–8 × 0.5 µm) and Baral (in Baral & Krieglsteiner 1985: 26; 5–8 × 0.3–0.5 µm) gave a too low spore width. The reason for such discrepancy lies at least partly in the fact that no oil immersion was applied. Too wide spores (5–7 × 1.5–2 µm) are stated by Bell (2005: 20, fig. 32 A–D) in her key, instead 4.8–5.3 × 0.8–1.1 µm can be evaluated according to her scale.

The epithet *auricolor* was adopted before 1900 by Cooke (1871: 700), Phillips (1887: 334), Saccardo (1889: 625), and Massee (1895: 148). Their diagnoses, except for Massee's, are purely based on the type collection of *O. auricolor* and lack microscopic data. The fresh apothecia are orange, flat with a raised margin, becoming dingy orange by hardly changing their shape when dry. Massee characterized the apothecia as surrounded by a delicate web of hyphae. He reported the spores as straight, 5–6 × 1.5 µm, although his drawing shows them much narrower. It seems possible that Massee described the spores from a specimen which belonged in the scope of *H. inflatula*.

O. epipora has been confused with *H. inflatula* starting with Nylander (1869), followed by Korf (1992), and apparently also by Dennis (1954) who followed Karsten (1870) in his believe that *Peziza inflatula*, which Karsten had erected 1 year before, was only a subspecies of Nylander's *O. epipora* (see also under that species, p. 1450). Rehm (1891) and Velenovský (1934, 1940, 1947) did not report either of the three epithets, but material referable to *H. inflatula* was found in their herbaria under the name *O. luteorubella*.

Type material of *Peziza inflatula* in Karsten's herbarium has never been found (Nannfeldt 1932: 254, Huhtinen pers. comm.). The original description in Karsten (1869) was based on a not stated number of collections on bark and wood of broad-leaved trees, especially *Populus*, made in September and originating from two sites (Mustiala and Pähkijärvi). The year was not stated but the record from Pehkijärvi, as this lake is now called, was perhaps made in 1867 because Karsten was very rarely in this area (S. Huhtinen pers. comm.) and collected there in 22.IX.1867 *Belonopsis excelsior* on *Phragmites* (Nannfeldt

1986). Judging merely from the descriptions of Karsten, Massee, and Berkeley & Broome, Nannfeldt (l.c.) expressed severe doubts about whether *O. inflatula* is distinct from *O. auricolor*. Based on a reexamination of the type of *O. auricolor*, Nannfeldt (1939: 244) adopted the older epithet *auricolor* to replace *inflatula*, but did not mention any of its characteristics. Most workers followed this opinion and applied the name *auricolor* to the species with short straight spores and unstalked asci, e. g., Dennis (1960a: 105, 1970: 352, 1978: 188), Moser (1963: 68), Bride & Caillet (1975), Ahmad (1978: 210), Thind & Sharma (1980), Chmiel (1982), Baral (in Baral & Krieglsteiner 1985: 26), and Ellis & Ellis (1985: 11). Apparently only Seaver (1951: 154) and Svrček (1954: 8, 1962: 92) retained the epithet *inflatula* by neglecting the epithet *auricolor*.

Only 6 years after Nannfeldt had reintroduced the epithet *auricolor*, he revised his opinion about the synonymy of *O. auricolor* and *O. inflatula* (in Lundell & Nannfeldt 1946), but this change in mind obviously escaped notice of most later workers. When he issued there a specimen as *O. inflatula* (Småland, Kärda parish, ‘Kalkunda bokhult’, on heaped-up branches of *Fagus*, mainly on bark, 29.VII.1944, Fungi exsiccati Suecici 1388), he noted on the label: ‘On examining my microscopical slides I find that I made a bad mistake, when identifying this species with *Peziza auricolor* Berk. & Br.' (Spooner 1987: 180, pers. comm.). According to Spooner's revision of FES 1388, this actually represents *H. inflatula* in the sense adopted in the present work. Another collection briefly described by Nannfeldt (1932, fig. 40 d) under the name *O. inflatula* (Uppland, Ärentuna, Storvreta [substrate not indicated], 24.IX.1928, S. Lundell) shows isodiametrical excipular cells in surface view, suggestive of a species of *Orbilia* rather than *Hyalorbilia* (no asci and spores were described).

Spooner (1987) provided a detailed description of the type collection of *Peziza auricolor* and concluded that this represents an earlier synonym of *O. curvatispora* Boud. (see under *O. auricolor*, p. 1527). Consequently, Spooner followed Nannfeldt's (in Lundell & Nannfeldt 1946) concept when he applied the epithet *inflatula* to three north European collections and one from Victoria (Australia), which he described with sessile asci ('not greatly contracted at the base, not furcate') measuring 24–28 × 4 µm, and straight to slightly curved, 4.5–7 × 0.6–1 µm large spores being 'cylindric, sometimes slightly broader towards the proximal end'. Two of these European specimens were also seen by Nannfeldt (FES 1388, issued as *O. inflatula*; FES 2588 as *O. leucostigma*), the third was collected by Dennis (10.V.1981, Isle of Gigha, Scotland, as *O. auricolor*; see also Kirk & Spooner 1984: 529). The drawing in Spooner (1987, fig. 23) refers to the Australian collection which he assigned to *O. inflatula*.

Korf's (1992) report of *O. epipora* included *H. inflatula* and *O. dryadum*, and Ekanayaka et al.'s (2018) report of *H. inflatula* refers to *H. arcuata* based on the curved spores.

The brief descriptions of the older authors do not permit a clear recognition of the species treated, and not even the genus is very clear. Rehm appears never to have used the epithets *inflatula* and *auricolor*. Considering the frequency of *H. inflatula*, this species can hardly have escaped his notice. Rehm's (1891: 455) interpretation of *Orbilia luteorubella* shows a slight similarity with *H. inflatula*, although he described the spores as 6–10 × 1–1.5 µm, narrowly fusiform and the paraphyses with roundish, 3–5 µm wide apices. Rehm's ecological characterization (dry branches of *Pinus*, *Ulmus*, *Alnus*, *Fagus*) clearly excludes *O. luteorubella*. Actually, an exsiccatum in M and H (VII.1881, *Alnus* bark, M. Britzelmayr, Rehm Ascomyc. 621 = Karsten 4846, as '?*Calloria luteorubella* /Nyl./ Karsten') represents *H. inflatula* (yet, the number 621 is not cited in Rehm 1891). Seaver's (1951: 154) observation of curved spores (5–8 × 0.5–0.7 µm, asci 18–24 × 2–3 µm) might refer to *H. tortuosa* or *H. fagi* rather than *H. inflatula*.

Karsten's brief and unillustrated original description of *Peziza inflatula* more or less fits the interpretation of Spooner, but does not allow a final decision, even at the generic level. We here follow the application of the name in Spooner's sense. Since no authentic material in Karsten's herbarium could be located, a neotypification is necessary. However, our genetic results suggest that different closely related taxa are involved in our present concept of the species. This raises the question which specimen should be proposed as neotype. Karsten's protologue reports the dry apothecia to be inflated like a membranous swollen bladder, which seems to refer to cup-shaped apothecia. In those species with narrow marginal cells we have more often seen cup-shaped apothecia, therefore, it might be better to select a specimen of those, although this macroscopic feature is not strictly correlated with marginal cell size. We here designate a collection from Chemnitz, Germany (ex H.B. 9328, Pl. 78: 1) as **neotype** of *H. inflatula*. The apothecia are cup-shaped and have marginal cells of *10–12 × 4–5 µm in sectional view, asci with average length (*25–29 × 4–4.5 µm, †18–25 × 2.8–3.2 µm), with two superimposed bundles of four spores, and rather short, straight or only very slightly curved spores (†5–6 × 0.9–1 µm, not described in the living state). An ITS sequence was gained from its apothecia, which clusters in a clade with the sample from Madrid that was studied in more detail in the living state (Pl. 77: 10), though with ~4% distance (see below).

Type studies (European taxa). The type of ***Peziza translucens*** (Roumeguère, Fungi gallici exs. 2382) was described on '*Quercus*, *Fagus* etc.' from Poligny (Jura, VII.1882). The Kew syntype specimen was restudied by Dennis (1964: 69) and found to be a synonym of *O. auricolor* (s.auct., = *H. inflatula*), whereas the syntype studied by Höhnel (1926b: 95) was said to be completely immature. The here examined syntype (PC 0088499, IVV: H.B. 7750) confirms Dennis' result (apothecia 0.5–1.5 mm diam., honey-yellow, saucer-shaped, asci in KOH 23–28 × 4–4.2 µm, arising from croziers, ascospores 6.3–7.4 × 0.9–1 µm, straight, marginal cortical cells not measured). The substrate (rotten wood) belongs to *Fraxinus*, according to its microanatomy.

No type material of ***Orbilia breviasca*** (Brandenburg, Tamsel, Berganlagen, on rotten wood, VIII.1904, P. Vogel n. 1712) could be located in B, HBG, BPI, and S. The species was thought by Hennings (1909) to be close to *O. luteorubella*, differing in much shorter asci, uninflated paraphyses, and narrower spores. The asci are described as 'short-clavate, apically obtuse-truncate', 20–25 × 3–3.5 µm. The short asci point to a *Hyalorbilia*, and the gelatinous apothecia (1–1.5 mm diam.) and straight spores (6–7 × 0.5 µm) to *H. inflatula*. However, the possibility cannot be excluded that Hennings overlooked the stipe of the asci. The apothecial colour ('yellow-orange') is unusual for *H. inflatula*. Kanouse (1939) referred collections from USA (Michigan) and Canada to this taxon. Her brief description includes non-capitate paraphyses covered by exudate, which might refer to a *Hyalorbilia*.

The abundant lectotype of ***O. cyathea*** grew on fissured bark of obviously *Quercus* (often on very old black stromata of a pyrenomycete), contrary to Velenovský's statement on the label ('on rotten wood of *Quercus*'). Surprisingly, Velenovský's (1934) prolotogue mentions five different genera of broad-leaved trees as support of *O. cyathea*, but not *Quercus*. As the site 'Liblice' is mentioned in the protologue, Svrček's (1954: 13) choice of this collection as lectotype seems acceptable. At the flanks the ectal excipulum is composed of a horizontal textura prismatica (individual cells 12–28 × 8–12 µm), contrary to the author's statement in the protologue ['parenchym exceedingly large-celled (50 µm)']. On his manuscript sheet, which includes sketches of several collections (but none of the lectotype), he figures both a textura prismatica and a t. angularis (the latter with excipular cells 50 µm diam), but only the large-celled t. angularis is reproduced in Velenovský (1934 pl. 11 fig. 17). The origin of the different sketches on this plate is not very clear: the textura angularis was perhaps from *Fomes fomentarius*, Carpathians, VII.1933, and seems to belong to an *Orbilia*; the t. prismatica was apparently from *Carpinus*, Radotín, 20.V.1926, and undoubtedly refers to a *Hyalorbilia*. Svrček revised several of Velenovský's specimens, including that on *Fomes fomentarius*, and found them to concur 'perfectly' with *O. inflatula*.

The collection data of the lectotype (oak, Liblice, VII.1925) can be found on Velenovský's manuscript sheet and were added by him apparently rather late. No microscopic data of this specimen appear to have been noted by him. Nevertheless, ascus and spore size as here evaluated from the lectotype (Pl. 77: 4) fit well the protologue and also the present concept of *H. inflatula*, as do the cupulate, pale yellowish-chlorinaceous apothecia (rehydrated 0.5–1.5 mm diam.). The marginal excipulum is composed of rather large, thin-walled cells [9–11 × (4–)5–10 µm], and the minute warts over the hymenial gel are hardly perceptible. The name *O. cyathea* is thus available for the variant with wide marginal cells, if a split of *H. inflatula* will become necessary in the future.

The abundant lectotype of ***O. linata*** (on wood of *Betula* log) contains cupulate, rehydrated 0.4–1 mm large, yellowish-ochraceous apothecia which were found to be immature (asci 21–29 × 4–5 µm, with croziers, medullary excipulum strongly gelatinized, ectal excipulum slightly so, at margin thin, of thin-walled t. prismatica). Judging from apothecial shape and size, this could well belong to *H. inflatula* (with narrow marginal cells). Svrček (1954) stated that it is 'totally identical' with *O. inflatula*, but did not say whether he saw any asci and spores. Velenovský (1934), who compared the taxon with his *O. cyathea*, described asci of 25 × 5 µm and broadly ellipsoid, biguttulate, 4–5 µm long spores, though not from inside the asci. Such free spores of unclear origin (hyaline, ellipsoid-obovoid, very finely warted, 6–7 × 2.9–3.3 µm, with two large LBs) were abundantly found among the apothecia in the present reexamination. Also Svrček saw them and named them 'conidia', but did not report their warted surface. Undoubtedly, Velenovský mistook these as the ascospores of *O. linata*. He also described brown, 2-septate, pyriform conidia, which he seems to have considered as its anamorph, but they belong to the associated *Brachysporium obovatum*.

Svrček mentioned only this collection (as 'holotype'), although Velenovský based his new species on two different collections. On his manuscript sheet Velenovský named the *Carpinus* collection 'var. *carpinacea*', which he stated to deviate by almost colourless apothecia, but in his monograph he merged it with *O. linata*. Since the protologue largely refers to the *Betula* collection (PRM 152443), we here designate this as **lectotype** of *O. linata*. No material of the *Carpinus* collection could be located at PRM. The apothecia on *Betula* are described as honey-yellow (melina) in the protologue, and it is probably this colour after which Velenovský named the species *linata*.

For the abundant holotype of ***O. pyrifera*** (on bark of *Quercus*) Velenovský (1947) gave the spores much too small (2.5–3 × 0.5 µm). Svrček's (1954) conclusion that *O. pyrifera* represents *O. inflatula* is confirmed here (Pl. 77: 5). The apothecia were cyathiform, dry deeply cupulate, and the thin-walled marginal cortical cells measured 10–15 × 8–10 µm. The taxon grew among black setae of a hyphomycete. On the excipulum Velenovský found pyriform, 1-septate, hyaline 'corpuscules' of 25 µm length, from which the specific epithet is derived, and which might represent the conidia of this hyphomycete. The holotype contains many such setae though no conidia could be found in the present study. Only a much older collection (18.VI.1925, Mnichovice) is named *O. pyrifera* in Velenovský's unpublished manuscript, which is not mentioned in the protologue, and which obviously belongs to *O. auricolor*. Also this collection was named according to the presence of 2-celled conidia which here undoubtedly represent the *Arthrobotrys* anamorph of *O. auricolor*.

Hyalinia rectispora* var. *majuscula was placed in close vicinity of *Hyalinia rectispora* Boud. by Grelet (1948b) on account of a similar spore shape, and was segregated hereof by much larger apothecia and a ligneous substrate. Grelet overlooked the severe difference in ascus base and type of ectal excipulum between the two taxa. Five specimens that belong to four collections were received from PC and found to be conspecific with the present concept of *H. inflatula*. All were signed by Grelet as '*Hyalinia rectispora*'. For one of them (15. VI.1914, Savigné, on *Quercus* board) Grelet (in sched.) noted 'vidit Boudier'. Three are mentioned in the protologue and can, therefore, be considered as syntypes. Collection VII.1925 (Savigné, *Pinus* bark, PC) is designated here as **lectotype** of *Hyalinia rectispora* var. *majuscula*. In this specimen the apothecia measured rehydrated 0.5–1.8 mm diam. (Pl. 80: 6a–b), the asci 20–24 × 4 µm (with croziers), and the spores ~6–7 × 1 µm. The medullary excipulum is distinctly gelatinized; the marginal excipulum was not studied.

Type studies (extra-European taxa). The following three names belong to specimens with a subtropical to tropical origin. Reexamination of type or authentic material showed that all three have very similar spores which deviate from typical *H. inflatula* in being rather short and often very slightly curved, comparable to *H. japonica*, *H. citrina* p.p., *H. fagi*, or *H. andina*. Their possible identity with *H. inflatula* could not be resolved, nor do they fit very well any of the other accepted taxa (in ascus size they exceed slightly or distinctly the length of *H. japonica*). Therefore, we refrained from including them in either description.

Peziza vulgaris* var. *myceticola from South Carolina was published in Berkeley (1875) without diagnosis but only with the remark that the species deviates from typical *Peziza vulgaris* Fr. [≡ *Calycina vulgaris* (Fr.) Baral] in more concave discs. A syntype in K was designated as lectotype by Dennis (1964: 70, fig. 54 left) who believed that it might belong to *Orbilia epipora*. His drawing shows unstalked asci typical of *Hyalorbilia*, but deviates from the present examination of this material (Pl. 79: 5) in distinctly more capitate paraphyses. When rehydrated, the cyathiform apothecia measured 0.8–1.4 mm diam., the ectal excipulum at the flanks was a slightly gelatinized t. prismatica, and the thin-walled margin cortical cells measured 9–11 × 6–9 µm (in section). The other syntype specimen cited in the protologue (on oak, South Carolina, No. 2683) was not received from K.

No authentic material of ***Hirneola lancicula***, from French Guiana, Cayenna, on unidentified wood (as 'lignum'), [F.M.R.] Leprieur, no. 1087, could be located in PC and TCD. The species was described by Montagne (1856) without microscopic characters, with small, gregarious, plano-concave, umbilicate, gelatinous, amber-brown apothecia with undulating margins. When transferring this taxon to *Orbilia*, Patouillard & Gaillard (1889) included with hesitation a collection from Venezuela: V.1887, Haut-Orénoque, Mapire, on rotten bark [as 'wood'], A. Gaillard. Two specimens of this collection (PC 0001063, HBG) were examined (Pl. 79: 4). The ectal excipulum at the flanks is a thin- to thick-walled t. prismatica, but the margin was not studied.

Penzig & Saccardo (1902, 1904: 85, pl. 57 fig. 3) described ***O. sinuosa*** based on two collections from Java [12.I.1897, Tjampea;

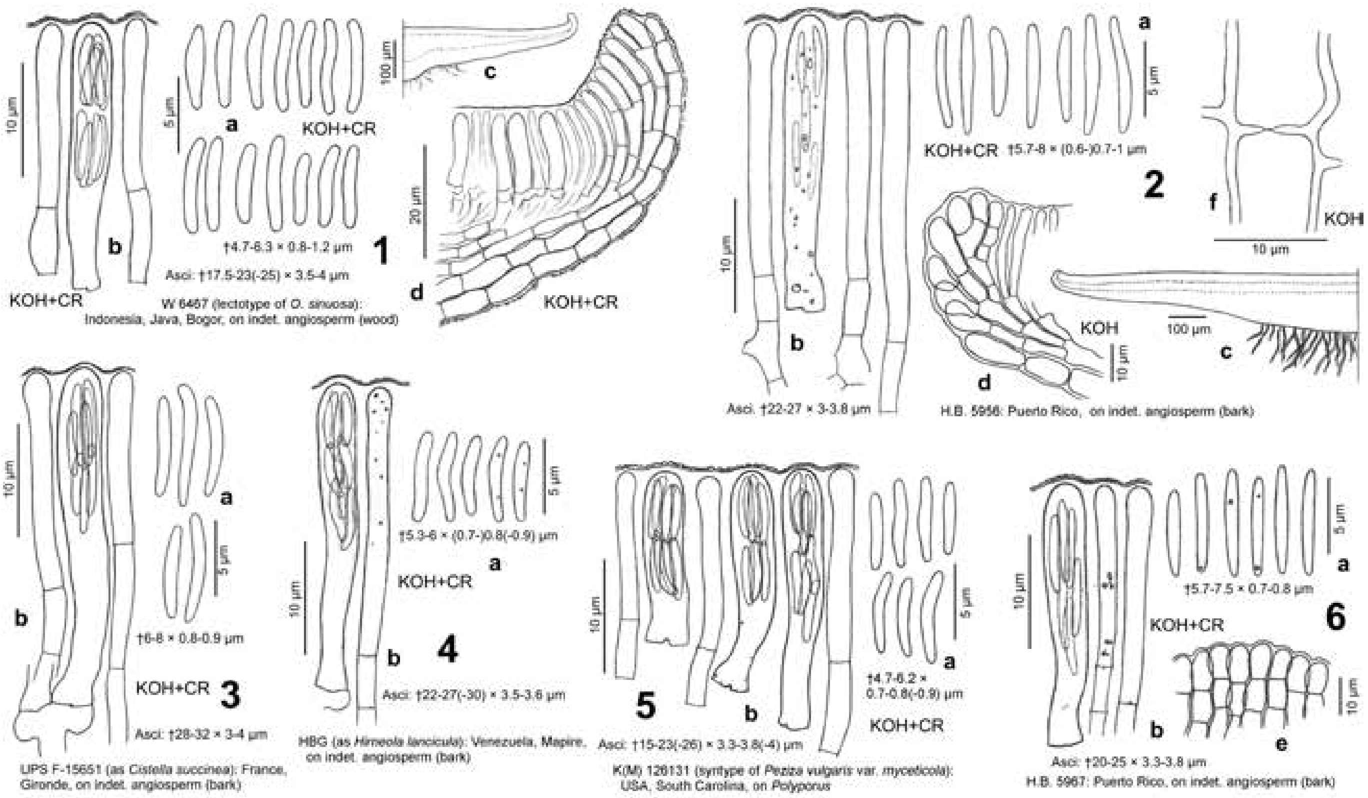

Plate 79. **2**, **6**: *Hyalorbilia inflatula*; **1**, **3–5**: *H.* cf. *inflatula*. – **a**. ascospores; **b**. asci (with croziers) and paraphyses; **c**. apothecia in median section; **d**. id., ectal excipulum and hymenium at margin and flanks; **e**. marginal ectal excipulum in surface view; **f**. id., near margin, showing thick walls.

2.I.1897, Bogor ('Buitenzorg') Botanical Gardens]. Only the specimen from Bogor could be located in W (Pl. 79: 1; 81: 7) and is designated here as **lectotype** of *O. sinuosa*. Although the apothecia were figured with a sinuous margin, from which the name derives, they showed in the studied specimen a roundish outline when rehydrated, with a rather even or only slightly undulating margin (0.25–1.4 mm diam). The other characters fit quite well the protologue. The spores are often slightly curved (allantoid) and sometimes even a bit helicoid (†4.7–6.3 × 0.8–1.2 µm, in the protologue '4–6 × 1 µm, slightly curved'). The asci were described much longer (28–35 × 4–5 µm) than found in the examined specimen (†17.5–25 × 3.5–4 µm). The merely slightly curved spores and the at most slightly gelatinized ectal excipulum with very narrow marginal cortical cells (4–10 × 3–3.5 µm) separate this tropical collection from *H. citrina*. Because of the rather short spores and their curvature some doubts remain whether *O. sinuosa* belongs in the scope of *H. inflatula* or perhaps *H. japonica*, for which the spores are too wide.

Ou (1936), copied by Teng (1939), reported under the name *O. sinuosa* the first record of *Orbiliomycetes* from China. The single sample (from Zhejiang) was considered by Liu (2006: 41) and Liu et al. (2006b: 109) to represent *H. inflatula*, though without reexamination (B. Liu pers. comm.). Judging from Ou's description of the slightly curved spores of 4–5 × 1 µm it could belong to *H. japonica*, but ascus size (35–45 × 5 µm) excludes that species and fits instead the upper range of *H. inflatula*.

Spooner's drawing of an Australian specimen (Victoria, on fallen log, 28.XII.1963, Beaton 176, see Fig. 171), referred by him to *O. inflatula*, should be compared with the above taxa, because the spores are figured predominantly slightly allantoid (6–7.3 × 0.7–1.1 µm as evaluated from scale).

A specimen in UPS collected by L. Quélet in France (Bordeaux, on bark, 25.VI.1884, L. Forquignon) and labelled '*Cistella* ~~*Mollisia*~~ *succinea* Q[uélet] 10 supp. t. 3 f. 11' represents authentic material of ***Peziza succinea***. The taxon was originally described from French Jura on rotten wood, but no holotype material came to our notice. Nannfeldt (1932: 266) found that the specimen from Bordeaux represents an *Orbilia* with a distinct hyaline subiculum at the base. Contrary to his statement of being 'hardly identical with *O. inflatula*', the present reexamination did not reveal any clear differences to that species worth mentioning. However, some of the spores are slightly curved (Pl. 79: 3), therefore this specimen appears to be intermediate to *H. fagi*. An illustration of the type is found in Quélet (1881, pl. 9 fig. 11) showing cupulate apothecia with radiating anchoring hyphae, and rod-shaped straight, 8 µm long, somewhat broad spores.

Not included collections. A specimen from Leipzig (on *Quercus*, IVV: H.B. 7408) deviates in exceptionally small apothecia, which measure rehydrated 0.25–0.35 mm diam. and are in addition distinctly stipitate. The exterior is covered by a very pale yellow-brown exudate, the marginal cortical cells are clavate but only †3–5 µm wide, the asci rather small (†14 × 3 µm), and the spores straight, *6–7 × 1 µm, with 1–2 small guttules at each end. The sample was collected with a crane 22 m above the ground on a dead, periodically dry, corticated, thin branch. The apothecia developed in a moist chamber in the laboratory, where the branch was brought after being collected. When received in the dry state and rehydrated, the excipular cells showed a certain drought tolerance. This sample is not included in the description. For the not included *Orbilia breviasca* and *O. linata* see under Type studies, and for *Dactylella passalopaga* under Anamorph.

Four tropical collections examined in the present study (Pl. 79: 1–2, 4, 6) showed a stronger gelatinization of the excipulum. Two of them (*O. lancicula*, *O. sinuosa*) are not included because of slightly curved spores. These and two from warm-temperate Europe and USA (*Peziza succinea*, *P. vulgaris* var *myceticola*) are discussed under Type studies. A collection from Queensland (Australia), mentioned by Spooner (1987: 178) under *O. inflatula*, deviates by rather long asci (†28–31 × 4–4.5 µm) and long, apparently straight spores (†7–8.5 × 0.8–1 µm), also in smaller, orange apothecia (mostly less than 0.5 mm diam). Similarly, a collection from Luxembourg (Pl. 77: 3a) on an attached, 2 cm thick branch of *Quercus* 1 m above the ground was not included because of its extraordinarily long spores with often ~3–4 SBs near each end, also because of the generally more irregular spore arrangement which never showed the typical superimposed arrangement of 4+4 spores (Pl. 77: 3b). Also Guo et al. (2014b: fig. 8) reported under the name *H. inflatula* four Chinese collections with spores of *5.9–10.3 × 0.9–1.2 µm with 3–4 rather large SBs in each half, which certainly do not belong in the scope of *H. inflatula*. The samples from Australia, Luxembourg, and China approach short-spored collections of *H. juliae* which, however, differ in wider spores. On the other hand, Guo et al. (2014b: fig. 7) describe under the name *H.* aff. *inflatula* various samples which fit typical *H. inflatula* (fig. 7B showing narrow marginal cells).

Anamorph. Like D.H. Pfister (pers. comm.) we did not succeed in obtaining a pure culture from ascospores. However, a single time we obtained conidiophores and conidia growing out of the apothecia that were placed at the lid of a Petri dish (Pl. 82: 10). The same anamorph was repeatedly found on or around apothecia on the natural substrate in various further European samples (Pl. 77: 10–13 and Pl. 82).

The conidia of '*Dactylella*' *passalopaga* as described by Drechsler (1936) from eastern North America fit quite well in their size (*60–80 × 4.5–6 µm) and number of septa (6–8), though being comparatively long. Because of the worldwide frequency of *H. inflatula* especially in temperate regions, we assume that '*D.*' *passalopaga* is the anamorph of *H. inflatula*. Similarly large conidia were mainly observed in the rare *H. caucasica* and the frequent *H. fagi*. The conidia of *H. fagi* are too short and mainly 3–6-septate, however, in order to belong to the true '*D.*' *passalopaga*. The conidia of *H. lignatilis* are a bit smaller and with fewer septa than observed in '*D.*' *passalopaga*, and the same is true for a number of further anamorphs in *Hyalorbilia*.

Phylogeny. In five European collections of *H. inflatula* ITS sequences were gained from apothecia (in two also LSU and SSU: H.B. 9080, 9915). Three of them (Chemnitz, H.B. 9080; Schwarzwald, H.B. 9915; Luzern, H.B. 8279b) possess an ectal excipulum of broad marginal cortical cells, whereas two (Chemnitz, H.B. 9328, neotype; Madrid, H.B. 7112) feature narrow marginal cells. All have an ascus length in the middle range. Our ITS analysis of these five sequences supports the existence of different taxa within the present concept of *H. inflatula*: the five strains clustered with high support in a clade which contains two strongly supported subclades in correlation with the marginal cells (Phyl. 5).

European strains with broad marginal cells showed a distance of only 0.8–1 % to each other, whereby H.B. 9915 and 9080 are identical. Likewise, the two European strains with narrow marginal cells differed by 0.8 % (5 nt) from each other. However, H.B. 7112 contains various ambiguous nucleotides. The distance between the two subclades lies at 5–6.2 %.

The S1506 intron was available for two samples with broad cells (H.B. 9080, 9915) and one with narrow cells (H.B. 9328).

indet. angiosperm; **4a–c**. H.B. 7360: France, La Tranche sur Mer, on *Fraxinus*; **5a–e**. H.B. 7758: Germany, Bad Reichenhall, on *Fomes*; **6**. 20.III.2007: France, Forêt de Chizé, on *Abies*; **7a–b**. W 6467 (lectotype of *O. sinuosa*): Java, Bogor, on indet. angiosperm; **8**. H.B. 5066: Luxembourg, Koedange, on *Populus*; **9a–b**. H.B. 8573: Germany, Naumburg, on *Tilia*; **10**. 14.III.2008: Germany, Tübingen, on *Hypoxylon*; **11a–c**. H.B. 4885a: Luxembourg, Dudelange, on *Prunus*; **12a–c**. H.B. 8882b: Germany, Chemnitz, on *Alnus*; **13**. H.B. 6391: Germany, Starnberg, on *Cyathus*; **14a–b**. H.B. 8127: France, Forêt de Chizé, on *Acer*; **15**. H.B. 8173: France, Forêt d'Aulnay, on *Fagus*; **16**. Rehm Ascom. 621: Germany, Oberstaufen, on *Alnus*; **17a–b**. H.B. 8150: France, Ile de Ré, on *Quercus*.

For H.B. 8279b and 7112 the intron was not available because the ITS1-primer was used. The two broad-celled samples are identical in the overlapping part of the intron, whereas the narrow-celled one differs hereof at 16 positions (6.5%) and a small and large indel region in the overlapping 295 nt. An intron (S943) with a length of 329 nt occurs in H.B. 9915, and was also observed in some other taxa of *Orbiliomycetes* (Tab. 27).

Liu et al. (2006a) gained ITS sequences from seven Chinese collections under the name *H. inflatula*, but LSU only for one of them (B.L. X076). Three of these stains (from Fujian and Guangxi) show a relationship to *H. arcuata* and *H. japonica* (see under these species), whereas three are associated with European *H. inflatula*: one from Xinjiang (B.L. 6564 = HMAS 139536) and two from Tibet (B.L. X034 = HMAS 96789; B.L. X076 = HMAS 96788). Two of them clustered with strong support as a sister group to the clade with broad marginal cells by showing a distance of 1.5–4% and 3–5% to them, respectively (6–11% and 11.5–14% to the clade with narrow cells), whilst B.L. X076 clustered with strong support as a sister clade of the three *H. inflatula* subclades, with a distance of 9–13% and 11–19%. For B.L. 6564 the marginal cells were examined and found to be broad (B. Liu pers. comm.). Finally, B.L. HB19 from Shennongjia Nature Reserve (Hubei) clustered, besides other subclades, within the *inflatula-polypori* clade. When including the LSU region (Phyl. 6), B.L. X076 (Tibet) clustered with medium support and with an LSU distance of 1.7% (547 nt) with the German H.B. 9080 and 9915 in a clade.

Near the 5'-end of the ITS1 region, H.B. 8279b and 9915 (with broad cells) possess an insert of roughly 180 nt, which exists with a similar length also in B.L. 6564 and X034, though only ~145 nt are available (the also incomplete ITS1 of H.B. 9080 did not cover this insert). The insert is much shorter (around 20 nt) in the two samples with narrow cells (H.B. 7112, 9328) and similarly short also in other *Hyalorbilia* sequences which cover the 5'-end of ITS1. However, the alignment is very complicated in this region. In the overlapping 125 nt of the long insert, H.B. 8279b and B.L. 6564 are identical and H.B. 9015 deviates merely by 1 nt. B.L. X034 concurs with H.B. 9015 at this position, but deviates at 5 further positions from the German strains.

All this illustrates the molecular variation in the *H. inflatula* aggregate. For the case that future studies confirm the here observed molecular correlation with the width of the marginal cortical cells, a split into two or more species might be required. In this case, names need to be selected among the here listed synonyms of *H. inflatula*. For instance, *Orbilia cyathea* matches morphologically those with broad marginal cells, while the neotype of *H. inflatula* proposed here refers to a population with narrow cells.

The here recognized *inflatula-polypori* clade comprises besides *H. inflatula* also *H. arcuata*, *H. citrina*, *H. fagi*, *H. helicospora, H. japonica*, *H. lignatilis*, *H. lunata*, and *H. polypori*. It received strong support only in our analyses of LSU or ITS+LSU (Phyls S5, 6). For *H. arcuata* and *H. japonica* only ITS was available, therefore, they are shown only in the ITS analysis. In the *inflatula-polypori* clade clustered also Ekanayaka et al.'s (2018) *H.* cf. *inflatula*, which showed in the LSU D1–D2 a distance of 2.5–2.7% to *H. inflatula* and 3–4.5% to *H. fagi*, *H. citrina*, and *H. polypori*.

Ecology. In temperate regions, *Hyalorbilia inflatula* is the most often collected species of the genus. Unquestionably, this frequency is partly due to the rather large, conspicuous apothecia. The species grows on rotten bark and wood, mainly on the underside of branches and logs fallen to the ground. Bark and wood are quite equally inhabited, but often a fungicolous growth was noted which includes pyrenomycetes as well as aphyllophoralean basidiomycetes. A single collection was on non-ligneous substrate (base of leaflets of *Licuala ramsayi*, a fan palm in northeastern Australia). A report by Massee & Crossland (1905: 301) on herbaceous stems of *Angelica* is without description and more probably refers to an *Orbilia*. An Australian collection on dung was reported by Bell (2005: 20, fig. 32 A–D) and fits well the present concept of *H. inflatula*.

The wide host range of *H. inflatula* includes a large number of genera of angiosperms, but also some of gymnosperms. The most preferred genera observed by us were *Fagus* {29}, *Quercus* {20}, and *Fraxinus* {16}. Host genera indicated in the literature but not seen by us are *Crataegus* (Velenovský 1934: 94, Svrček 1954: 13, Ellis & Ellis 1985: 12), *Cupressus* (Ellis & Ellis 1985: 11), *Eucalyptus* (Romero 1994: 113), and *Robinia* (Bride & Caillet 1975). Helfer (1991: 50) listed *Gloeophyllum odoratum* and Svrček (1962) *Xanthoporia nodulosa* as additional supports. Quijada et al. (2014a) reported collections from Tenerife on laurel forest trees such as *Apollonias barbujana*.

H. inflatula was found from planar to subalpine altitude, and from atlantic to continental regions. The species apparently occurs worldwide. Most collections are from cold-temperate humid to mediterranean (semihumid) but also hemi- to oroboreal and cold-continental zones, in various vegetation types, such as *Alnetum*, *Fraxino-Aceretum pseudoplatani*, *Salicetum*, *Fagetum* etc. Based on a biodiversity project in southeastern Norway, Raitviir & Huhtinen (2003) identified the species as one of the most common lignicolous discomycetes in Norway.

A few collections were made on dry, hanging, 15–25 mm thick branches in 1–22 m above the ground, in a xeric environment. Although the trees grew rather close to running water in some of these samples, the apothecia were completely dry when collected, and exhibited a desiccation tolerance of the vegetative cells of at least 1–3 months, whereas in populations growing on the ground this tolerance was very low. Mature apothecia were found throughout the year, though with a maximum in spring and summer (April–September).

H. inflatula is widely distributed across whole Europe, but we have also seen samples or documentations from other continents, including subtropical to tropical humid regions in America, Asia, and Australia, although their conspecificity is more or less questionable, e. g., in the types of *O. lancicula* from Venezuela and *H. sinuosa* from Indonesia. Collections from Macaronesia (Tenerife, La Gomera, Madeira) were made in the thermo- to meso(sub)mediterranean subhumid to humid laurel forest (*Lauro novocanariensis-Perseetum indicae*; see also Quijada et al. 2014a). D.H. Pfister (pers. comm.) found the species quite frequently in the northeastern United States. Also Seaver wrote that it occurs in eastern North America from 'Toronto to Louisiana'. A single report for South America is that by Romero (1994, Argentina), and from Middle America it was recorded by Medel et al. (2013, Guatemala) in cloud and *Cupressus* forests at 1800 m. Reports for Asia and Australia are those of Ahmad (1978, Pakistan), Thind & Sharma (1980, India, Northwestern Himalayas), Liu (2006: 35) and Liu et al. (2006b: 108, China including Tibet, at 180–3500 m a.s.l., but see under Phylogeny), Raitviir (1991:

Map 7: Known distribution of *H. inflatula* in Europe and Macaronesia (yellow = not included collections).

358, northeastern Asia), and Bell (2005, eastern Australia).

A list of numerous collections on various substrates exists for Belgium (B. Declercq pers. comm.). Two of them were included in the specimen list as there exist documentations for them. Also for the Netherlands the NMV distribution atlas (www.verspreidingsatlas.nl) shows numerous records, but only for one we saw a documentation (S. Helleman pers. comm.). Liu (2006) listed not less than 114 collections, but some of them were here reidentified as *H. japonica*.
